MACHINING LOCOMOTIVE FRAMES

PRACTICE AT THE JUNIATA SHOPS OF THE PENNSYLVANIA RAILROAD

By FRANKLIN D. JONES*

THE frame of a locomotive may be called the foundation or backbone, as it holds in position the driving and reversing mechanism, spring rigging and other important parts which form the running gear. The complete frame is composed of right and left sections which extend longitudinally from either the cylinders or "bumper" at the front, to the foot-plate at the rear of the fire-box. These sections are not always composed of one continuous piece, but are often formed of two or three parts which are joined or spliced together by tightly fitting taper bolts. The general arrangement of the frame depends, of course, upon the design of the locomotive. When the frame is erected, the two sections or halves are bolted to the cylinder castings and they are further stiffened and held in alignment by cross-ties and braces. This matter of bracing is very important, as a rigid structure is necessary to withstand the severe strains to which the frame is subjected. As the driving wheels are held in position by the frame, the latter not only receives heavy fore-and-aft thrusts, but also severe lateral strains, especially when the locomotive strikes a curve at high speed; consequently, if the frame is weak and yielding, a fracture is only a question of time, and, from the beginning, there is likely to be more or less trouble with the driving wheel journals and rod bearings because the running gear is not held in alignment. Designers have had considerable difficulty in providing adequate frame braces on locomotives equipped with the Stephenson valve mechanism, because of the room required between the frames for the eccentric rods, links, etc. This difficulty, however, has been largely overcome by the extensive use of the Walschaerts valve gear which is located entirely outside of the driving wheels and permits braces to be used without interfering with the valve motion, and at a point where they are needed most.

The machining of a locomotive frame would be a rather difficult proposition for the average machine shop, because of the size of the work and its unwieldy proportions, but in a modern locomotive shop, the operation is commonplace. At the Juniata shops of the Pennsylvania Railroad, the methods of handling this class of work are of exceptional interest, principally because of the high standard of efficiency maintained for the various machining operations. While this work is comparatively rough, if judged by the toolmaker's standards, considerable accuracy is necessary for certain surfaces, but the framework from start to finish is particularly noteworthy as an example of rapid machining rather than skillful and accurate work. The Juniata shops have, under normal conditions, a capacity for building a complete locomotive every day, and this rate is sometimes exceeded, so that the machining of frames is an everyday occurrence. Practically all of the locomotives built in these shops at the present time, are equipped with cast-steel frames instead of wrought-iron frames which were used almost exclusively a few years ago. Frames that are cast are much cheaper than the forged type and another advantage of using cast steel is that pads or other projections can be easily and neatly formed on the frame pattern.

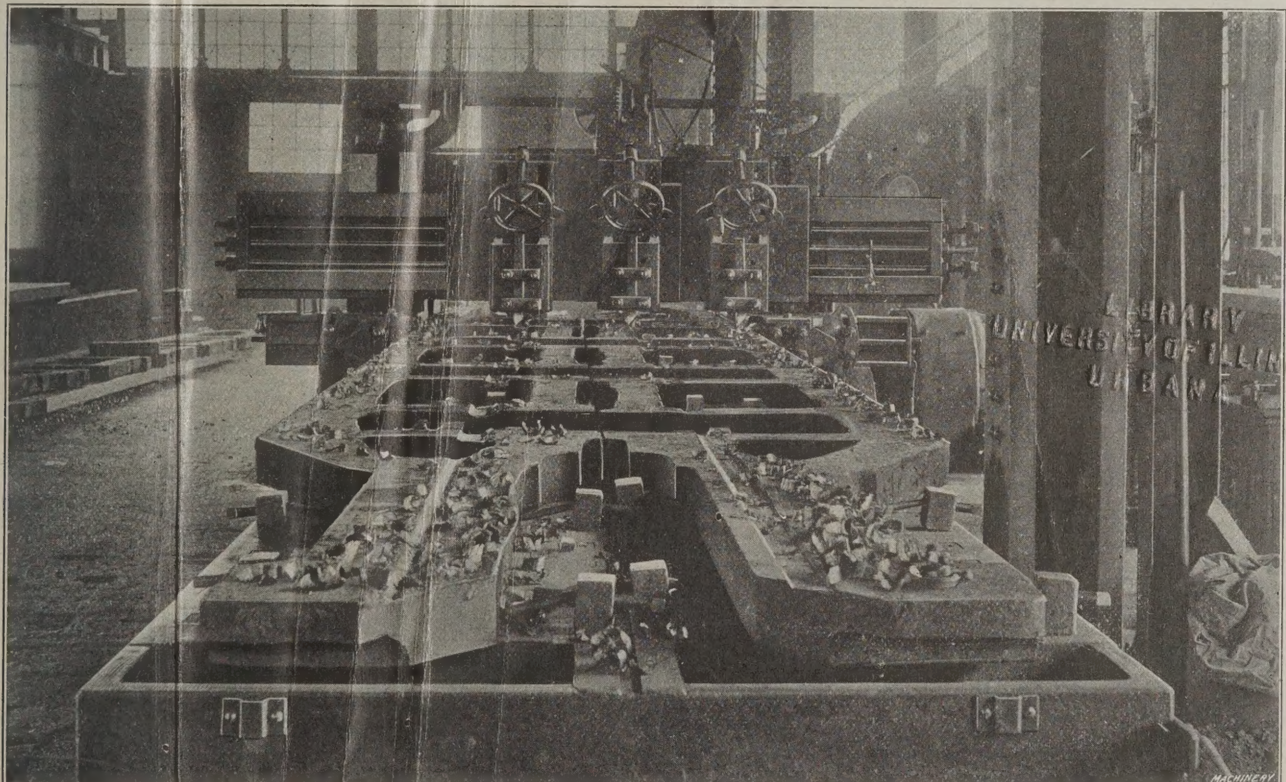

Fig. 1. Planing Two Frames simultaneously on a Powerful Planer equipped with Five Tools

Straightening and Planing the Frames

The cast-steel frames are usually warped more or less as they come from the foundry, owing to unequal cooling, and

* Associate Editor of MACHINERY.

it is necessary to straighten them prior to machining. This straightening is done under a large steam hammer as indicated in Fig. 2. The frame is heated sufficiently to insure a permanent "set" when straightened, and it is made approximately straight by giving it a few blows with the hammer. The work is then ready for the first machining operation which is that of planing the sides and edges. Two frames have spongy, sandy spots, blow-holes or similar defects on the cope side, a generous allowance is left for planing in order to remove all porous material. Owing to the power of this machine, very heavy cuts can be taken without difficulty, as indicated in the illustration Fig. 1. The planer is motor-driven and sometimes as much as 90 horsepower is required for driving, owing to the heavy "hogging" cuts,

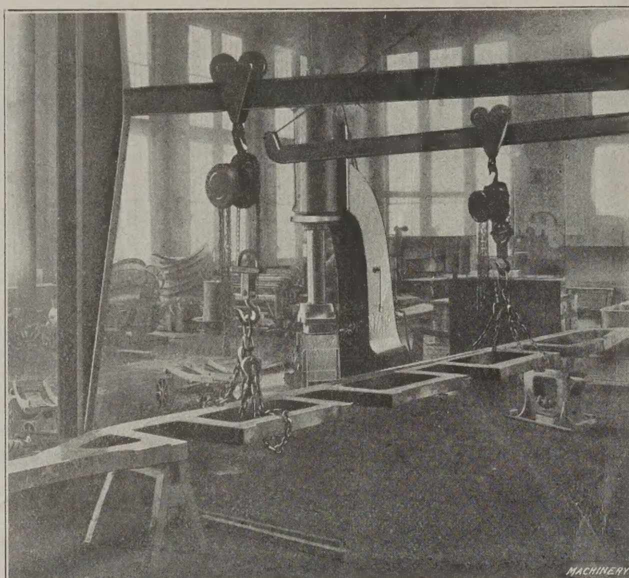

Fig. 2. Where the Warped Frames are straightened prior to Machining

Fig 3. Cast-steel Locomotive Frame on its Way to the Shop

or sections are planed simultaneously on a very rigid planer having five tool-heads. A view of this machine taking a roughing cut over the sides of two frames is shown in Fig. 1. The work is held on the platen by screw-stops and toe-dogs or "spuds" which are placed in an inclined position to force the work down. Stops are also set against the frames at the most advantageous positions to take the longitudinal thrust which are taken in the tough cast steel. When roughing, the tools frequently cut to a depth of from ½ to ¾ inch with a feed of 3/16 inch. The average depth of cut for the five tools, however would be somewhat less than the figures given. After the three heads on the cross-rail are started, the right and left side-heads are set for planing the edges. The work is set up for rough planing the first side, with the top edge

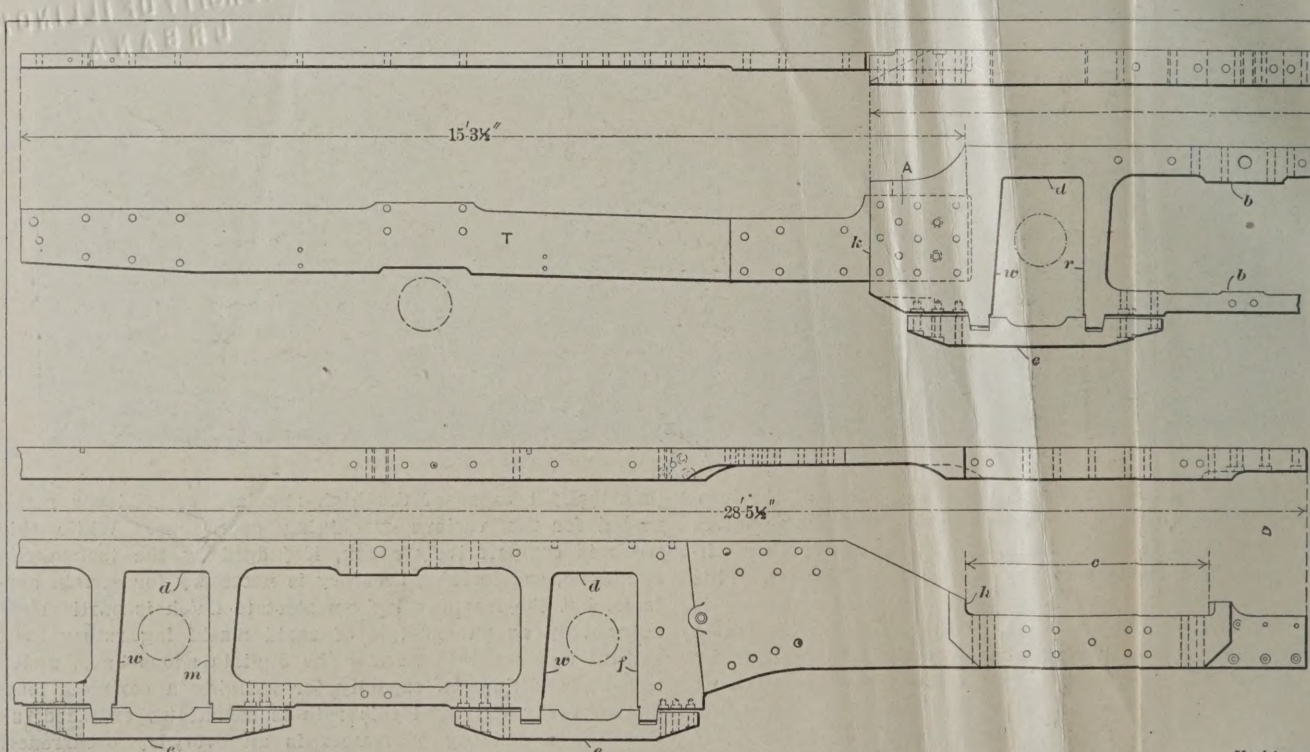

Fig. 4. Frame for a Passenger Locomotive of the 4-6-2 Type

of the cut. Part of the time, all five planing tools are at work, the three tool-heads on the cross-rail being used to plane the sides of the two sections, while the right and left side-heads plane the edges. The three upper tools are started so that each rough planes about one-third of the surface formed by the two castings. In this way the roughing is, of course, done in much less time than would be required if an ordinary two-head machine were employed. As many of these castings of each section outward. This is done so that the top edges can be finished with reference to pads for braces or brackets which are located on the inside of the to and bottom rails of the frames. After the roughing cuts on one side are completed, the finishing cuts are taken with brad flat tools which are given a feed varying from 1 inch to ¼ inch per stroke. Only two of the cross-rail heads are use for finishing, so that each frame can be planed by a contiuous cut in order

to obtain a smooth surface free from ridges. The frames are next turned over for roughing and finishing the opposite side, which is the position of the work illustrated in Fig. 2. The opposite edge of each frame is now in the outward position, thus permitting the ends of the pedestals to be rough planed. The finishing tools are set for planing the second side by means of a post or height gage to which the cutting edges are adjusted. In this way the proper thickness is quickly obtained, although a fixed caliper gage is used to check this dimension. After the sides have been finished in this manner, a frame of the type illustrated in Fig. 4 is planed at *A* for the reception of the trailer frame *T* which fits into a pocket as shown. This pocket is finished to the correct width and depth in another machine, and this completes the planer work.

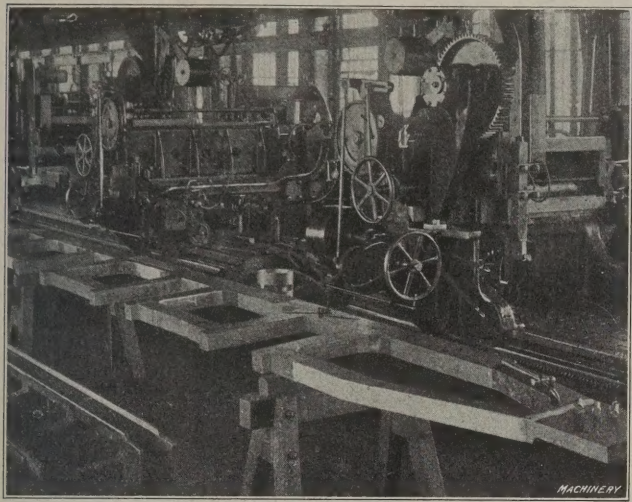

Fig. 5. Frame mounted on Horses for Laying-out Operation

Laying Out the Frames

The frames are next laid out for slotting, though this operation is only necessary for every fifth or seventh frame (depending on the size) owing to the method of slotting them in stacks, as will be explained later. The work is placed on horses (as shown in Fig. 5) and steel templets are used to give the required outline. One of these templets conforms to the shape of the pedestal jaws and another gives the outline for the cylinder fit at the front end. Before placing the templets on the frame, the surfaces on which finished lines are to be scribed, are moistened with water and then coated with a soft red stone called "keel." This leaves a dull red finish on which the scriber lines are easily seen.

The templets are aligned by the planed edge of the frame and they enable the required outline to be quickly scribed on the finished surface. A number of bolt holes which cannot be drilled to good advantage by the use of jigs are also laid out by the use of templets which have small holes corresponding in location with the holes to be drilled and these are transferred to the work by using a light punch. After the templet is removed, two concentric circles are stamped around each center with special punches similar to those shown in Fig. 6. These punches have V-shaped annular ridges which form neat rings or grooves, one of which represents the size of the hole while the other remains as a "witness" to show whether or not the hole has been drilled central. The punches are made in various sizes and they are much superior to the old method of scribing and dotting a circle, when laying out holes.

Slotting the Frames

The slotting operation, which is the next in the regular order, is performed by the large machine shown in Fig. 7. A stack of from five to seven frames (the number depending on the size), can be slotted simultaneously, so that it is only necessary to lay out the one which is to be placed on top. As the illustration shows, the machine has three slotting heads. These can be traversed longitudinally along the bed by power and each slotting ram has a rapid power cross-movement, so that different heads can be easily and quickly adjusted to the required position. In setting up a stack of these frames, each section is placed against angle-plates at the rear which are in line with the slotter bed. All the frames are first adjusted longitudinally in order that the faces of

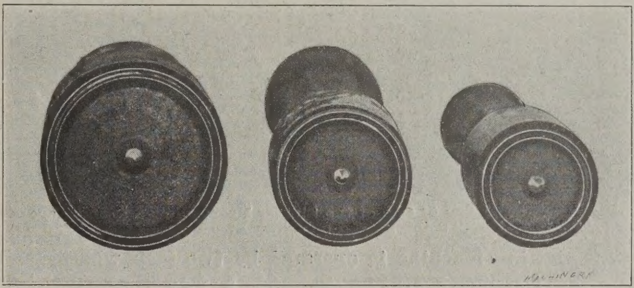

Fig. 6. Special Punches used for laying out Holes

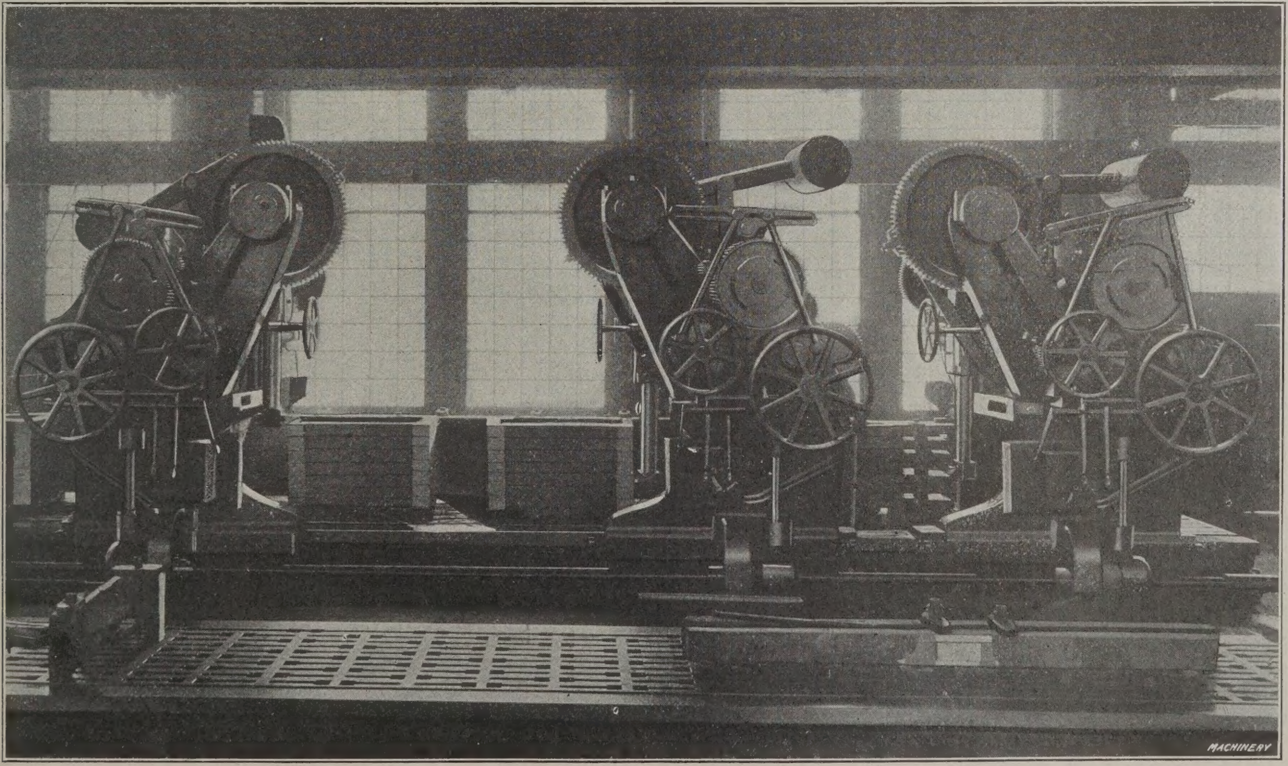

Fig. 7. Large Three-head Slotter used for Slotting the Jaws of Locomotive Frames

all jaws will true up when the top frame has been planed to the lines previously scribed. The crosswise position of the work is then checked by testing the alignment of the lower frame with the bed. When this lower section is accurately located, the frames above are set by it in a crosswise direction by using a large square.

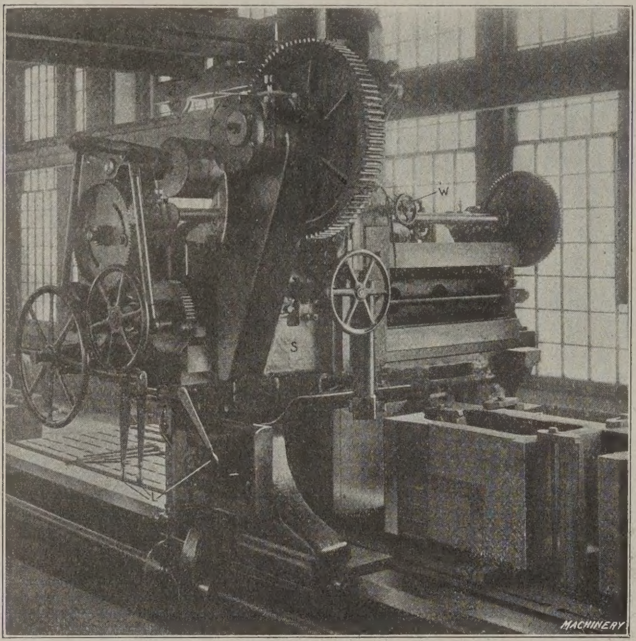

Fig. 8. Detail View of One of the Slotter Heads—Seven Frames are being slotted simultaneously

This slotting machine is operated by two men who proceed with the slotting operation in such a way that the three heads are used simultaneously as much as possible. The method of machining a stack of three-jawed frames similar to the type illustrated in Fig. 4, will illustrate how the machine is handled. One man begins slotting the shoe face *m* of the middle jaw, while the second man is rough planing the pocket *c* for the cylinder. When the first man has slotted the face of jaw *m*, he moves to the front and begins slotting shoe face *f*. In the meantime, the second man starts a finishing cut over surface *c*, and then begins work on the bracket pads *b* with the third head. The reason why the first man moves from the central jaw to the front, is that he is then in a position to watch the slotting head which has been started on a finishing cut along pocket *c* by the second man. In this way the two men shift from one point to another, the order of the operations depending, of course, on the arrangement or design of the frames being machined.

Fig. 8 is a detailed view, showing one of the three slotter heads. The slotting ram and its reciprocating mechanism is carried by a slide *S* which can be traversed laterally along the cross-rail shown. The rapid-traverse movements of this slide and also the power movements for shifting the entire head longitudinally along the bed, are controlled by the vertical levers *L* seen at left end of cross-rail. This view shows the slotting tool just beginning a cut across the front or shoe face of the jaws. After the shoe faces *f*, *m* and *r*, (which are square with the top of the frame) have been slotted, the tapering wedge faces *w* are finished. As those familiar with the construction of locomotives know, one side of the frame jaws is made tapering to provide an adjustment for taking up lost motion between the driving-wheel boxes and the frame shoes. It might also be mentioned, incidentally, that the rear jaws are given this taper rather than the front ones, because the latter are subjected to a greater pressure when the engine is running ahead and it is better to have this pressure against a vertical surface than one that is tapering. The taper or wedge side is planed, on this particular slotter, by swiveling the cross-rail on which the ram is mounted, to the required angle as indicated by suitable graduations. The slotting operation also includes the finishing of the top surfaces *d*, as well as the lower ends of the pedestals for the braces *e* which are bolted across each pair of jaws. In order to strengthen the frames, all corners have large fillets, and when these are being formed the slotting tools are turned by swiveling the tool-bar about its axis, the handwheel *W* (Fig. 8) being used for this purpose.

The most important part of frame slotting, from a standpoint of accuracy, is that of planing the square shoe faces, which must be finished the right distance from each other, within close limits, because these are the surfaces which determine the location of the driving-wheels when shoes of a standard thickness are used. Gages are used for measuring these distances, the front and rear jaws being gaged from the central one which is machined first. The distance between shoulder *h* and face *f* is also carefully gaged, as this shoulder bears against the cylinder saddle and determines the longitudinal position of the frame. The jaw faces of the right and

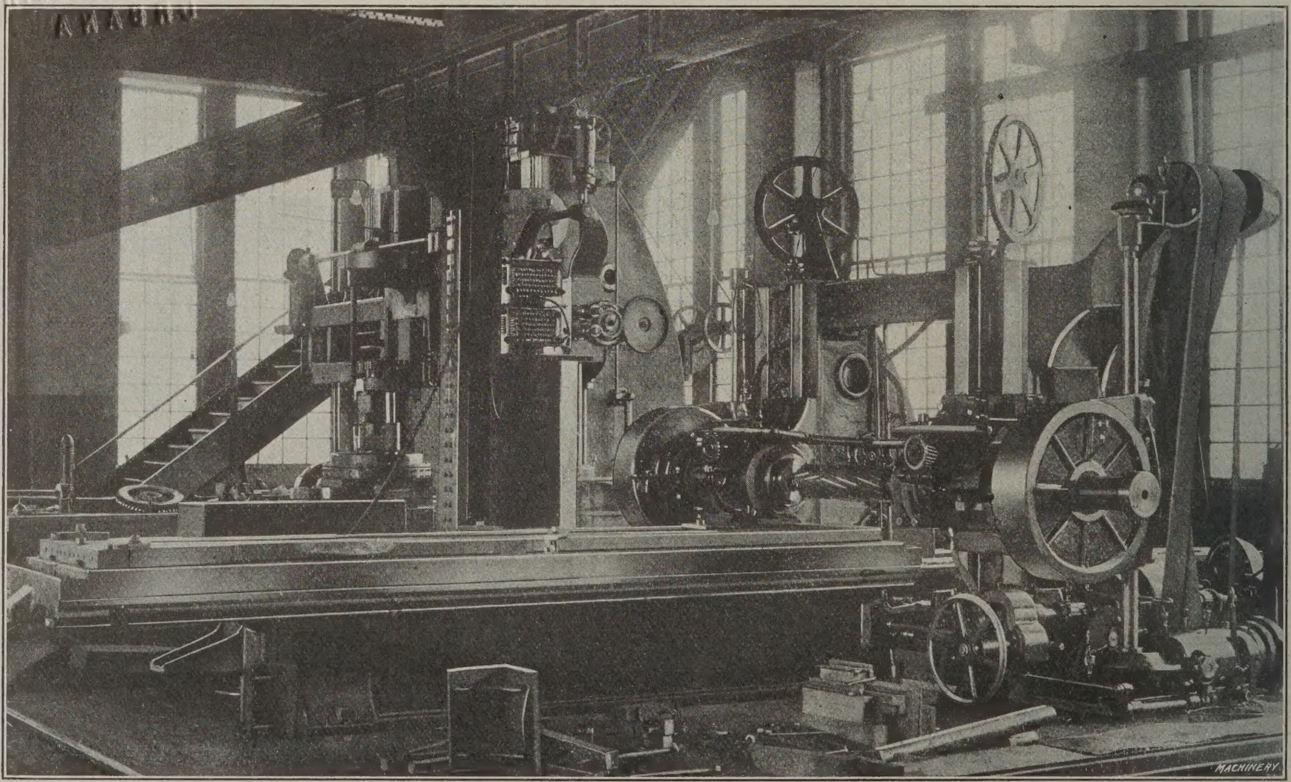

Fig. 9. Horizontal Milling Machine on which Trailer Frames are milled

left frame sections, must lie in the same plane and any irregularity in the location of shoulders h would affect the position of the jaws. The end k of each main section is also finished to provide a surface for locating the jig used for drilling the bolt holes for the trailer frame splice. Surface k is machined to a given distance from face r as shown by a fixed gage.

Milling the Trailer Frames

One of the most interesting operations on the frames is that of machining the section T, Fig. 4, called the "trailer"

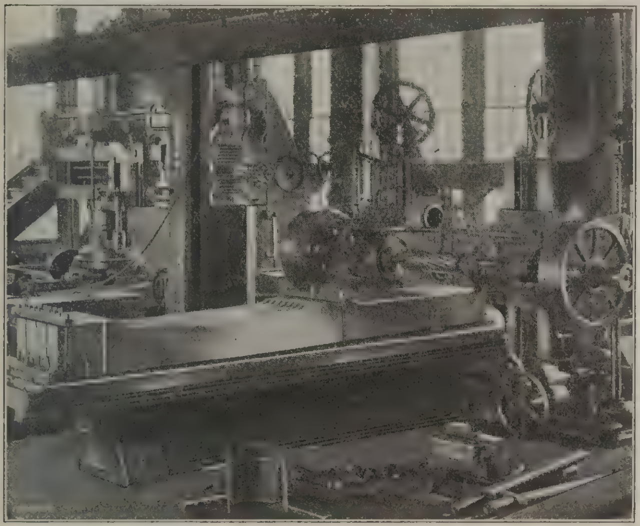

Fig. 10. Eight Trailer Frames set up for Milling the Edges

or rear frame. Of course, it will be understood that these trailer frames are only used on locomotives of the passenger type having trailing wheels, which differ from the drivers in that they simply carry weight and are not connected by the side-rods. The trailer frames are forged and they are finished on the sides and edges in the powerful horizontal milling machine shown in Fig. 9. These forgings are not made very close to the finished size, because with the

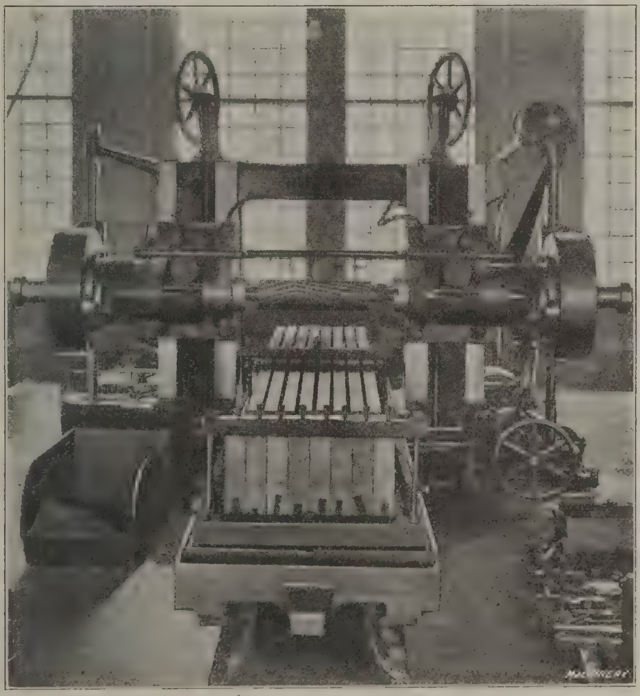

Fig. 11. End View of Trailer Frames and Milling Machine

improved milling practice, the metal is removed so rapidly, that it would not be economical to forge too close to the finished dimensions. The amount of metal removed in machining these frames is indicated by the fact that a rough frame weighs about 2212 pounds, whereas one that is finished weighs only 1725 pounds. The frames are first milled on the sides, two being placed on the machine, at one time as illustrated in Fig. 9. The work is shimmed up with liners or thin wedges and it is held by ordinary clamps as shown. A stop-bar is placed across the outer end to take the thrust of the cut. As the milling cutter advances, the clamps are shifted from one point to another. The cutter used is 33 inches wide, and when the edges are being milled, practically the entire width of this cutter is in use. It consists of three 11-inch units having inserted blades which are held in accurate helical grooves, giving a constant cutting angle for the full width of the blade. These cutters are made in the Juniata shops and they are partly responsible for the efficient milling practice in connection with frame and rod work.

After both sides of all the frames in a lot have been machined, the edges are milled to the proper contour. At the present time, eight of these frames are milled on the edges simultaneously. The way the work is set up is indicated in Figs. 10, 11 and 12. Two broad clamps are placed across the top and the frames are held laterally by screw-stops along the sides. The rear clamp is provided with eight set-screws which insure a bearing on each frame section. The outer frame on the operator's side, has lines showing the required outline for the finished edges. These lines are transferred from a steel templet before the frames are placed on the machine. The frames are first set up as shown in Fig. 10, and then they are turned over for milling the opposite edges. As section F, Fig. 13, and middle section I, are tapering,

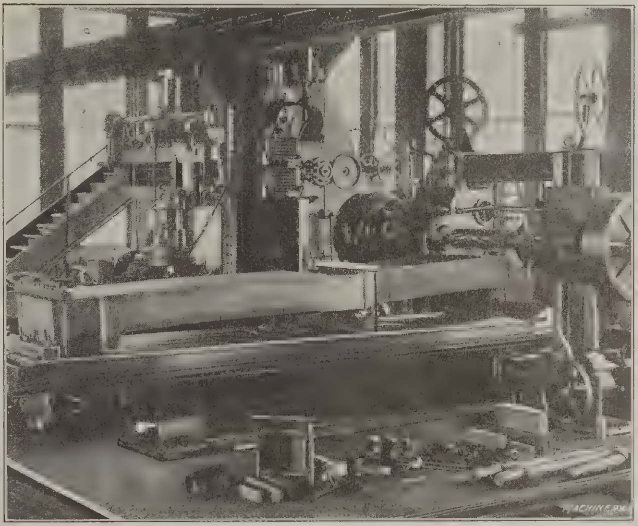

Fig. 12. Stack of Trailer Frames blocked up for Milling Taper End

it is necessary to block up the work as indicated in Fig. 12, in order to secure a straight tapering surface. This particular illustration shows the frames set for milling the tapered end F, Fig. 13. The irregular outline at the center and the radius at the wide end, are formed by adjusting the milling cutter vertically by hand as the work feeds forward.

In order to show how rapidly these rough forgings are machined to the proper size and shape, we shall give the actual time required for milling the various surfaces of the frames and the approximate depth of the cut. The various surfaces to which the data refers are marked in Fig. 13 by letters, and the lengths in each case are also given. Part A having a length of 5 feet, 8½ inches is milled in 56 minutes, and the average cut varies in depth from ½ to ⅜ inch. Of course it will be understood that the time specified is for eight frames, so that if we only consider one frame, section A is milled in 7 minutes. The time taken for section B is 21 minutes and the depth of cut varies from ¾ to ⅞ inch. The time for section C is 1 hour 6 minutes, depth of cut ¾ to ⅞ inch; section D, time 43 minutes, depth of cut ⅝ inch; section E is finished by planing prior to milling operation; section F, time 1 hour 40 minutes, depth of cut ½ to 2½ inches; section G, time 28 minutes, depth of cut ⅜ to 1 inch; section H, time 41 minutes, depth of cut, 1½ to 2½ inches; section I, 34 minutes, depth of cut ¼ to ⅞ inch; section J is finished by planing; section K, time 1 hour 15 minutes, depth of cut ⅛ to ½ inch; section L is finished by planing; section M, time 55 minutes, depth of cut ⅛ to ⅜ inch; section N is finished by planing. The time given for milling the sides

K and M is for two frames. The amount of metal removed from the edges of the eight frames is approximately 1356 pounds, whereas 2542 pounds are removed from the sides, giving a total of 3898 pounds. The total time required for milling the edges is 6 hours 29 minutes and for the sides, 8 hours 40 minutes, giving a total cutting time of 15 hours 9 minutes for eight frames, so that the amount of metal removed per hour of cutting time is approximately 257 pounds. It should be mentioned that the foregoing figures do not cover the time required for setting and clamping the work on the machine.

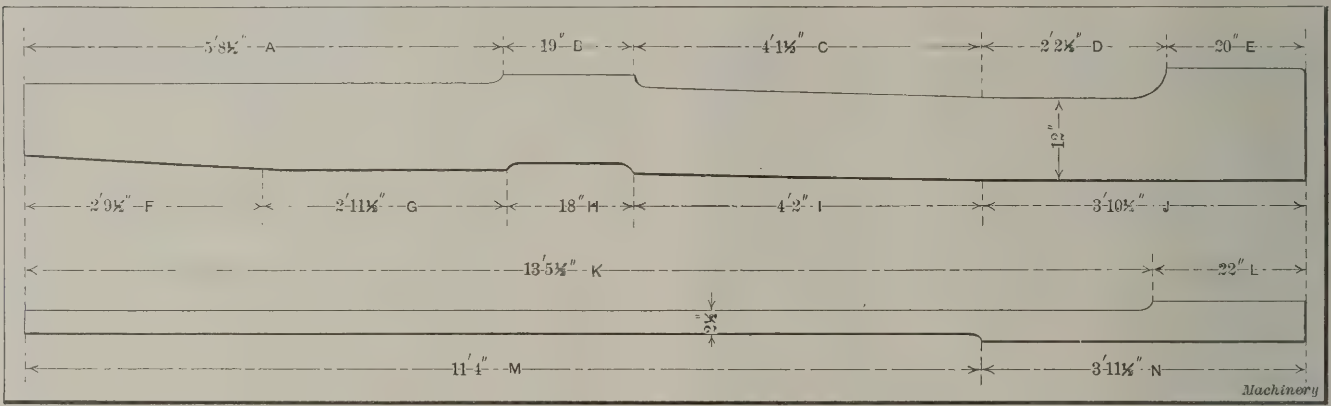

Fig. 13. Diagram showing Lengths of Milled Sections—Data covering Time and Average Depth of Cut is given in Text

Drilling and Finishing the Frames

There are a great many parts attached to the frames, such as brackets for the spring and brake rigging, stiffening braces, pedestal braces and many other parts, all of which require bolt holes, so that the drill press work is quite extensive, as is indicated in Fig. 4. Three large radial drilling machines are used for this work. The frame is first set up for drilling all the side holes, as shown in Fig. 14, and it is then placed in a vertical position for drilling the pedestal-brace bolt holes. Most of the holes are drilled by the use of plate jigs which are located by previously machined surfaces and, in some instances, by lines drawn for this purpose when the frame is laid out. High-speed steel drills are used and these are flooded with soda water so that very rapid work is possible. As it is important to have accurately fitting frame bolts, the various holes are finished by reaming at the time the frames are erected, as will be described later.

After the frames are drilled they are removed from the machine shop to the erecting department, as the work has now progressed to the point where it is ready for assembling. Before referring to this last step in connection with the framework, attention should be called to the fact that all of these different operations are performed progressively, the work being advanced from one machine to the next without making any retrograde or backward movements. This is also true of other classes of work, the machines being arranged, as far as possible, so that the work moves along in a direct line as it passes from the stock pile to the various machines and, finally, to the place where it is to be assembled. When we consider how many parts are incorporated in a single modern locomotive and then remember that approximately one such locomotive is being built daily at the Juniata shops, the importance of direct methods and their bearing on the rate of production can readily be appreciated.

When the frames reach the erecting department all corners are rounded by pneumatic hammers (as indicated in Fig. 15) before assembling. The chisels used for this work are shown in Fig. 16. They are shaped somewhat like a gouge but have a concave cutting edge. The corners are finished to the required radius by a single cut and almost as smoothly and neatly as could be done in a planer with a form tool. Two frames which have been finished in this way and are ready for the erecting gang, are shown in Fig. 17. This rounding of corners gives the frames a finished appearance and also makes it much easier to handle them, as all sharp edges have been cut away. It is also thought that a frame having round corners is less liable to fracture than one having square

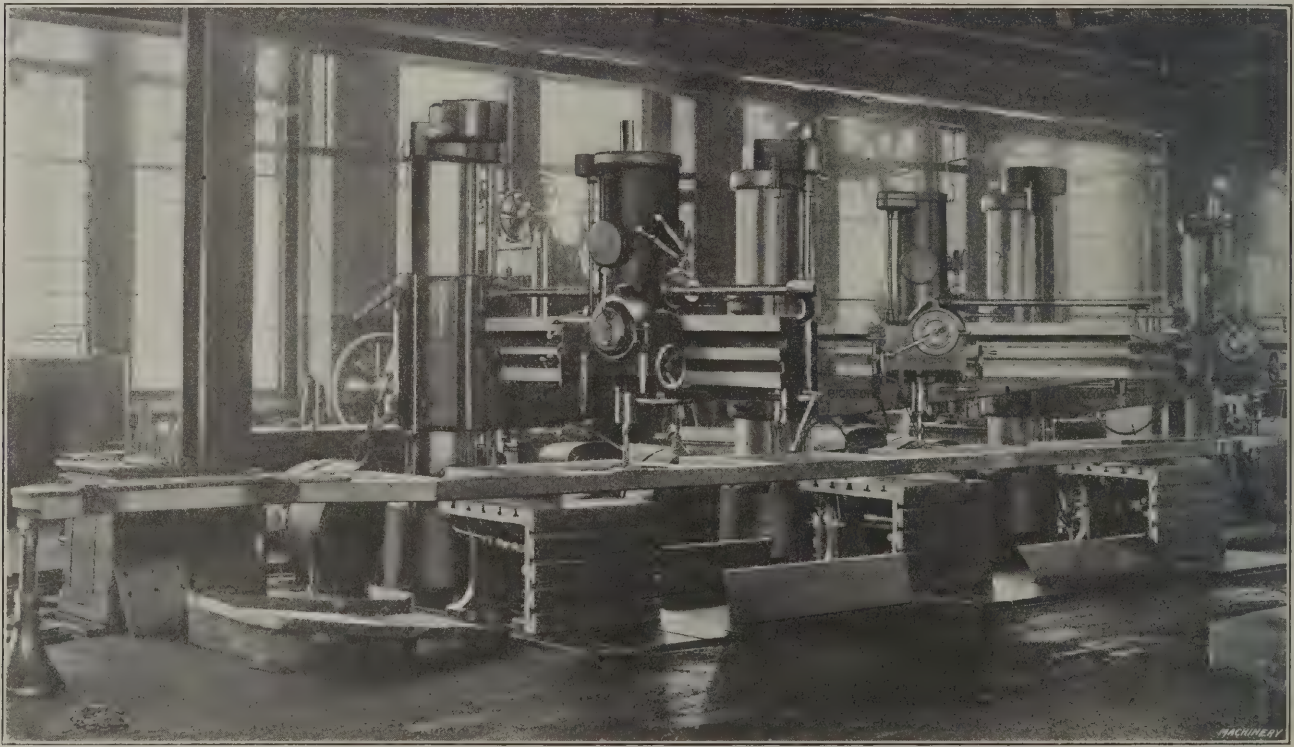

Fig. 14. Gang of Three Radial Drilling Machines used for Locomotive Frame Work

ragged corners, the theory being that a minute indentation at the corner may, in time, develop into a fracture.

The main frame and the trailer frame (in this particular case) are next aligned and the bolt holes for the splice at *A*, Fig. 4, are reamed. After the splice bolts are inserted, the right and left frame sections are tied together by the different cross-

Fig. 15. Rounding the Corners of a Frame prior to Erecting

braces, and this is the first step in erecting a locomotive. The two sections are mounted on blocks and jacks and they are then set level and parallel with each other. The various cross-ties and braces are temporarily clamped in position for reaming the previously drilled holes. As all the parts are accurately drilled, the holes are usually in close alignment so that little reaming is necessary to produce a smooth hole which will insure an even bearing throughout the length of the bolt.

The reaming is done by means of an air motor, and the time required for reaming a hole and driving a bolt "home," is a matter of seconds rather than minutes. The reamer is entered into the hole and the motor driving chuck is applied to the end. As the reamer only has a taper of 3/32 inch per foot (which is the standard for all frame bolts) it is quickly fed to the required depth. The reamer is then backed out while it rotates in the same direction, and the chips are

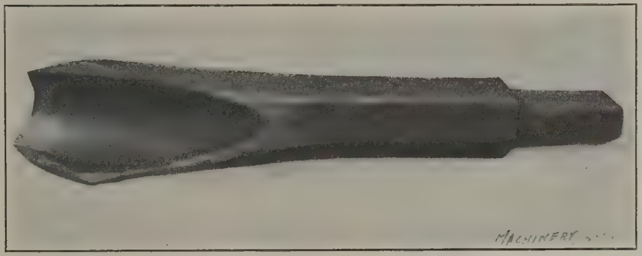

Fig. 16. Gouge-shaped Chisel used for Rounding Corners

blown from the hole by turning the air exhaust of the motor into it. A standard bolt is next inserted and driven home by a few blows of the sledge. This entire operation of reaming the hole, cleaning it and driving in the bolt, is done in a suprisingly short time. As these men are constantly at this work, they have become very expert. No gages are required for reaming, as the workmen know just how far to feed the reamer in for any given bolt. When a hole is being reamed, the motor is held by two men, while a third man measures the distance between the reamer driving chuck and the frame in order to determine when the reamer has reached the required depth. When a reamer becomes too dull to work effectively, it is sharpened in a special grinding machine. The importance of keeping the reamers in good condition can best be appreciated by those who have tried to true up a hole with a dull reamer. Before the erection of the frames is complete, they must be bolted to the cylinder castings which form the principal support at the front. Fig. 19 shows an assembled frame after the cylinders, braces, guide-yoke and other parts connected with the spring and brake rigging, have been attached. When the work has reached this stage, it is only a matter of a few hours when the frame will be buried behind the driving wheels of the assembled locomotive. Those who are interested in locomotive erection are referred to the article on this subject by Mr. Ralph E. Flanders, published in the railway edition of MACHINERY for June, 1910.

Turning Frame Bolts

The method of turning the frame bolts used in assembling the frames, is interesting, owing to the rapidity and simplicity

Fig. 17. Frames after the Chipping is completed

of the operation. The machine used resembles an ordinary four-spindle drilling machine, as will be seen by referring to Fig. 18. The spindles are equipped with chucks having hexagonal pockets, not unlike a socket wrench, which fit the heads of the bolts and cause them to revolve while the body is being turned. The turning is done by cutter heads located in the

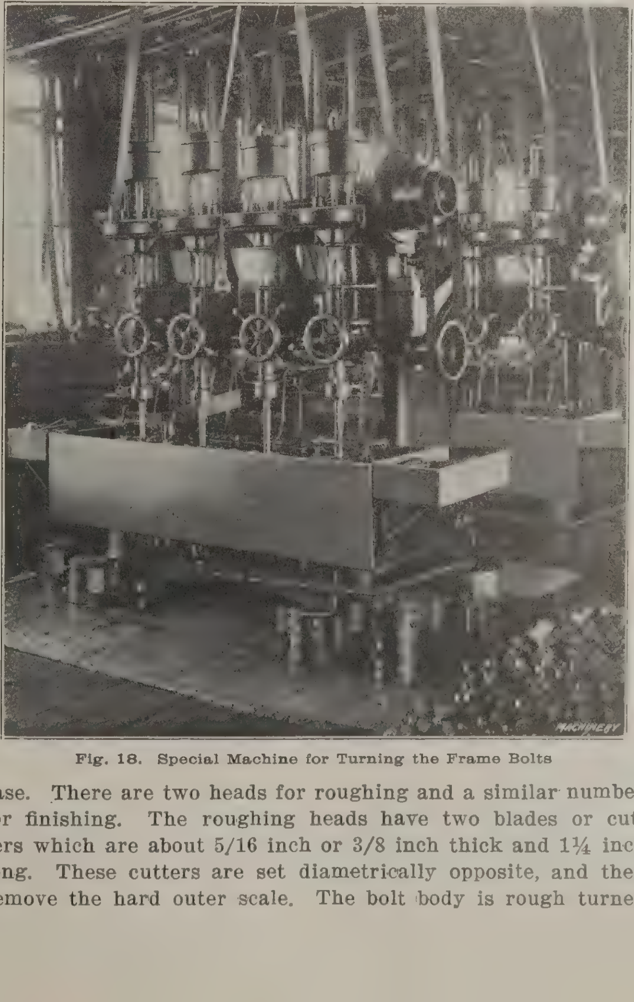

Fig. 18. Special Machine for Turning the Frame Bolts

base. There are two heads for roughing and a similar number for finishing. The roughing heads have two blades or cutters which are about 5/16 inch or 3/8 inch thick and 1¼ inch long. These cutters are set diametrically opposite, and they remove the hard outer scale. The bolt body is rough turned

close to the finished size, but this first operation leaves it straight or of one diameter throughout. The work is then placed in a finishing head. These heads also contain two cutters which differ from those used in the roughing heads in that they are as long, or longer, than the bolt body and are set to turn the bolt body to the required taper. The turning

Fig. 19. Frame after Cylinders, Braces and other Parts have been assembled

operation, in each case, is performed by feeding the revolving bolt down through a cutter head just as a drill would be fed through its work. Several of these cutter heads may be seen at the base of the machine. They are mounted in floating holders so that they can adjust themselves to the bolt being turned. Very rapid work can be done in this machine and one man keeps the four heads in operation. The threading of the bolts is done in regular bolt-threading machines.

* * *

The production of gold in 1910 amounted to $96,055,214. The total building construction in Chicago in 1910, including new buildings, additions and alterations, amounted to $96,932,700. *The sum of these two figures* lacks more than twenty-two million dollars of the actual destruction by fire in the United States of buildings and contents during 1910. Careful observation of the operation of automatic sprinklers leads to the inevitable conclusion that at least half of the $214,003,300 which went up in smoke could have been saved if the principal buildings which burned had been adequately protected by this form of fire prevention apparatus.

PAWLING & HARNISCHFEGER HIGH-SPEED CRANE TROLLEYS

The Pawling & Harnischfeger Co., Milwaukee, Wis., is the builder of the high-speed crane trolley here illustrated. These trolleys are of the "man-riding" type, that is, they have a cage for the operator, though this is not shown in the illustration. The travel speed of the trolley is about 700 feet per minute and the hoisting speed, with a 5-ton load, 250 feet per minute. The trolley is of the "inside running" type and it operates on a plate girder cantilever arm as indicated in Fig. 1, which shows two of these high-speed hoists handling rails at the wharf of the Texas City Transportation Co. The cantilever arm can be moved longitudinally about sixty feet beyond the face of the dock and over a boat tied to the wharf, as the illustration shows. This construction was adopted owing to the impossibility of moving a hinged apron of the ordinary construction, past the rigging of large sailing vessels. The extension of the cantilever arm also permits loading and unloading lighters tied on the outside of a

Fig. 1. Cranes at Wharf of Texas City Transportation Co.

ship. A 100-horsepower mill type motor is used for hoisting, and a 35-horsepower railway motor carrying a foot-brake, for the traverse movement. The load is sustained by a disk motor brake of large proportions and of a new design which will permit a quick adjustment of the air gap.

The special feature of the hoisting mechanism is the arrangement for taking the hook off the hoisting rope and slipping the same rope into a single-rope grab bucket of the latch open type. Rope guards are arranged on the bucket in such a way that they can readily be opened when inserting the hoisting rope which is also the closing line of the bucket. A novel application of a single line bucket of this type is to

Fig. 2. High-speed Hoist built by Pawling & Harnischfeger

use it with a set of holding lines like those used on a two-line bucket. The holding line is wound upon a drum operated by a motor which is just large enough to keep the slack out of the rope when raising or lowering. In this way it is possible to discharge the bucket at any desired height by means of a large foot-operated band brake on the holding drum. When the bucket is fully open and therefore latched, the foot-brake is released and the weight of the empty bucket is again placed on the closing line. The bucket can then be lowered without closing until it strikes the stock pile. This design was developed in order to concentrate the entire capacity of the hoist motor on a single drum which is also used for the hook service. When the bucket is not in use, the holding line is disconnected and wound up on its drum which then remains at rest. The holding drum motor has about the same function as the spring in a curtain roller in that it tends to run ahead of the hoist motor when going up and to lag behind when lowering; therefore, the holding line is never slack and it is impossible to jerk the line when the bucket is discharged. In connection with the hook service, a lifting magnet of 2½ tons capacity is used. The feed cables for this magnet are wound up and "paid out" by a small motor-operated winding drum. The operation of this cable take-up is exactly the same as that of the holding drum mechanism, the cable being always under a slight tension whether raising or lowering.

* * *

EFFICIENCY IN CYLINDRICAL GRINDING*

By F. B. JACOBS†

Anyone who has followed the progress made in cylindrical grinding for the last ten or fifteen years, will admit that the present-day grinding machine, which owes a large part of its success to the modern grinding wheel, has been one of the prime factors in cutting down the cost of production, by furnishing a rapid and efficient method for accurately finishing the component parts of high-grade machinery. To follow the development of the grinding machine from the crude toolpost grinder of the early sixties, to the present-day self-contained grinder capable of finishing such work as chilled rolls for steel mills, piston-rods for marine engines, and an endless variety of work of like nature that heretofore was finished by the slow process of turning, would without doubt be very interesting. For the present, however, let us merely consider a few of the methods employed by up-to-date concerns for obtaining the maximum output from the grinding machine.

The thoroughly up-to-date machinist who looks over the advertisements in the leading trade papers has probably noticed that the manufacturers of grinding machines are not at all bashful in their claims for the efficiency of their machines, and that several makers of grinding wheels play a close second. But notwithstanding all that has been published concerning the efficiency of grinding machines and grinding wheels, the average shop foreman seems to be perfectly satisfied as long as the operator of the grinding machine turns out work that is nicely finished, in just a little shorter time than it could be done by obsolete methods.

There are several reasons for this condition of affairs: One is that the average shop foreman served his time before the introduction of modern grinding; another is that the majority of grinding machine operators have made themselves believe that because they are employed on accurate work, they should be a long time in doing it. Among other reasons are the improper selection of wheels, slow traverse speeds of work, running the wheel too far over the ends of the work, grinding long work without backresting, setting the reverse dogs for each individual piece, and neglecting to use the automatic cross-feed. These are by no means all of the reasons for curtailed production. However, they are the most important to be considered in the problem of producing accurately ground work at minimum costs.

The average shop foreman who served his time long before the introduction of modern grinding methods, has had no practical experience concerning them. For this reason he is satisfied with results that otherwise would be more closely investigated. The makers of grinding machines and grinding wheels are at the present time getting excellent results and high efficiency with their products, and there is no good reason why the average shop foreman cannot get the same results, if local conditions will permit.

As mentioned, the average grinding machine operator seems to have the idea that because he is employed on accurate work, he should be a long time in doing it, feeling his way along carefully, and at the end obtaining the finish by the slow and out-of-date method of letting the wheel "grind out." In justice to the thousands of operators employed on grinding machines, it should be stated that the amount of time "killed" on the grinding job by "soldiering" is insignificant when compared to the time wasted through lack of knowledge concerning modern methods. In nine cases out of ten, the grinding machine operator did not have a competent man to "break him in" on the job. He had to work out his own salvation. It was a case of making good or getting fired. Therefore, he is not wholly to blame if he chose what seemed to be the easiest way of doing his work accurately. Another mistake, and one which is quite common in some localities, is to have the operator run two cylindrical grinding machines at once. The result is that one of the machines is running on a "blind" feed about half of the time. This may look all right, but it must be remembered that overhead expenses are going on while production is at a standstill. The practice recommended by the most successful makers of grinding machines, is that one operator should run but one machine at a time, in order that the machine may produce the maximum of work.

THE HUMOR OF RUNNING RAILWAY TRAINS ON TIME

The idea of arranging railway timetables so that trains can actually run on time seems very funny to the London *Globe*, judging from the article published in its columns a few months ago regarding the West of France State Railway. Why it should be so funny to make the actual running time of trains agree with published schedules used and relied on by the traveling public is not clear to us. Perhaps this is only another manifestation of a queer sense of humor that is said to pervade the British Isles. An extract from the article which was headed "Railway Humor," follows:

"A novel method of promoting closer harmony between railway timetables and the actual running times of trains has been adopted by the West of France State Railway. That the trains on most of the French lines rarely ever run to the scheduled time has long been notorious, but it appears that this little inconvenience has been satisfactorily overcome by the administration of the line mentioned above, and that in the simplest manner imaginable. If the trains will not run according to the timetable, what could be easier than to revise the timetable so as to keep pace with the lagging trains? Here is a scheme that the subtle "Bradshaw" probably never dreamt of, and hence, no doubt, its grim retention of that bewildering maze of mathematical facts—as they ought to be. For "Bradshaw" is no respecter of speed—or the lack of it. If a train is supposed to run from London to Birmingham in three hours, "Bradshaw" simply says so, and there's an end, even if the trains run twenty minutes late on each trip. But they have recently started arranging these matters better in France.

"The new winter timetable of the West of France State Railway is not based on preceding issues, but upon the actual times occupied by trains in their respective journeys during recent months. This system is certainly much easier than going to all the trouble of accelerating the service, and has besides the extra advantage that the trains on that line at least will no longer be late. Whereas hitherto the stipulated times of departures and arrivals were purely mythical, they will henceforth be statements of fact, unless, of course, it should again become necessary to apply additional brake power to the—timetable."

If this be humorous let all the countless travelers, who have wasted valuable hours at railway stations waiting for trains, join in one wild guffaw of laughter! Make timetables truthful? How ridiculous!

THE MANUFACTURE OF STEEL BALLS*

ROUGH GRINDING, HARDENING, AND FINISH GRINDING

By ROBERT H. GRANT†

In the article on ball making in the February number of MACHINERY, the methods of making the blanks and preparing them for the dry grinding were explained. In the present article the grinding and hardening operations will be dealt with. The old English method of grinding the balls was mentioned in the previous article, the balls being ground between two circular plates, the upper one of which was revolved by hand. The increased demand for balls in the bicycle industry soon brought about improved methods for grinding, the first step being to fasten the top plate to the spindle of a drill press, while the bottom plate rested on the table of the machine. In this way work was produced very much faster but no better quality was obtained than formerly.

Fig. 1. Battery of Early Type of Ball Grinding Machines

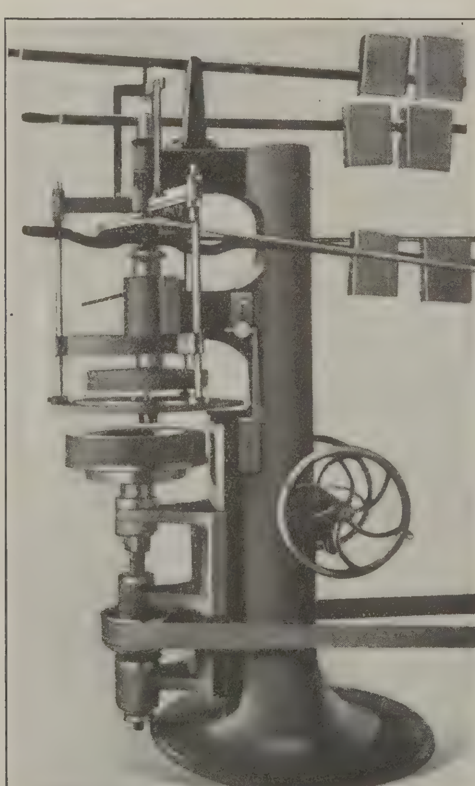

Fig. 2. Richardson's Ball Grinder

About the time when the first steel balls were manufactured in this country, special grinding heads of a much more substantial character were devised. Fig. 1 shows a row of oil grinders, such as were first made in this country. The head is made in the form of a goose neck, and has three bearings. The lower, or main, bearing has a quill the same as a drill press, with a rack cut in it. A lever with pinion teeth cut on the end meshes with this rack and provides the means for raising and lowering the head. The spindle, which has a large faceplate fastened to the lower end, carries the upper grinding ring, which is fastened to the faceplate by three screws. The main drive is through a set of bevel gears on the countershaft directly over the spindle of the machine. A vertical shaft transmits the power from the countershaft to the spindle. As all the blanks at this time were either pressed or forged, instead of being turned, the amount of stock to be removed was considerably more than it is when turned ball blanks are used. For this reason the time required for grinding ¼-inch balls was from one-half to three-quarters of an hour, and if the rings were badly worn the balls would come out of the grinder considerably out of true. It was, therefore, necessary to devise a better and quicker process—a rough grinder—for removing the surface of the balls. It is especially necessary to remove the surface to some depth when the balls are forged, as the outside is then apt to be decarbonized.

The Richardson Rough Grinder

The first rough grinder for balls, as far as the writer knows, was made by Mr. Henry Richardson, president of the Waltham Emery Wheel Co., Waltham, Mass., in 1877. Mr. Richardson, in speaking of this machine, has mentioned a few interesting facts about his experiments along this line. He took a regular 16-inch bastard file and ground a 90-degree groove in the center, almost the entire length of the file. The groove was ground clear through the file so that it would allow a 5/16-inch ball to project through to such an extent that the ball could be ground by a wheel without the latter touching the file. An emery wheel was then fastened to the faceplate of a lathe, and the file was clamped to the carriage in a vertical position. A plate with an elongated slot, which could be moved up and down on the tailstock spindle, was then made. The file with the balls was now placed against the emery wheel, and the plate on the tailstock was placed against the balls. The lathe was then started. The balls at once began to move in the V-groove in the file, and by moving the plate on the tailstock spindle up and down, the balls were turned in all directions, producing in a very short time a blank which was a comparatively true sphere.

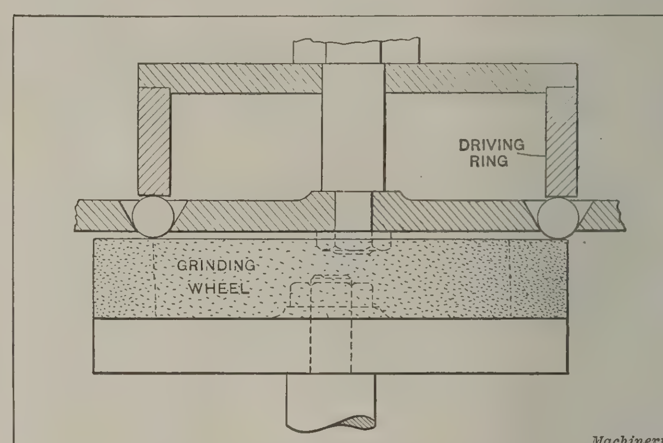

Fig. 3. Diagrammatical View of Principal Arrangement in the Richardson Ball Grinder

Mr. Richardson then made a trial machine which worked very satisfactorily, but as a photograph of this machine was never made, no record of its appearance is preserved. In 1878 he went to England and sold the English patents to Mr. Wm. Bown. A sample machine, as shown in Fig. 2, was made at this time. The patent held by Mr. Richardson did not, however, properly cover the invention, so that he was unable to get full returns for his efforts. The only claim of any im-

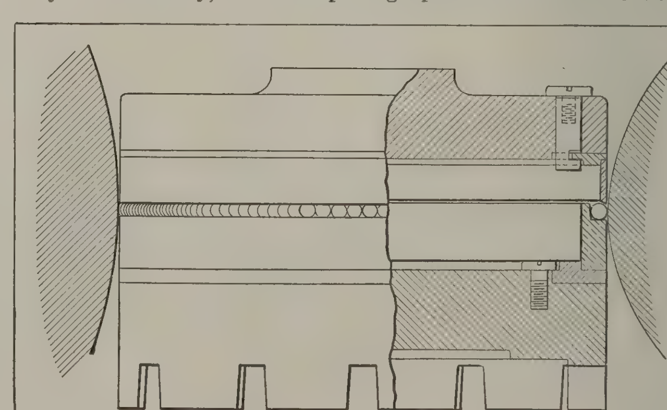

Fig. 4. Principle of the John J. Grant Rough Grinder—U. S. Patent No. 535,794

* See MACHINERY, February, 1912: "The Manufacture of Steel Balls—Making the Blanks."
† Address: 912 Oakland Ave., Ann Arbor, Mich.

portance which he held was as follows: a ring of balls in a V-groove, revolved by a driving ring and exposed to an emery wheel. This claim was the direct result of his experiments, and by itself was very far-reaching. It gave the ball makers, who soon began to spring up all over the country, a great deal of trouble in their efforts to "go around" it.

As shown in Fig. 2, the emery wheel is placed on the lower spindle which is mounted in the movable head; this head is operated by the handwheels at the rear of the machine. The emery wheel is eccentric with the top ring, so that the whole surface of the wheel will successively come in contact with the balls. This keeps the wheel in perfect shape. The V-groove in which the balls rest is formed by two annular rings or plates (see diagrammatical view in Fig. 3); the outer one is held and adjusted by three long bolts (shown in Fig. 2), while the inner plate is fastened to a rod which passes through the drive shaft to the top of the machine. This inner plate is operated by the middle lever shown, so that the balls thus can be "dropped" when finished. The driving ring which revolves the balls is adjustable in an up and down direction by means of the lower lever, and is clamped in the proper position by the small lever on the main bearing.

upper or driving ring was so thin that it was possible to grind but a few balls before the emery wheel would wear it away. As shown in Fig. 4, the balls were held at the periphery of the stationary ring in a V-groove. The drive ring was extended over the balls far enough to drive them, and was driven by a pulley on the spindle which held the drive ring. The speed was not over 60 revolutions per minute. A saddle, which was stationary on the base of the machine, carried the emery wheel heads, each head having two wheels, so that the surface coming in contact with the ball would be as wide as possible. The driving pulley was placed between the emery wheels, all being driven from the same countershaft. The upper or drive ring could be raised by a lever at the top of the machine, and the lower ring could be revolved by throwing out a latch with a foot lever. This allowed the machine to be loaded and unloaded very rapidly. Notwithstanding the fact that this machine was very slow, as compared with the Richardson machine in which the emery wheel was on the balls at all times, it was successful, and it was possible for the Simonds company to produce a ball better than those produced by any other manufacturers, and the company, therefore, soon controlled the ball trade.

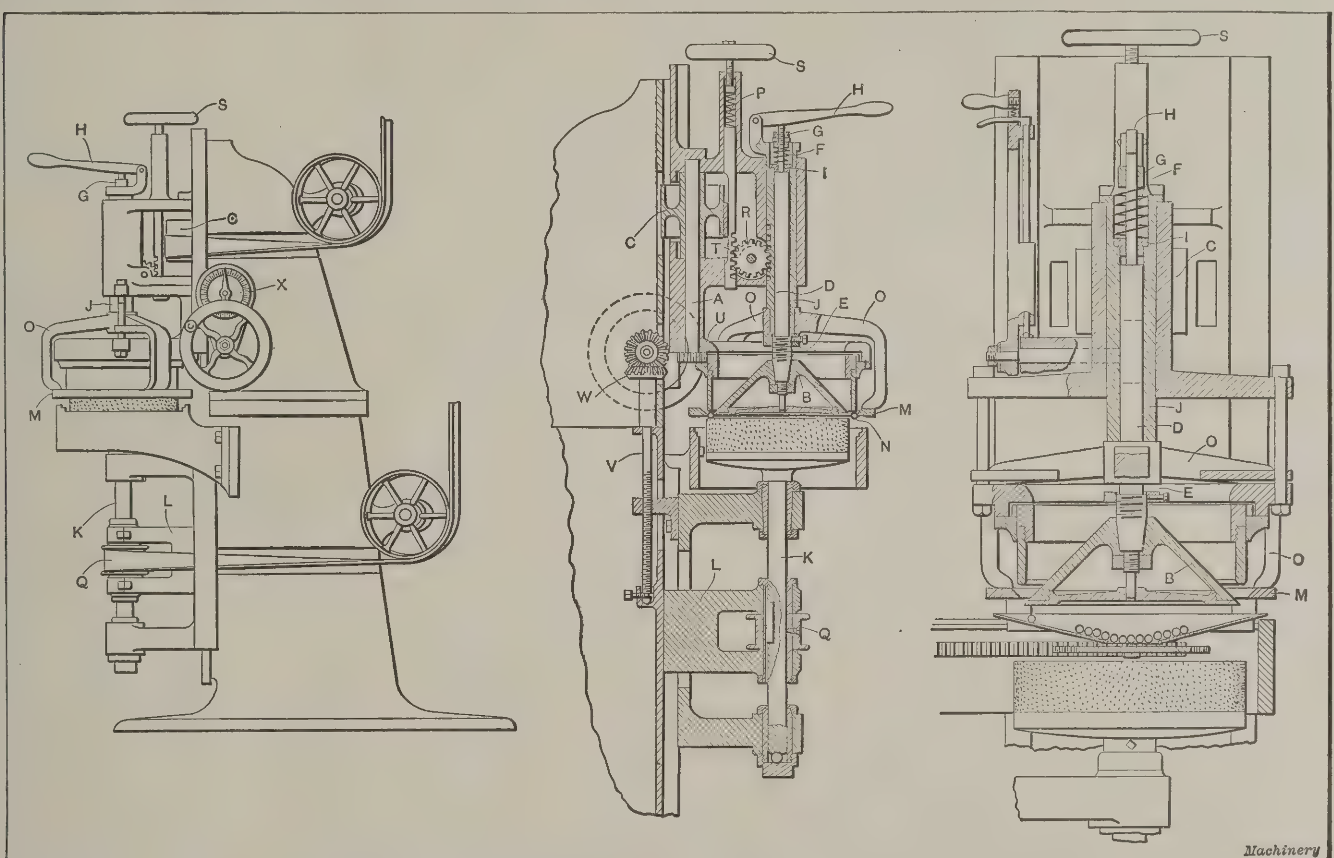

Fig. 5. Robert H. Grant Dry Grinding Machine—U. S. Patent No. 520,019

This driving ring runs in the opposite direction to the emery wheel; the latter is run at a peripheral speed of approximately 5000 feet a minute.

On account of the fact that the outside of the balls run faster than the inside, as they are driven around by the drive ring, the balls assume a spiral motion, thereby exposing all sides to the emery wheel. An approximately accurate sphere is thus produced.

The John J. Grant Rough Grinder

In 1888 when the Simonds Rolling Machine Co., of Fitchburg, Mass., was grinding balls by the old English method, it could only produce balls which were true within 0.003 inch. This accuracy was considered sufficient at that time. Mr. John J. Grant, who was at that time employed by this company, and who had improved the Simonds rolling machine, proceeded to devise a machine which made it possible to produce balls far superior to any ever made. The principle of his first machine, which was a rough grinder, is shown in Fig. 4. This machine produced excellent work, but was very slow in its operation, as the balls had to travel one-half of the circumference of the groove in the ring without coming in contact with the emery wheel. On balls of smaller sizes, the

In 1891, the Grant Anti-Friction Ball Co. was formed by Mr. J. J. Grant, and a great many experiments in the dry grinding of balls without the V-path and drive ring were undertaken, but the experiments were not successful. It was, therefore, necessary to buy Mr. Richardson's patent, and around this was built the most successful dry grinder ever produced.

The Robert H. Grant Dry Grinder

In Fig. 5 are shown general and sectional views of the grinding machine designed by the writer, as originally made. It will be seen that the Richardson path is used in a modified form. The drive ring is driven through a gear on the drive ring holder, this gear, in turn, being driven by pinion U which is fastened to the shaft A. This shaft carries pulley C at its upper end. The cone B has a plate with hardened segments screwed to its lower end which form the inner part of the race N. The cone is fastened to the shaft D which is adjustable by collar E. On the upper end of the shaft is a spring F which is compressed between the collar I and the adjustable sleeve G. By means of the lever H, the shaft D can be lowered, thereby allowing the balls to drop into a receptacle after being ground, as shown in the view to the right. On the

rear of the quill J, which carries the shaft D, is cut a rack in which pinion R works. The shaft T which operates pinion R is adjusted by the spring P, controlled by the handwheel S. On the lower part of the quill J is fastened the spider O which carries the ring M, to which are screwed the hardened segments forming the outer path.

It will be seen that when the rough forgings are placed in the V-path, the driving ring is stationary, but the inner ring can vibrate on account of the action of the spring F. The outer ring M is permitted to vibrate slightly through the means of the spider O, quill J, pinion R and spring P. In this way the rough forgings will be ground only on the high spots until the balls become round.

The loading and unloading is done without stopping. When the balls are finished, the emery wheel is lowered and a pan is pushed under the path of the balls. The handle H is pulled down, thus allowing the balls to fall into the pan. The spider O is then lowered by means of the lever on the end of the shaft carrying pinion R. This allows the balls to be ground to be fed into the path N, and permits the grinding to commence without interruption.

The emery wheel, which is eccentric with the path of the balls, so as to allow the balls to successively cover the whole surface of the wheel, is carried by the lower head. The spindle K carries the pulley Q which is driven by a belt running over idlers to the countershaft above. Head L is raised and lowered by the screw V and the bevel gears W. The indicator X, having a pointer as shown, is connected to this mechanism, and shows the operator how many thousandths inch more he must remove from the balls. With the introduction of this machine the cost of making balls was cut in two, and the quality obtained was far superior to anything which had so far been produced.

The Hawthorne Method of Rough Grinding

About the time when the writer had designed the machine just described, the Hawthorne Mfg. Co., of Bangor, Me., decided to enter into the manufacture of steel balls. This company originally manufactured boot calks and other lumbermen's supplies. Some articles were manufactured for this concern by the Simonds Rolling Machine Co., and representatives of the company frequently visited the Simonds plant. They observed the great number of balls that were beginning to be used in this country, and hence concluded to enter into this field. The first grinder employed by this company made use of sand instead of emery. A bed of sand had been found in which the grit was so hard that it would cut the surface of a ball and last for a considerable length of time before being pulverized. The grinding was done in a closed path in which water and sand were used freely. The sand was fed from bins overhead, and washed out by water when pulverized. This was a very cheap process, as far as the grinding material was concerned, but did not produce a perfectly spherical blank. The oil or finishing grinders had to be relied upon to round up the balls, and a great many seconds and thirds were produced. The process was applicable, however, to the small balls mostly used at that time, nearly all balls being employed in bicycles. For larger balls, such as are now used in automobiles and other machines of the present day, these machines would have been useless.

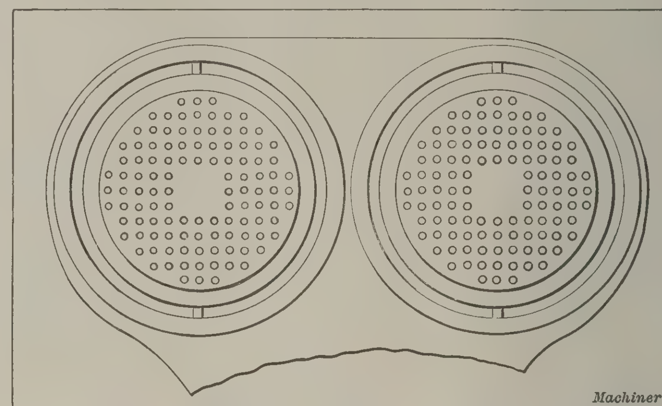

Fig. 8. Arrangement of Balls in the Putnam Grinder

The Putnam Ball Grinding Machine

About 1899, Mr. H. M. Putnam, who for several years was connected with the Simonds Rolling Machine Co., started the Fitchburg Steel Ball Co., and invented a dry grinder, as shown in Figs. 6, 7 and 8. This machine, which had to be constructed without the Richardson path, was made in the following manner: The lower plate A which corresponds to the drive ring, was driven through the tube B which carries the pulley C. The plate D which is countersunk as indicated at E, Fig. 7, (see also Fig. 8) is made from saw steel and hardened; it is then forced onto spindle F which carries pulley G. The cylinder H is adjustable by means of the screw thread K, and can thus, by means of handwheel O, be raised or lowered by the operator so that the balls will come in contact with the emery wheel L. This wheel is fastened to the upper spindle N, which

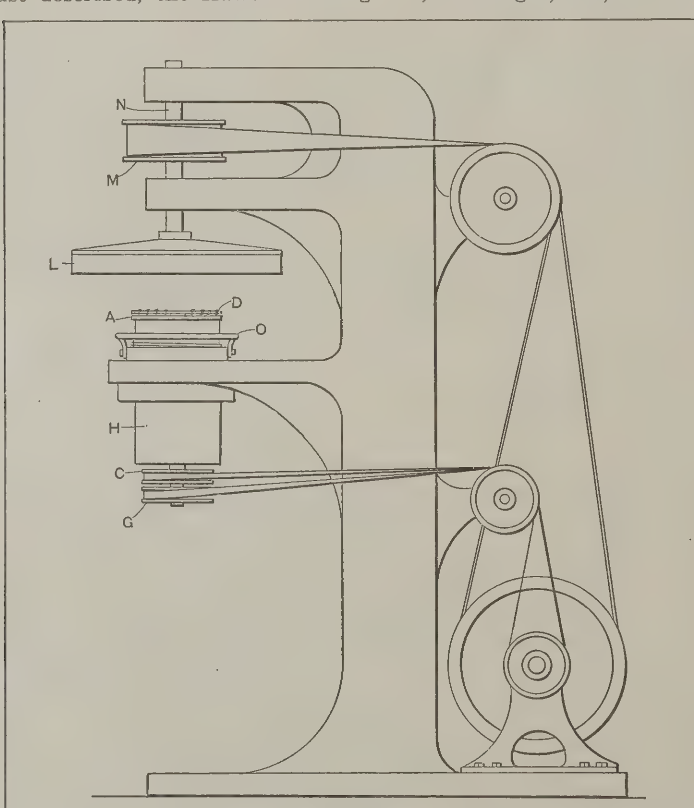

Fig. 6. The Putnam Dry Grinder—U. S. Patent No. 664,823

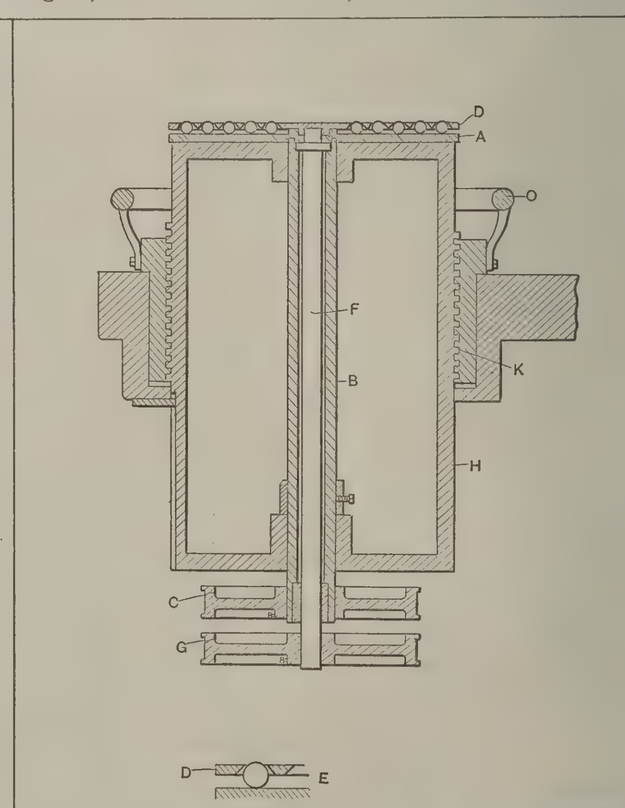

Fig. 7. Details of Principal Parts of the Putnam Grinding Machine

is driven from pulley M by a belt passing over two idler pulleys to the countershaft on the floor, as shown. This machine is very simple, but it does not grind an accurate ball on account of the balls being at various distances from the center, thereby giving them different rates of speed. The outer balls are ground faster than those at the center, and thus balls of all kinds of diameters and degrees of accuracy are produced. The balls are not held firmly in the path as in the Richardson grinder, but are simply confined in the countersunk holes so that they will not be thrown from the plate. This allows the ball to take its own course, and it becomes badly out of round

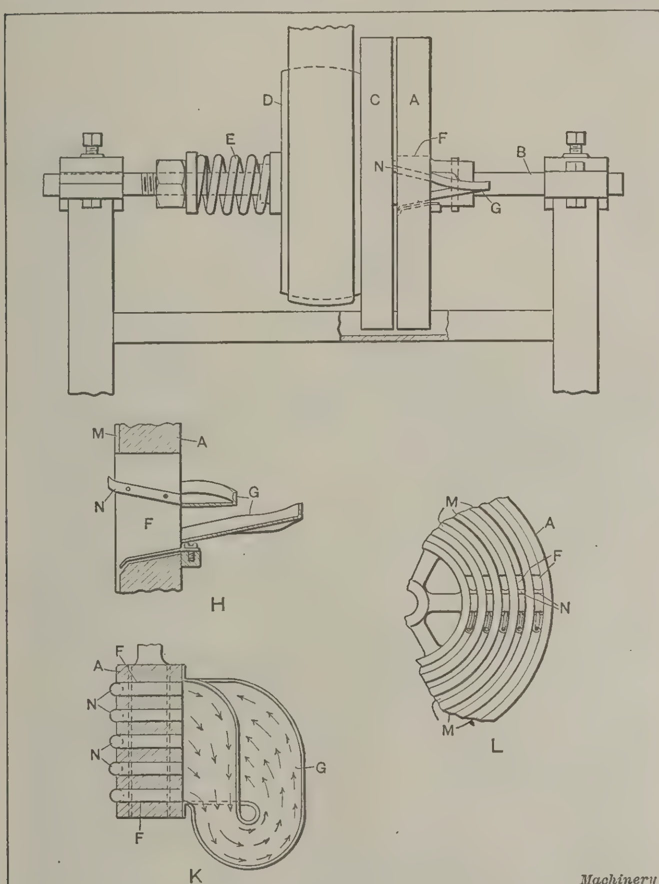

Fig. 9. The Hoffmann Ball Grinding Machine—U. S. Patent No. 803,164

during the grinding process. The writer is of the opinion that this machine might have been improved, but the company discontinued business soon after the machine was built.

The Chicago Steel Ball Co.'s Grinder

About the same time the Chicago Steel Ball Co., of Chicago, Ill., brought out a dry grinder which had several good features, and which was somewhat similar in operation to the well-known Hoffmann machine which will be described in detail in the following. The Chicago Steel Ball Co.'s machine had the emery wheel and the drive wheel placed in a vertical position. There were several concentric circular paths on the drive ring, and the balls were transferred from one into another, thus giving the balls a different spiral motion on account of being at various distances from the center. This machine ground a very accurate ball, but on account of its poor construction and the poor method used for transferring the balls from one path to another, it was but little used, and, therefore, had no particular influence on ball manufacturing methods.

The Hoffmann Grinder

What may be considered as one of the best ball grinding machines constructed was invented in 1905 by Mr. E. G. Hoffmann, who was at that time connected with the Hoffmann Ball Co., in England. This machine required several years for its development, but when completed it produced a very accurate ball, and is greatly appreciated by ball manufacturers.

In the article on ball manufacture published in the February number of Machinery, the Hoffmann ball turning machine was described. The blanks produced by this machine are accurate, and but little grinding is required on them. These balls, therefore, are especially suited for grinding in the Hoffmann grinder, as this machine is very slow, and cannot be used to advantage on pressed blanks or forgings, unless they have been previously rough ground by some other process. The machine is automatic, and requires little or no attention, except for gaging the balls at intervals during the grinding. The machine requires from three to five hours for removing 0.001 inch on a ½-inch ball.

In Fig. 9, diagrammatical illustrations of the Hoffmann machine as originally designed, are shown. Pulley D is driven by a belt from the countershaft, and revolves upon a stationary shaft B. The pulley is fastened to the disk C which has a series of grooves in its face. Plate A, which also has a series of concentric grooves to correspond with those on disk C, is stationary and is fastened to shaft B. The balls are placed in the machine so as to fill all the concentric grooves, spring E forcing disk C against plate A, thus holding the balls in place. The machine is then started, and the balls, by means of the mixer and interchanger shown in two views at H and K, are changed from one groove to another.

As indicated at H, K and L, slots F are cut through the stationary disk, a slot being directly opposite each of the grooves M. In each slot is placed a finger N which projects slightly beyond the bottom of the groove into the corresponding groove in the rotating disk C. The function of the finger is to stand in the path of the balls so as to positively dislodge each ball from the groove as it reaches the point where the finger is located. Each finger discharges the ball from the corresponding groove upon a table G which affords a surface upon which the balls may roll, and which also directs the balls back toward the grooves below the fingers, the table being slightly inclined toward the lower portion of the slots F. It will be seen that this keeps the balls moving from one groove to another so as to place them at

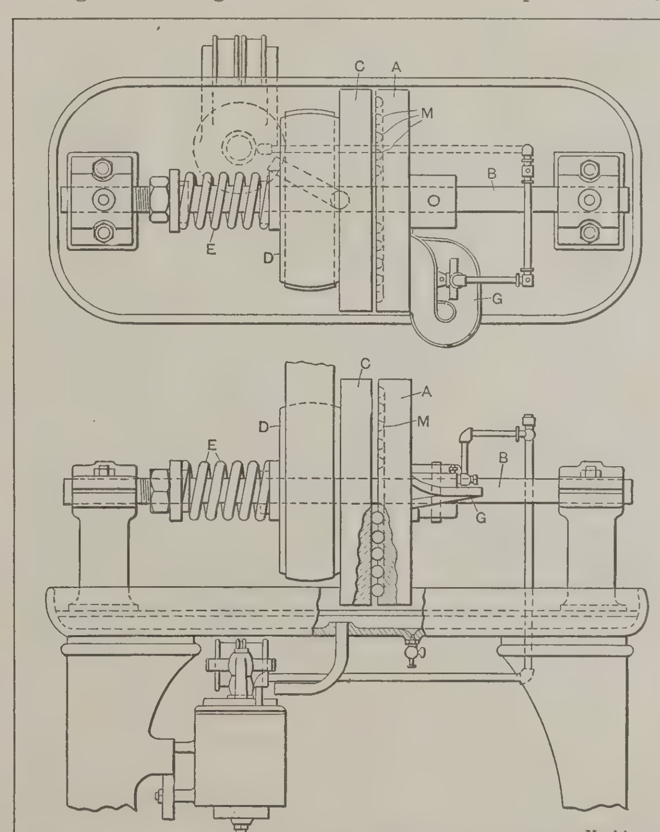

Fig. 10. Improved Hoffmann Ball Grinding Machine—U. S. Patent No. 868,926

different distances from the center at each revolution of plate A. This results in the grinding of a very accurate ball.

The grinding is done with oil and emery introduced in the required quantities upon the table G, and fed into the machine by the balls. This machine was further improved by the introduction of an emery wheel in place of the grinding ring C. The improvement was very marked, as the grinder C, when made of cast iron, was apt to be spongy, and softer in some spots than in others; it would, therefore, quickly wear out of shape. The replacing of this disk by the emery wheel overcame these difficulties. Kerosene oil is used to keep the grooves clear of the loose particles of abrasive material, and

prevents the balls from being badly scratched or cut. A very peculiar fact about this grinder is that the emery wheel is run at only 75 revolutions per minute, instead of at the peripheral speed of 5000 feet, generally required by emery wheel manufacturers.

Annealing and Hardening

After the balls have been rough ground so as to remove all scale and decarbonized surface resulting from the forging operation, they are taken to the hardening room where they are first annealed. This annealing removes any internal stresses caused by forging or other methods of blanking. The

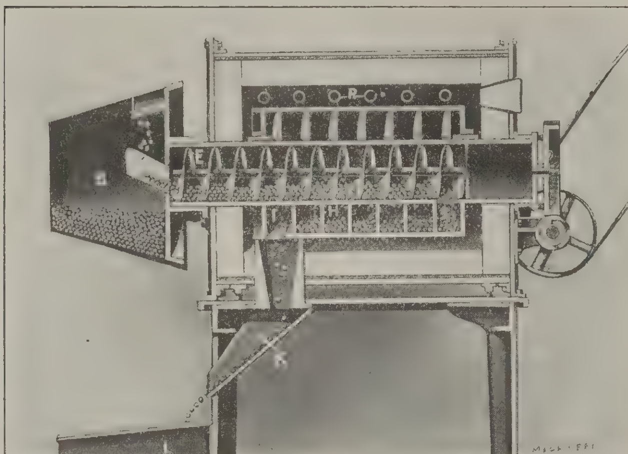

Fig. 11. Section of Ball Heating Furnace, made by the American Gas Furnace Co.

process, as indicated in Fig. 11, is automatic. The balls are fed into the hopper *B* which is revolved by a worm and worm-wheel placed at the opposite end of the machine. From this hopper the balls are fed into the spiral *E* which they follow until they reach the opposite end, where they drop into the outer spiral *H*, which is revolved in the opposite direction. Finally the balls fall out of the cylinder at *I* into the funnel *K*. The machine is heated by gas with burners at *R*, thus preventing the heat from coming into direct contact with the balls and decarbonizing the surface.

After being annealed, the balls are put through the same machine to be heated for the hardening. They are heated to exactly 1275 degrees F., the temperature being determined

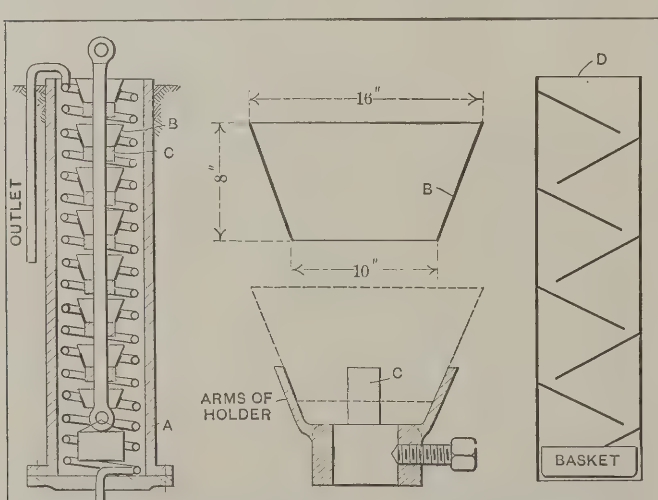

Fig. 12. Tanks used for Quenching Balls

by a pyrometer. The thermo-couple is placed near the point where the balls leave the cylinder.

The smaller balls are dropped into a reservoir of oil, while the larger ones are immersed in brine. The oil reservoir, shown at *A* in Fig. 12, consists of a length of 30-inch water pipe, one end being provided with a head strongly bolted to it so that it is water-tight. The pipe is sunk into the ground so that the top can receive the balls, as indicated at *L*, Fig. 11. Inside of this cast-iron pipe is placed a coil of 1¼ inch water pipe, in which cold water is circulated in order to keep the bath cool. A rod with a number of inverted galvanized iron cones *B*, adjustably fastened onto the rod by the holders *C*, is then placed in the bath. (Parts *B* and *C* are also shown in detail in Fig. 12.) When the balls drop into the bath in the pipe, they strike the side of the upper cone, which shoots them off at an angle until they strike the opposite side of the next cone; this reverses their direction of motion, so that they reach the basket at the bottom in a zigzag path, thoroughly cooled off. When the balls are thus cooled off, the rod with the basket at the lower end is pulled out, and the balls in the basket are allowed to drain, the oil draining back into the pipe.

The best oil for the hardening of balls is cotton-seed oil; while it is very expensive, it has sufficient body to cool the balls thoroughly, and it does not need to be replaced. It is only necessary to add to it, from time to time, due to the loss from evaporation.

The larger balls are hardened in brine. The machine shown in Fig. 11 is placed at the edge of a tank of the type shown at *D*, Fig. 12. This tank has a series of shutters made in the form of steps overlapping each other as indicated. These steps force the balls to traverse in a zigzag path through the brine in the tank for a considerable time before dropping into the basket at the bottom.

Fig. 13. General View of the Grant Dry Grinding Machine, with Samples of Largest and Smallest Balls ground in it

The largest balls are heated for hardening by being placed on the tiling of a regular casehardening furnace, similar to that made by the Brown & Sharpe Mfg. Co., and are allowed to heat slowly through to the center, the balls being revolved gradually. Two or more balls, according to size, are then placed in a wire basket and rapidly swung to and fro in the brine tank until thoroughly cooled off. All balls, as soon as they are taken from the hardening tanks are placed in a kettle of boiling soda, not only for the purpose of washing them, but also to prevent the air from coming in contact with them at a time when they are extremely hard. The balls are then placed in the drawing kettles, which are filled with oil heated to 325 degrees F.

Finish Grinding

The balls are now ready to return to the finish dry grinding department, where the same machine as shown in Fig. 5 is used (except that a finer grade of emery wheel is employed) to reduce the balls to the proper size for the oil grinders. For this finish dry grinding the inner and outer segment are ground true, so that the path formed is a perfect track for the balls.

In Fig. 13, the improved Grant machine (Fig. 5) is shown, with the two extremes in size of balls which this machine will grind. In Fig. 14 is shown the special grinding machine which is used for grinding the segments that form the path for the balls. These special grinders are very simple in construction, the wheel head being solid and the spindle on which the segment plate is fastened being driven by a worm through a shaft from a pulley in the rear. The two adjustments up and down and in and out are operated by the shafts which project in the front. By this grinding, the segments are made absolutely true, and by grinding the drive ring by the emery wheel on the machine on which it is used, the balls will make contact on three points absolutely true with each other, and hence the balls produced will be absolute spheres, ready for the final oil grinding.

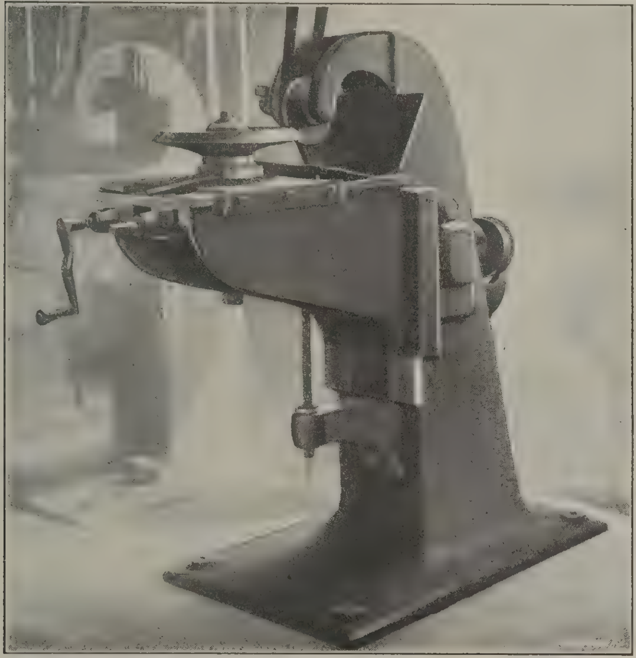

Fig. 14. Special Grinding Machine used for Grinding the Segments for the Path of the Balls in the Machine shown in Fig. 13

Fig. 17 shows the ordinary type of oil grinders. These are usually placed in groups of three. The machines are provided with a quill, on which a rack is cut for raising and lowering the head by means of the lever shown projecting at the front of the machine. The machines run about 450 revolutions per minute. The oil grinding constitutes the final finishing operation, and requires considerable skill. The operator must know just how much oil and emery to use, and how long to run the rings so as to make the balls round up.

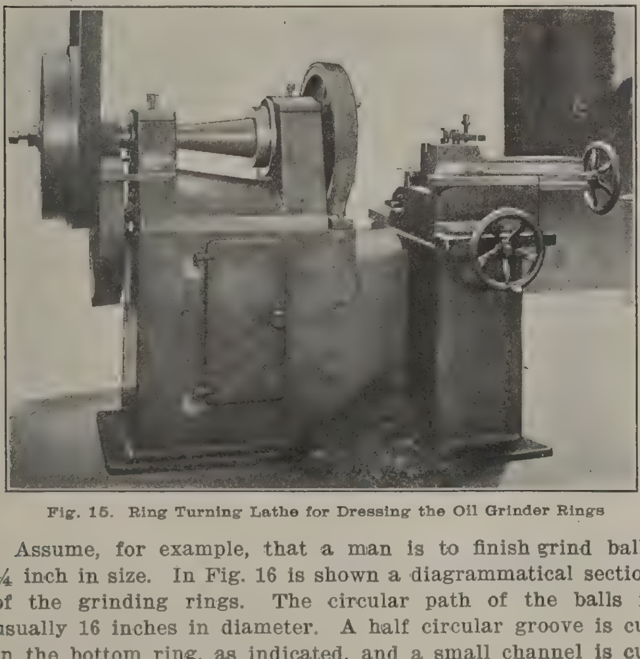

Fig. 15. Ring Turning Lathe for Dressing the Oil Grinder Rings

Assume, for example, that a man is to finish grind balls ¼ inch in size. In Fig. 16 is shown a diagrammatical section of the grinding rings. The circular path of the balls is usually 16 inches in diameter. A half circular groove is cut in the bottom ring, as indicated, and a small channel is cut at the bottom of the groove to allow the oil and emery to reach the bottom of the ball. The top ring is simply a cylinder shrunk onto a plate. This plate can be used over and over again, by merely breaking off the cylinder when used up and shrinking a new ring in place. The upper cylinder has a shallow groove in it for the balls. After the balls have been placed in the ring, the oil and emery are poured in, and the upper ring is lowered onto the balls, the machine then being ready to start. The ¼-inch balls should have 0.006 inch left for the finishing operation. The operator gages the balls and sets his clock on the head of the machine as many minutes ahead of the clock in the room as he knows will be required to obtain very nearly the final size. At this time he must stop the head and again measure the balls. The operator runs three heads, and as each head finishes its work at different intervals, he has ample time to stop any one head and take out three or four balls from different parts of the ring. After washing them in benzine, he measures them with his micrometer, testing both the size and roundness; if not to size, he replaces them and applies the required amount of oil, emery and speed, until he obtains a ball that is as nearly perfect as possible in all respects.

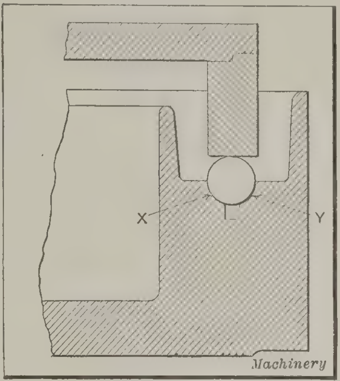

Fig. 16. Illustration of Principle of Action of Oil Grinders

The grinding ring should be of porous medium soft cast iron, as the oil grinding is merely a lapping process, and the

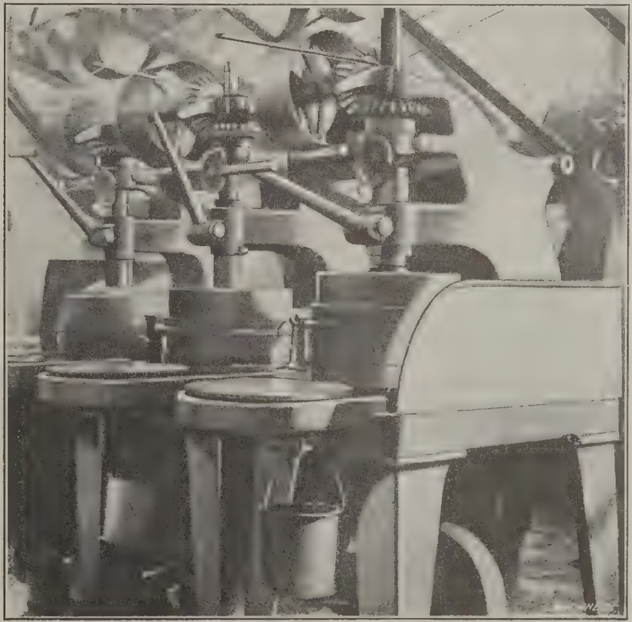

Fig. 17. The Oil Grinders

ring must wear away to allow the balls to round up. On account of the larger diameter at the outside Y than at the inside X of the balls, Fig. 16, there is a greater peripheral speed at the outside. This causes the balls to move in a spiral path as they revolve, so as to bring all points of the surface in contact with the ring. The operator, when using a new ring for the first time, must make allowance for the ring not having become penetrated with emery, and also for its being cold. Later the output can be greatly increased. The heads on the grinders must be kept in perfect alignment, so that the balls will be ground on the entire circumference of the rings.

Fig. 15 shows a special ring turning lathe for dressing the oil grinder rings. It is necessary that these rings be free from chatter marks and imperfections of any kind, so that even the first sets of balls ground by them will be perfect; otherwise the first balls would have to be classified as seconds or thirds on account of poor grinding.

MACHINERY

RAILWAY EDITION

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS

49-55 LAFAYETTE STREET, NEW YORK CITY

27, CHANCERY LANE, LONDON, W. C., ENGLAND

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

MARCH, 1912

PAID CIRCULATION FOR FEBRUARY, 1912, 25,095 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

SHOULD ENGINEERING SOCIETIES PAY FOR CONTRIBUTIONS?

The papers read before American engineering societies are of two main classes. One class describes installations of machinery and apparatus, and the considerations that had to be taken into account by the engineers in charge. These papers are generally valuable and unobjectionable, notwithstanding their advertising nature. The advertising that the concerns and engineers get from the presentation of papers is the incentive that causes them to be prepared. The other class comes from college professors, and chiefly describes tests conducted by students for their theses. The professor advertises himself and his college with little effort by giving the results of his students' investigations in a paper. These papers are legitimate and commendable when the investigations have led to results of practical value. Both classes of papers are contributed at little or no cost to the authors and mean little or no personal sacrifice.

A third class of contributions, of which there are entirely too few examples, comes from men who give their personal time and energy to the subjects of their papers. They give freely to the engineering world that which has cost them much thought and time to reduce to a form that can be generally understood and appreciated. Great credit is due them for their generosity and enterprise. But, is the brief recognition accorded these able men adequate compensation? Is not the American Society of Mechanical Engineers losing many valuable contributions that would be offered by individuals if they could afford to give the time and labor to their preparation? How can the difficulty be met except by offering compensation for the results of investigation made by men who cannot afford to give their work freely?

The society's sub-committee on machine shop practice is required to present those details of practice that can be collected and described only by the men in daily contact with the conditions of manufacturing. These men are generally paid wages much lower than the salaries of engineers, yet we ask them to contribute their time and energy for the benefit of the mechanical engineering world. Their reward is the honor of having their papers read before the society, which is probably highly appreciated, but which may be of little actual value to the individual. Will the ethics of engineering societies prevent doing what seems necessary to secure the records of the most advanced practice?

HARDENING VS. TEMPERING

A contributor to MACHINERY has written a letter in reference to the tool tempering furnace described in October, 1911, taking exception to calling it a tempering furnace when it is clearly a hardening furnace.

The exception is well taken. Every reader of MACHINERY who knows anything about hardening steel is well aware of the distinction between hardening and tempering. To harden a piece of carbon steel, we must heat it to a "cherry red," then quench it in a bath which is usually pure cold water. In the state produced by cooling in the bath the steel is too hard for use, being brittle and liable to chip or crack. The hardness is reduced by heating the piece to the temperature which experience has demonstrated to be sufficient to reduce the hardness to that consistent with the use of the tool.

Heat treatment of carbon steel almost invariably consists of two operations, first hardening and then "drawing" the hardness or tempering it to the required degree. The definition of "tempering" in the Standard Dictionary, edition of 1899 is: "To bring (a metal) to a certain degree of hardness by heat and suddenly cooling. In tempering steel, the metal is usually heated until it assumes a color, as yellow, brown, purple, or blue, and then plunged into water. The degree of heat (as shown by the color) at which the cooling takes place determines the degree of hardness."

This definition clearly shows a lack of understanding of the distinction between hardening and tempering, but in justice to the lexicographer it may be said that tempering is a term that is often loosely used to mean both hardening and tempering, that is, both operations necessary for the proper heat treatment of carbon steel, although it should not be so used by those who know and understand the true meaning of the term.

THE GROWTH OF THE MOTOR TRUCK INDUSTRY

The recent automobile shows held in New York City were startling revelations to many business men of the importance of the motor truck industry, from both the manufacturers' and users' standpoints. For several years it has been the fashion of editors, economists and others to deplore the fact that the inventive genius and manufacturing enterprise of the country apparently was almost exclusively concentrated on the improvement and construction of automobiles for pleasure. It seemed that the more useful and enduring business of commercial car building was practically neglected. While these strictures were in the main true, the developments of the past two or three years show that a substantial body of designers and builders was planning and making commercial vehicles that are satisfactorily meeting the exacting demands of business in large cities and towns.

Commercial trucks have arrived at the practical stage, and although they still have defects and undesirable complexities, the men capable of operating them are becoming available, and business concerns are using them. The expense of keeping horses in large cities grows greater every year. Stables must be located where rents are low, and this means in sections generally remote from business centers. The time lost in traveling between the stables and the warehouses is a serious item which becomes still more serious in Manhattan where stabling is available mostly in Brooklyn and Jersey City. Ferriage and bridge tolls are added costs of daily operation.

In times of weather stress, horses are subject to accidents and the ills incident to exposure. Loads must be reduced or teams doubled to move normal loads. The motor truck is subject to mechanical troubles, but its practically unlimited power, great capacity, speed and short overall length are advantages that will become more and more apparent as drivers become trained to operate trucks efficiently.

To secure greater efficiency of men and trucks, power loading and unloading facilities will be developed. These will not only accelerate the moving of freight, but will make the operation of power trucks more attractive to a desirable class of men. One of the existing difficulties is getting men competent to drive motor trucks who are willing and able to handle heavy boxes and parcels. Cranes that will lift a box from the sidewalk to the truck will make the loading quicker, easier and safer for men and merchandise.

It is interesting to reflect on the change that will inevitably develop in the personnel of truck drivers. As a class they are now known as ignorant, "horsey" and abusive men, more familiar with saloons than churches. When they become largely a class of men trained to efficiently control powerful road locomotives, the discipline of mind and body necessary to the understanding of machinery and its control must necessarily produce in them the characteristics of a more desirable class of citizens. A drunken driver of a power truck will be too dangerous to tolerate, and he must disappear.

STANDARDIZATION WORK OF THE S. A. E.

The work of standardizing the characteristics of automobile elements undertaken by the Society of Automobile Engineers is proceeding satisfactorily, notwithstanding the many difficulties that beset it. The general method followed is adjusting shapes, center distances, dimensions and capacities of accessories to common standards that will insure interchangeability, and thus make possible variations of the equipment without necessitating changes in the construction of the basic structure to accommodate them.

Standardization will enable the manufacturer and the user of automobiles to change from one make of motor car element to another at pleasure. Take for example the magneto. To secure interchangeability of magnetos, it is essential that the distance from the base to the shaft center of all magnetos shall be a standard dimension; also that the distance from the bolt holes to the end of the taper shaft, the taper of the shaft and the overall height, length and width, be common. Within these restrictions, each maker will be free to express his ideals of construction and design without interference. The advantages that should accrue from this standardization work, carried on as it is under the direction of representative automobile engineers, can hardly be overestimated.

The work of the committees also includes fixing the physical and chemical characteristics of aluminum and copper alloys, iron and steel, etc. Committees have been appointed on the following subjects: aluminum and copper alloys, ball and roller bearings, broaches, carbureters, frame sections, gear tooth shapes, iron and steel, leaf and coil springs, lock washers, miscellaneous parts, automobile nomenclature, seamless steel tubes, sheet metals, truck standards, wheel dimensions and fastenings for tires. The secretary of the society in alluding to the difficulties of the work says:

> The old-fashioned practice of wrapping a given process up in mystery, or surrounding it with a halo of secrecy still persists. Trade secrets still exist and petty jealousies still continue, and all of these prevent frankness and the accumulation of complete committee knowledge. It is not fair to ask that all trade secrets be laid before committees, nor is it necessary that trade secrets should be exposed in order to give sufficient knowledge to a committee to enable it to proceed intelligently. It is fair to ask that all personal feeling and all trade jealousy be laid aside for the benefit of all concerned. The work of our society in adopting standards has received hearty recommendation from many outside sources, and only a few comments to the effect that the society was attempting the impossible. It is probably a safe statement to make that even these unfavorable comments would not have been made had the writers of them been familiar with what the committee were really trying to do. The adverse critics have been universally those who have not come forward, attended the meetings or even read any of the material placed before them.

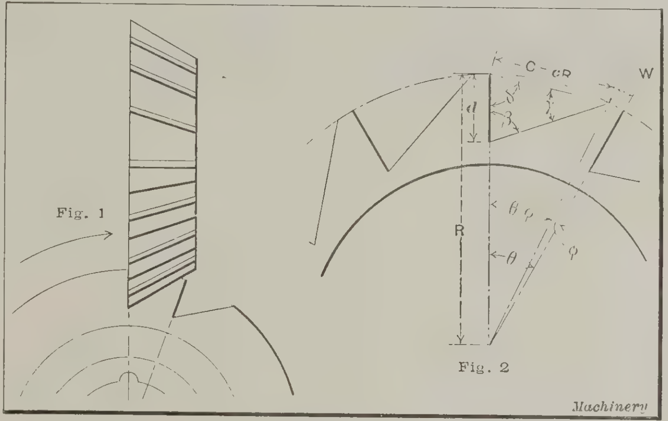
Practically all the vanadium used in the United States is obtained from Peru, South America. Extensive deposits of vanadium ore are located there and are controlled by American interests.

MILLING AXIAL TEETH IN CUTTER AND REAMER BLANKS*†

By GEORGE W. BURLEY‡

The ordinary method of setting the fluting cutter when milling axial teeth in cutter and reamer blanks, parallel to the axes of the blanks, is a cut-and-try method which, while it may give fairly good results in the hands of a skilled operator, is nevertheless rather wasteful of time and, in the majority of cases, indefinite in its results. The first part of the operation is to set the fluting cutter central with respect to the axis of the blank. In other words, where the fluting cutter is a single-angle cutter—as is usual for this class of work—it is arranged so that the vertical face is in the vertical plane passing through the axis of the blank, as is indicated in Fig. 1. The next step in the operation is to arrange the cutter so as to obtain the correct depth of flute. This is done by raising, in the first place, the knee, table, and blank an amount which, under any given circumstances, experience has indicated to be approximately correct.

With the blank in this position, two consecutive grooves are milled, the movement of the blank when indexing being in the direction represented by the arrow in Fig. 1. If the width of the land formed between the two grooves is about right, the position of the blank is assumed to be correct, and all the teeth are cut with the blank in this position. If the width of the land appears to be too great, the blank is further elevated so as to deepen the grooves, the amount of additional elevation being left entirely to the judgment of the operator. If the width of the land is too small, then the blank is lowered



Figs. 1 and 2. Diagrams illustrating Method of Finding Formula for Depth of Tooth Space

slightly to reduce the depth of the cut and increase the width of the land. This is obviously an inexact method and one not calculated to produce satisfactory results.

An exact method of determining the depth of the cut required for any given conditions in regard to the number of teeth to be cut in the blank, the diameter or radius of the blank, the angle of the fluting mill, and the width of the land to be formed, can, however, be adopted, the result of applying such a method always being satisfactory. The following is a consideration of the case. The conditions are shown in Fig. 2.

Let

* With Data Sheet Supplement.

† The following articles relating to the design and manufacture of milling cutters and reamers have previously been published in MACHINERY: "Setting Angles for Inserted-tooth High-speed Milling Cutters," December, 1911; "Face Milling Cutters for Finishing," December, 1911; "Milling Radial Teeth in Cutter Blanks," November and December, 1911, engineering edition; "Recutting Milling Cutters without Annealing," December, 1911; "Method of Setting Cutter for Fluting Spiral Mills," September, 1911; "Fluting Spiral Mills," August, 1911; "Fixture for Backing off Milling Cutters in the Lathe," June, 1911; "The Making of Reamers," July, August, and September, 1911 (see also the articles referred to in a note with the July installment); "Relief of Teeth of Cutters and Reamers," May, 1911; "Milling Cutters and Their Efficiency," May, 1911, engineering edition; "Reamers for Cutting Brass," April, 1911; "Spacing the Cutting Edges of Reamers," February, 1911; "Spacing of Cutting Edges of Reamers," November, 1910; "Apparatus for Hardening Milling Cutters," June, 1910; "Nicked Tooth Milling Cutters," April, 1910; "Milling Cutters with Inserted Teeth," December, 1909; "Length of Recess in the Bore of Milling Cutters," December, 1909, engineering edition; "Lathe Attachment for Backing off Teeth of Stepped Reamers," November, 1909; "Fixture for Grinding Radius Cutters," November, 1909; "Clearance on Milling Cutters," March, 1909. (See also the references to additional information given in a note with this last mentioned article.)

‡ Address: University of Sheffield, Sheffield, England.

N = the number of teeth (assumed to be equally spaced) to be cut in the blank.

W = the width of the land to be formed on each tooth.

β = the angle of the fluting or grooving cutter.

θ = the angle subtended at the center of the cutter or reamer by each tooth.

Then

$$\theta = 360 \div N$$

and may be called the tooth angle of the cutter or reamer. Let the radius of the finished (*i. e.* ground) cutter or reamer be R; θ is the angle subtended at the center of the cutter or reamer by the circular arc from which is formed the land of width W. This land may be either flat (as when formed by a cup-wheel) or concave (as when formed by a disk-wheel), but, in each case, the width of the land is measured in a straight line. The difference between the actual width of the land ground and the arc length (Fig. 2) is exceedingly small (though, other things being equal, it will depend upon the clearance), and, therefore, in this connection negligible. As the arc W subtends an angle ϕ at the center of the cutter or reamer, the angle $(\theta - \phi)$ is the angle subtended by a chord C. The angle $\delta = 90 - \frac{(\theta - \phi)}{2}$, and

$$\gamma = 180 - \left(90 - \frac{(\theta - \phi)}{2} + \beta\right) = 90 - \left(\beta - \frac{(\theta - \phi)}{2}\right)$$

The angle ϕ in degrees is obtained from $W \div R$, which is ϕ in circular measure. The chord C is, obviously, a function of radius R; hence its value is $c\,R$, where c is a constant for any particular values of θ and ϕ (from which it can be calculated) and, therefore, of N and $\frac{W}{R}$.

Let d = the depth of the cut required. Then, from Fig. 2,

$$\frac{d}{\sin \gamma} = \frac{c\,R}{\sin \beta},$$

from which we get

$$d = \frac{c\,R \sin \gamma}{\sin \beta} = \frac{c\,R \sin \left\{90 - \left(\beta - \frac{\theta - \phi}{2}\right)\right\}}{\sin \beta}$$

$$= \frac{c\,R \cos \left(\beta - \frac{\theta - \phi}{2}\right)}{\sin \beta} \qquad (1)$$

Recapitulation

It will be seen that by means of this formula, the depth of cut required for any given set of conditions can be calculated, the steps in the calculation being as follows: ϕ is obtained from $W \div R$ (the value of which is selected according to whether it is a milling cutter or a reamer which is to be fluted, and according to the kind of work which it has to perform. For medium-sized milling cutters, the quotient $W \div R$ varies from 0.020 to 0.060, while for reamers and small cutters its value lies between 0.040 and 0.120; θ is calculated from $360 \div N$; $c\,R$ is taken from a table of chords, it being the chord corresponding to $(\theta - \phi)$; and $\cos\left(\beta - \frac{\theta - \phi}{2}\right)$ and $\sin \beta$ are taken from the trigonometrical tables. Substituting the latter three values in Equation (1), we determine the depth of cut required.

It should be noted here that the very slight rounding which is usually given to the extreme angular point of the fluting cutter has been neglected in this consideration of the problem. This is because it is not possible to deal with it in a simple manner, and also because the amount of rounding is, in the majority of cases, not sufficient to affect materially the results of our calculations.

For practical purposes, the above formula is cumbersome, and, therefore, almost useless. To make it useful and of practical value, it has been converted into another formula, namely:

$$d = x\,R \qquad (2)$$

in which x is the depth of cut for a cutter or reamer of unit radius, and is equal to

$$\frac{c \cos \left(\beta - \frac{\theta - \phi}{2}\right)}{\sin \beta}$$

This is a constant for any given set of conditions, since, in such a case, W, N, and β, and, therefore, $W \div R$, θ, ϕ, and c will have fixed values. In the accompanying Data Sheet Supplement are given the values of x for a large number of different combinations of $W \div R$, N, and β; $W \div R$ ranging from 0.020 to 0.120 by increments of 0.020; N ranging from 6 to 44 by steps of 2; and β varying from 50 to 85 degrees.

Since the radius of the cutter or reamer blank is invariably made greater than the required radius of the finished cutter or reamer—the usual allowance on the diameter being about 0.008 inch per inch of diameter*—it is necessary to modify Formula (2) in order to fit it for application to conditions actually prevailing in practice. Obviously, in this case, to $x\,R$ must be added the difference between the radius of the blank and that of the finished cutter or reamer. Hence, the formula is:

$$d = x\,R + (R_1 - R) \qquad (3)$$

where R_1 = the radius of the blank. Another form is this:

$$d = R_1 - (1 - x)\,R \qquad (4)$$

Either of these two formulas may be used in practice, the value of x being taken from the accompanying tables in the Supplement.

To illustrate the use of this method, we will take the case of the fluting of a 5-inch cutter, which is to have 36 teeth, and a land-width ratio (*i. e.*, $W \div R$) of 0.020, the angle of the fluting cutter being 60 degrees. The blank, we will suppose, has been turned to a radius of 2.520 inches. Then, by consulting the accompanying tables, we find that $x = 0.1013$, and, therefore $x\,R = 0.2532$ inch; but $(R_1 - R) = 0.020$ inch; hence, $d = 0.2532 + 0.020 = 0.273$ inch, which is the required depth, and is an amount which can be easily read off the micrometer dial of the elevating screw of the milling machine.

It may sometimes be necessary to determine the value of x for a set of data not included in the accompanying tables. In such a case, this value can be calculated sufficiently accurately by the "simple proportion" method. To exemplify the use of the tables for this purpose, let us take the case of the fluting of a cutter involving the following data:

N = 40 teeth;
β = 70 degrees; and
$W \div R$ = 0.050.

From the tables we find that when $W \div R = 0.040$, $x = 0.0494$, and when $W \div R = 0.060$, $x = 0.0402$. Therefore, when $W \div R$ equals 0.050, $x = \frac{0.0494 + 0.0402}{2} = 0.0448$ inch.

When there are differences in regard to two of the data, the determination of x is a more complicated problem than the above. Take, for example, the case where $N = 31$ teeth, $\beta = 65$ degrees, and $W \div R = 0.030$. In this case, the values of x for 30 and 32 teeth when $W \div R = 0.030$ are first calculated as above, and then their mean is taken as the required value of x. Thus, x for 30 teeth = 0.1018 (by above method); for 32 teeth, $x = 0.0911$; and for 31 teeth, $x = \frac{0.1018 + 0.0911}{2} = 0.0964$ inch.

This method of determining the value of x for intermediate combinations is sufficiently close for all numbers of teeth above 12, and all the angles of fluting cutters in general use.

* * *

The invention of a new kind of armor-plate is reported from Germany. The peculiarity of the new armor is its extreme lightness as compared with the Krupp armor, while it is said to have equal, if not greater, resisting power. The armor is made of an aluminum alloy faced with a thin hardened steel plate. The naval authorities have made tests and reported favorably upon the new armor, and gun shields made from it have been ordered for one of the new German cruisers.

* This allowance is rather too liberal for large diameters. The allowances for grinding should not be in exact proportion to the diameters, as this gives too large values for cutters of large size. However, the assumption made has no influence on the formulas or on the tables. Anyone who prefers to use a smaller allowance for grinding can do so, and yet make use of the tables.—EDITOR.

MANUFACTURE OF LINCOLN-WILLIAMS TWIST DRILLS

By CHESTER L. LUCAS*

Twist drills are such common tools about a machine shop that it is surprising how little is generally understood about the methods employed in their manufacture. Any machinist can tell how a tap is made and any good toolmaker can make one, but we seldom hear of a twist drill being made in the average shop. This no doubt is due to the special machinery necessary to mill and relieve the flutes properly; therefore the manufacture of twist drills is almost exclusively in the hands of specialists.

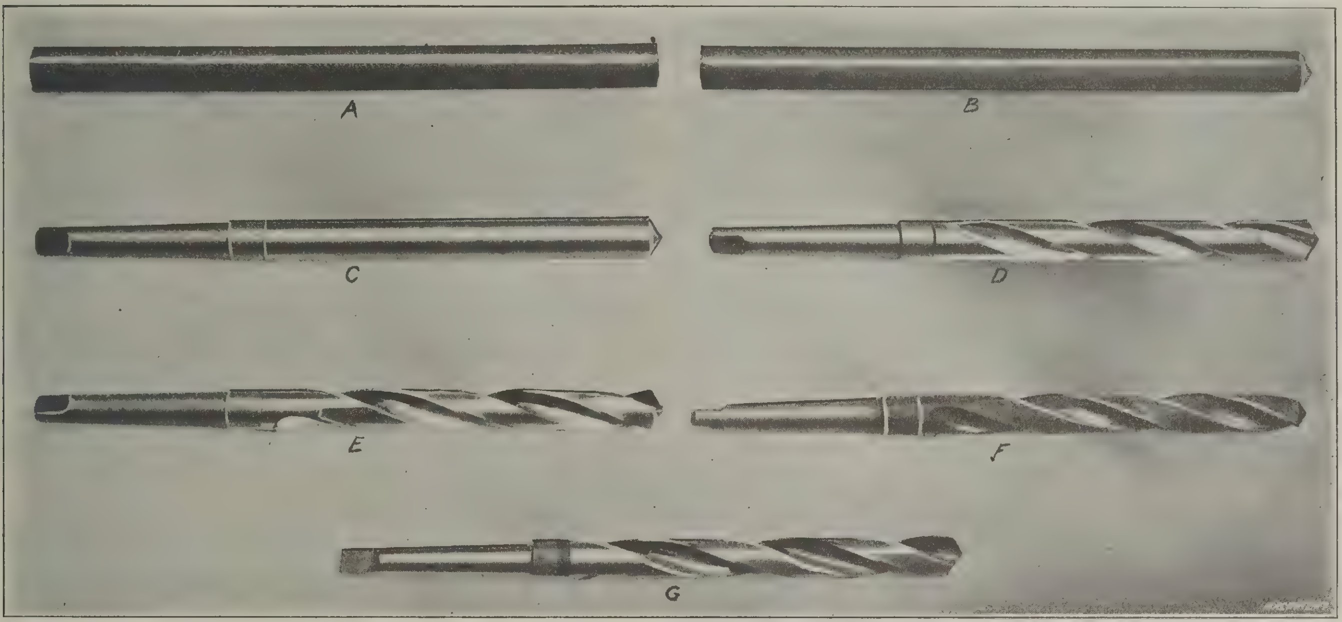


Fig. 1. Results of the Important Operations in Making a Twist Drill

One of the well-known firms in this line is the Lincoln-Williams Co., of Taunton, Mass. The company has moved into a new brick factory of modern design that is well equipped for the manufacture of twist drills. The entire factory is devoted to making this one product, involving the use of much special machinery. Through the courtesy of the management, the writer was allowed to photograph and describe some of the interesting operations connected with the work.

Preparation of the Steel

The stock room in which the steel is stored is kept locked all of the time, and access is permitted to very few men. The reason for this is to prevent the different brands of steel from getting mixed. As both high-speed and carbon steel are employed in making the various standard and special drills, and as the smaller sizes of drill rod vary but a few thousandths of an inch between sizes, the importance of this precaution is apparent.

Fig. 2. Cutting off the Stock

Fig. 2 shows the cutting-off department, where the bars are cut to lengths, one of which appears at A, Fig. 1. At the left are the cutting-off machines that cut the larger sizes of steel to length. The operator at the right is sharpening a saw for the cold-sawing machine that is used for cutting up some of the steel. For all drills, the steel is selected enough larger than the finish size to admit the turning off of all the "skin" from the outside of the stock.

The lengths of steel are next centered on one end and pointed on the other end to an included angle of 121 degrees. This end of the blank is used as the blade end of the finished drill and obviates the wasting of 1/4 inch of steel that would be necessary if centered in the usual way. The blank, centered and pointed, may be seen at B, Fig. 1. The smaller sizes of drill blanks are cut off and centered in screw machines, as illustrated in Fig. 3, and the very small drills are cut off and pointed only, no center being required. This work is done in Brown & Sharpe automatic screw machines.

Forging, Annealing and Straightening

A good many drills of the smaller sizes are made with taper shanks that are much larger than the body of the drill, usually with either No. 1 or No. 2 Morse tapers. After being cut off, the stock for such drills is forged down, reducing the blade section approximately to size. This operation is shown in Fig. 4, and of course it is obvious that this treatment improves the steel and results in a better drill.

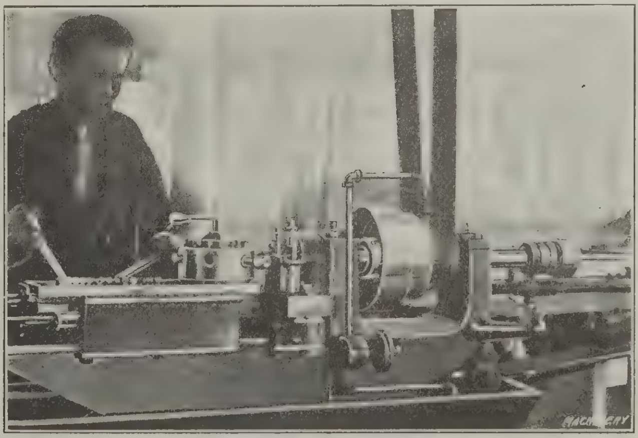

Fig. 3. Pointing and Centering the Drill Blanks

The blanks must now be annealed to facilitate the turning. Fig. 5 shows one of the large oil furnaces in which the blanks are heated. Cast-iron boxes, one of which may be seen being taken from the furnace, are filled with the lengths of steel, covered and sealed and placed in the furnace. Here they are heated slowly for a number of hours and allowed to cool very gradually.

The straightening operation is illustrated in Fig. 6. Here the operator is shown straightening forged blanks. These

* Associate Editor of MACHINERY.

blanks have been centered and pointed. He places a blank between the centers of the bench fixture *A*, gives it a twirl, at the same time noticing the high points with relation to the adjustable rest *B*. To facilitate the work, a screen *C* is placed so as to diffuse the light; when artificial light is needed, it is placed behind this screen. After locating a high point, the operator takes the drill from the centers, places it across the supports of the straightening press *D*, and bends it slightly to straighten it. In view of the fact that the work depends wholly upon judgment, it is surprising how well and how quickly the blanks are straightened. A straightening stand is used for the larger blanks. The stand is surmounted with an iron surface plate upon which the blanks are rolled. This operation shows up the high places and the blanks are straightened in a larger screw press not shown.

Fig. 4. Forging the Blanks for Special Drills

Rough- and Finish-turning

The small and medium sized drills are turned on lathes like that shown in Fig. 7. The work is held on male and female centers and driven by a dog in the usual way. The tools are made of high-speed steel, and for every turning operation in drill-making in this factory tool-holders with high-speed steel bits are employed. Each lathe performs but a single operation. One lathe rough-turns the shank; the next lathe rough-turns the blade; a third lathe finish-turns the shank and the fourth lathe finish-turns the blade. In turning, an allowance of from 0.005 to 0.007 inch is allowed for the grinding on this small and medium sized work. At *A*, Fig. 7, is a gage for testing the size from time to time. These lathes are fitted with automatic feed-releasing mechanism so that one operator may attend to four machines without trouble. This mechanism consists of a bracket *B*, bolted to the carriage; through this bracket a pin extends downward, coming in contact with arm *C* at the proper time to throw the internal half-nut out of mesh with the lead-screw at the end of the cut.

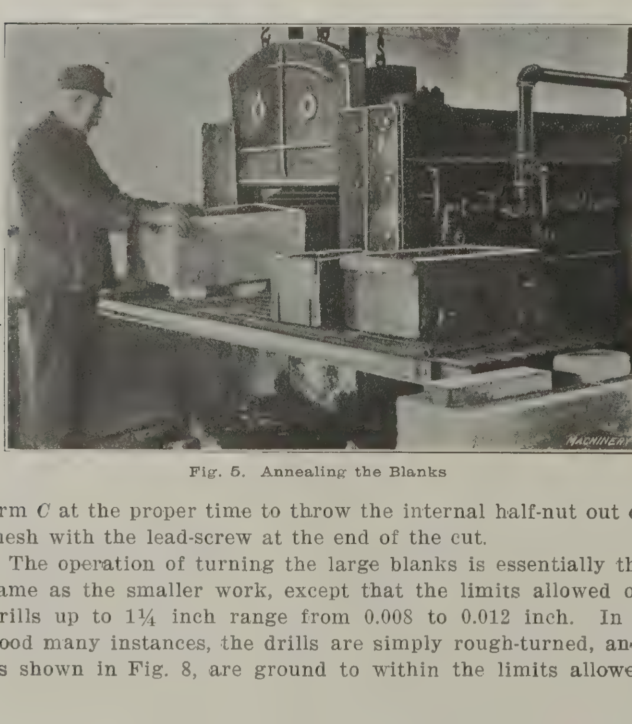

Fig. 5. Annealing the Blanks

The operation of turning the large blanks is essentially the same as the smaller work, except that the limits allowed on drills up to 1¼ inch range from 0.008 to 0.012 inch. In a good many instances, the drills are simply rough-turned, and, as shown in Fig. 8, are ground to within the limits allowed for hardening and final grinding. This is quicker than turning and leaves a good surface for the succeeding operations.

Milling the Tangs and Finishing the Ends

Fig. 9 illustrates the method of milling the tang. The drill blank *A* is held in clamp *B*, while the two cutters *C*, which are mounted at the proper distance apart, mill the tang. At *D* may be seen the worm and worm gear that are disengaged automatically at the end of the cut. It takes about half a minute to cut the tang of a ½-inch drill. The partly completed drill now appears as at *C*, Fig. 1.

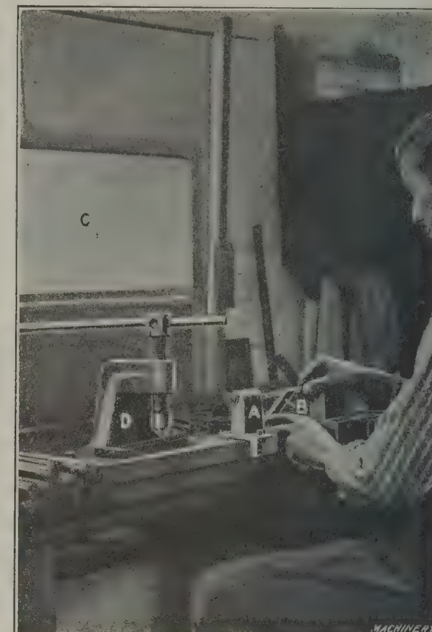

Fig. 6. Straightening the Blanks

Another simple operation, shown in Fig. 10, is that of rounding the shank end of the drill. This is done to remove corners and edges that might otherwise become bruised, thus interfering with the fit of the taper shank. The drill blank *A* is held in the clamp *B* and fed into the box-tool *C* that shapes the end of the shank. Both tool and holder are very strong.

Milling the Grooves

One of the most interesting operations connected with the making of twist drills is the milling of the flutes. Fig. 11 shows a small section of the department where the flutes in the large drills are milled. The drill blanks are fed downward to a pair of cutters that simultaneously mill the two grooves. Of course, it is obvious that the drill must turn while the milling operation is being performed, so as to obtain the spiral flutes. These machines are semi-automatic in their operation, so that one operator can keep several of the machines in operation without difficulty. The result of the milling is shown at *D* in Fig. 1.

The method of grooving the small drills is essentially the same, although the machines are of the horizontal type. Fig. 12 shows a row of the machines that are used in milling the grooves in drills under ¼ inch in diameter. By means of the same automatic feed-releasing mechanism as is used on the turning lathes and tang-milling machines, the feed is thrown out at the end of the milling operation. While being milled, the drill is automatically turned to give the spiral cut to the grooves. As the small drills have straight shanks, they may be held by chucks while being milled. In milling, a cutting compound, of borax, lardoleum and water, is used.

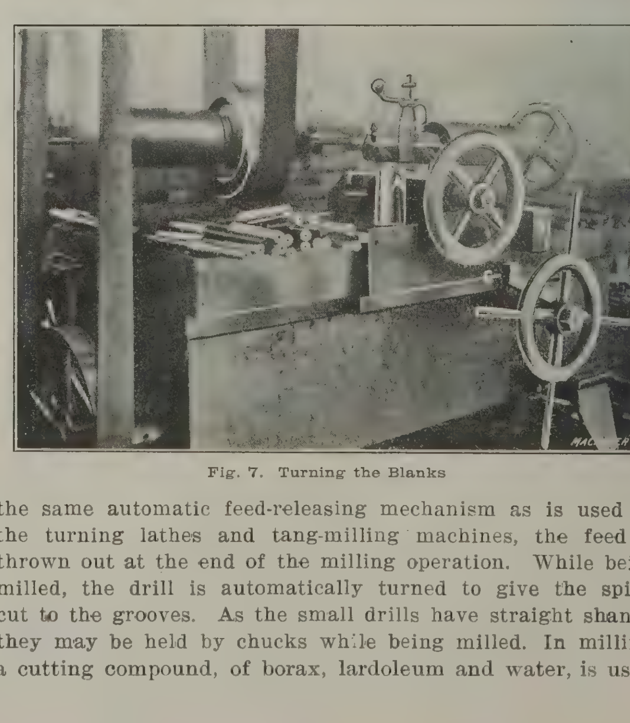

Fig. 7. Turning the Blanks

Increase Twist

To many men, the meaning of "increase twist" as applied to twist drills is not clearly understood. A drill with increase twist is grooved at a constantly increasing angle of spiral, commencing at the point. This variation in the angle of the groove is brought about by the gradual decreasing of the rate at which the drill blank turns while being fed to the grooving cutters, the forward movement of the drill remaining constant. Thus the "twist" steadily increases. The reason for cutting the grooves with increase twist is to increase the area of the groove as it progresses towards the shank, thus allowing the chips more room to work out of the grooves.

Fig. 8. Grinding the Blade Section, preparatory to Milling

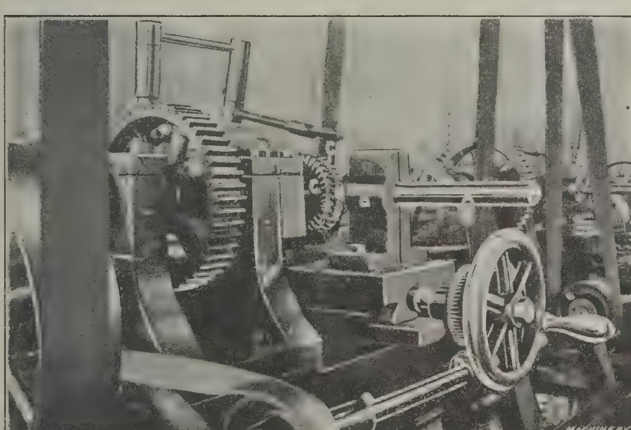

Fig. 9. Milling the Tangs

At first thought it is not quite clear how the increasing of the angle of spiral, or twist, increases the area of the groove. Suppose, to take the extreme view, there were no turning of the drill while being grooved; in such a case it is apparent that the resulting straight groove would be much wider than a spiral groove of any angle. To increase the angle of spiral is to approach the straight line; therefore any increase in the angle of spiral or twist, increases the width of the groove and consequently its area.

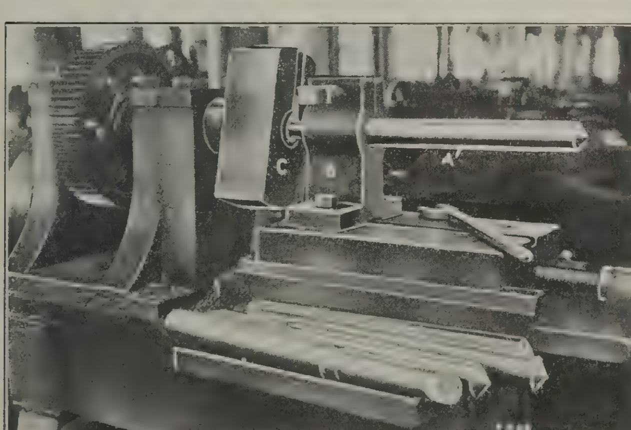

Fig. 10. Rounding the Ends of the Shanks

Milling the Clearance to the Grooves

The edges of the cutting lips of twist drills must be given clearance the same as any other metal-cutting tool. The clearance on Lincoln-Williams drills is milled with cutters; "cutter-cleared" they are termed in the trade. One of the machines for milling clearance may be seen in Fig. 13. The drill is held in the sleeve *A* that runs loosely in tailstock *B*. From the point, it is drawn through bushing *C*, at the same time being slowly turned. Cutter *D* works through an opening in this bushing, removing the clearance. The amount of metal removed for clearance depends, of course, upon the size of the drill, varying from approximately 1/32 inch on the large drills to a few thousandths inch on the smallest drills.

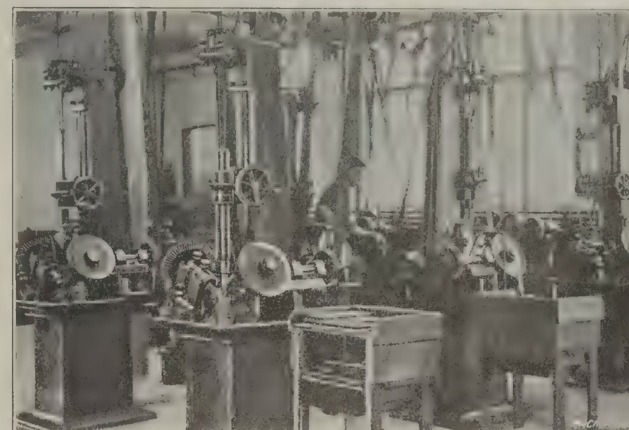

Fig. 11. Milling the Grooves

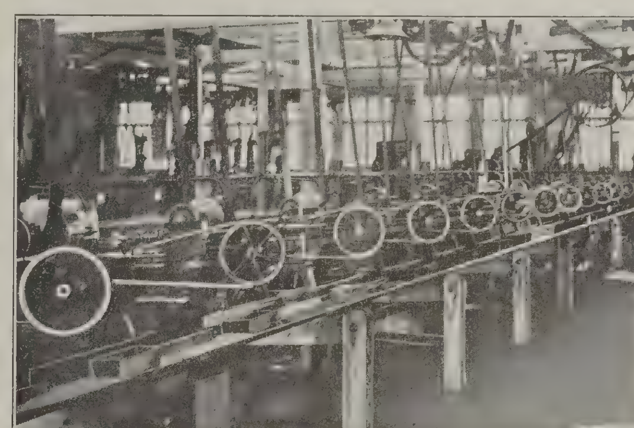

Fig. 12. Milling the Grooves in the Small Drills

The illustration Fig. 14 shows the principle that is followed in "clearing" drills by milling. In a cutter-cleared drill, the stock is milled away in a straight cut, commencing a short distance from the cutting side of the lip and extending parallel to the length of the drill into the groove behind. The result is a clean, even clearance throughout the length of the drill, as may be seen at *E*, Fig. 1.

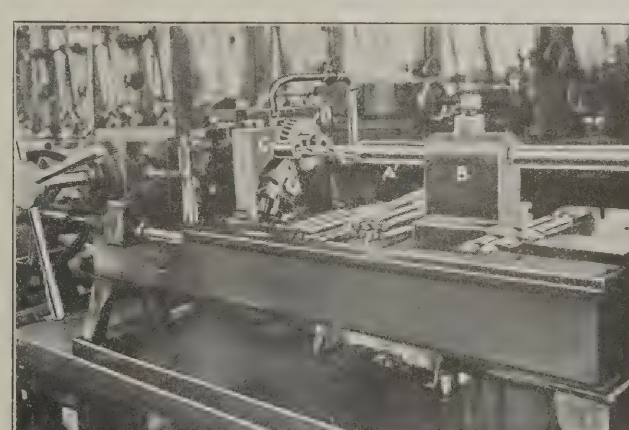

Fig. 13. Clearing the Drills

The ends of the blades of the drills are next relieved, or

sharpened, as we would call it if the drills were ready for use, and then another equally simple operation follows: that of marking the name upon the recess between the shank and blade. The size is also stamped on at this time, and the drills are ready for hardening.

Hardening the Drills

After the clearance has been given to the ends of the lips of the drills they are ready for hardening. Fig. 15 shows a section of the department where the high-speed drills are hardened. The furnaces are all gas furnaces and are of several sizes so as to accommodate the different sizes of drills that must be heated. One of the hardeners is shown heating a drill preparatory to hardening in the oil tank behind him.

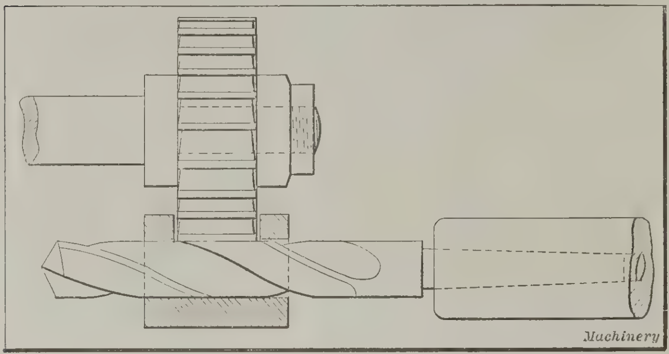

Fig. 14. Details of Clearing Operation

Fig. 15. Hardening High-speed Drills

For hardening these high-speed steel drills the furnaces are regulated to control the heat at approximately 2300 degrees.

In hardening the carbon steel drills, lead pots are used for heating the drills. Fig. 16 shows one of the hardeners at work hardening carbon steel drills. The tank for quenching is an ordinary hogshead filled with brine. The brine is kept cool and at a constant temperature by means of a circulation of cold water that passes through a coil of pipe within the brine barrel. This cold water is pumped from the cistern that may be seen in the right foreground of Fig. 16; thus the continuous stream of cold water circulating through the coil maintains an even temperature in the hardening tank.

Fig. 16. Hardening Carbon Steel Drills

The special tongs used in hardening small drills may be seen in the background of Fig. 17. These tongs will hold twelve drills so they may be hardened at once. One jaw of the tongs is grooved with twelve parallel grooves, while the other jaw holds a flat spring that has twelve "fingers" that bear upon the drills, compensating for any unevenness in the other jaw. The smaller pair of tongs is for holding small drills, as shown. At the right of this illustration may be seen two lots of small drills that are ready for hardening, and in the foreground is a lot of drills that has just been hardened. Fig. 18 is shown to illustrate the way in which the small drills are hardened. The lead pot is heated from beneath by fuel oil. The surface of the molten lead is kept covered with broken charcoal to prevent the formation of dross. It takes but a few seconds to heat up a row of drills and but a few seconds to quench them, so the work proceeds very rapidly. With the above method of even heating, and the constant temperature of the hardening bath, there can be little chance for poorly hardened drills, if the steel is of good quality—and it is.

Fig. 17. Special Tongs used in Hardening Small Drills

Oil-tempering the Drills

Hot oil furnishes the best known method of tempering any kind of a tool that requires an even temper throughout its length, and, of course, it is desirable that drills be evenly tempered throughout their lengths. At *A*, Fig. 19, may be seen the tank in which the drills in this factory are oil-tempered. As will be noticed, the tank is on rollers, running on a track above the gas furnace *B*. The drills are placed in an iron basket *C*, lowered into the hot oil, and left there until they have been brought up to the temperature of the oil, which is approximately 450 degrees F. This gives the drills a degree of toughness that it is impossible to attain in any other way. The box *D* contains sawdust for drying the drills after being taken from the hot oil. At *F*, Fig. 1, may be seen the drill after hardening.

Fig. 18. Method of heating Drills in Lead Pots

Straightening

In spite of all the precautions that are taken to have the drills come from the hardening tank straight, a good many drills will be warped to a more or less degree. To straighten

such drills, they must be heated at the top of the curve and pressure applied. This operation is practically the same as the cold straightening being done in Fig. 6, except that the small drills, under ¼-inch, are straightened on a lead block with a soft metal hammer. Heat is applied with a small gas torch.

Cleaning out and Grinding

After leaving the hardening department, the drills go to the cleaning bench, where they are brushed out with fine emery and oil as shown in Fig. 20. The operator takes three or four drills at once, and holding them at the angle of the flutes, brushes out all of the scale and dirt left by the hardening process.

The final operation in the making of a twist drill is to grind the shank and blade true with the centers, for of course there is bound to be a little distortion, even after straightening Other reasons for grinding after hardening are to size the drill and give it sharpness throughout the length of the blade. This operation is illustrated in Fig. 21, the finished drill being shown at *G*, Fig. 1.

Inspecting and Testing

After hardening, every drill is examined for fire cracks and tested for hardness. After grinding, each drill is tested for size of blade and correctness of taper in the shank, if the drill is of the tapered-shank variety. In addition, drills are selected

Fig. 19. Tempering Drills

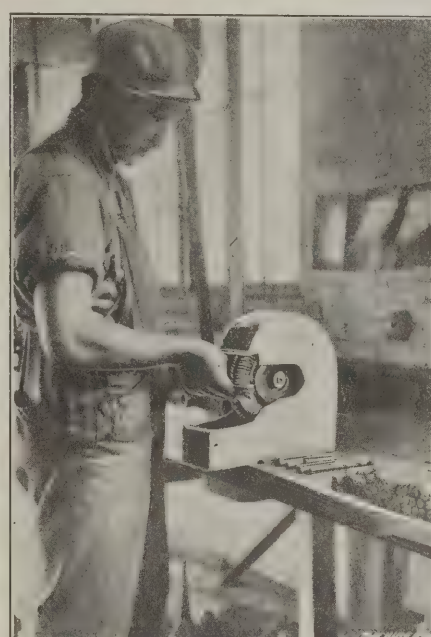

Fig. 20. Cleaning out the Drills

at random from the different lots, and tested in actual use, for the Lincoln-Williams Co. believes that the proof of the drills is in the drilling. For this purpose, semi-annealed steel

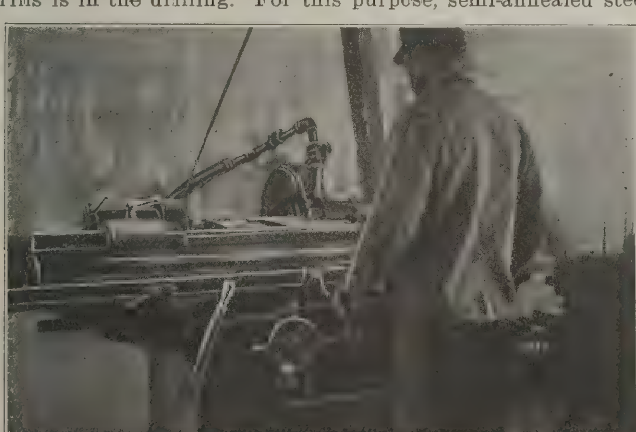

Fig. 21. Grinding the Hardened Drills

is used, and careful records are kept of the performances of the tested drills.

Welding Special Shanks

Fig. 22 illustrates the operation of electric welding special shanks to small drills that are used by woodworkers in bit-braces. The special square shanks are first forged; the drills are made and hardened and the last operation is to weld the two parts together. The drill is held in the spring collet that is closed by handwheel *B*. Several of these collets, which are

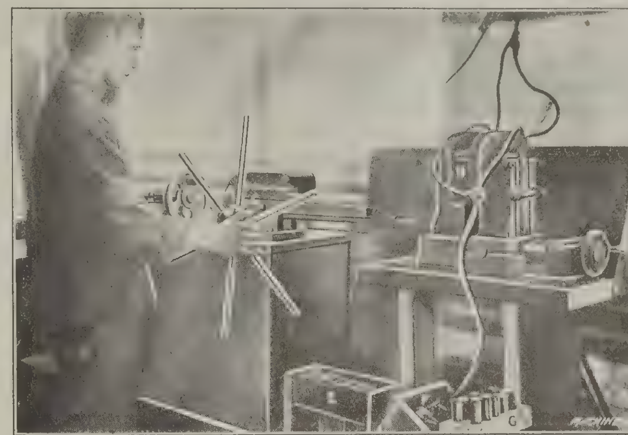

Fig. 22. Welding Special Shanks to the Blades

made of copper, may be seen in the block *G*. At *E* is a rack of drills and at *F* may be seen a box of shanks. The shank is held in the head *A* of the machine. The current quickly brings each part to a welding heat; handwheel *C* runs the head of the machine forward, uniting the two parts while at a white heat. The operation of the head, by means of the handwheel, automatically admits and cuts off the current that comes through the coil at *D*. By means of the handwheel that may be seen at the right of the coil, the amount of current may be regulated to suit any of the sizes of drills that are required to be welded to special shanks. With this machine, approximately 4000 drills may be welded per day of ten hours.

* * *

GASOLINE OR OATS?

Many persons who have studied the case of the auto *vs.* the horse are of the opinion that within ten years the use of horses will be forbidden upon the streets in the congested parts of cities. One of these experts asserts that by 1920 not a horse will be allowed south of Fourteenth St. on Manhattan Island. Another authority says that today the horse is hampering business in all the crowded delivery sections of cities and that horse-drawn vehicles take up so much room that in New York City alone, if the horse were done away with, three hundred miles of streets could be saved.

It is all a question of dollars and cents, this gasoline or oats proposition. Even with an ordinary pleasure automobile it simmers down to that. Tests have shown that the balance is in favor of the motor-car just as it is in the case of the heavier vehicles that do the truck-horse work. A six days' trial, for purposes of comparison, was made not long ago. The automobile ran four hundred and fifty-seven miles in that time at a cost of one and one-half cent per passenger per mile. Depreciation was charged in this cost, too. With a horse and buggy the distance covered in the six days was one hundred and ninety-seven miles and the cost was nearly two cents per passenger per mile.—*Harper's Weekly.*

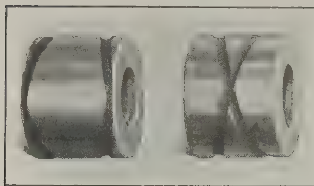
* * *

The National Twist Drill & Tool Co., Detroit, Mich., uses a simple method of etching on cutters and other tools. The steel is brushed with asphaltum varnish which is allowed to stand a few minutes until it thickens and hardens to the right degree. Then the desired inscription is pressed through the asphaltum with a rubber stamp and the etching fluid (aqua regia) is applied with a medicine dropper. Good results are obtained, but some practice and experience are required to judge just when the varnish has dried to the right consistency.

OIL GROOVE CUTTING TOOL*

A SPECIAL TURRET TOOL FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINE

By DOUGLAS T. HAMILTON†



Oil-grooved Pin

Cutting a helical oil groove in a cylindrical piece of work in the Brown & Sharpe automatic screw machines is a feat, the successful accomplishment of which demonstrates some of the possibilities of these machines in the hands of a resourceful designer. A turret tool for performing this work was designed by the Brown & Sharpe Mfg. Co., and was used for cutting an oil groove in a needle bar connection pin for the Wilcox & Gibbs sewing machine. This turret tool, which is illustrated in Figs. 1, 2, 3 and 4, is designed on the generating crank principle, so that the cutting tool is moved back and forth in a straight path parallel with the axis of the work while the latter is rotating. The cutting tool while

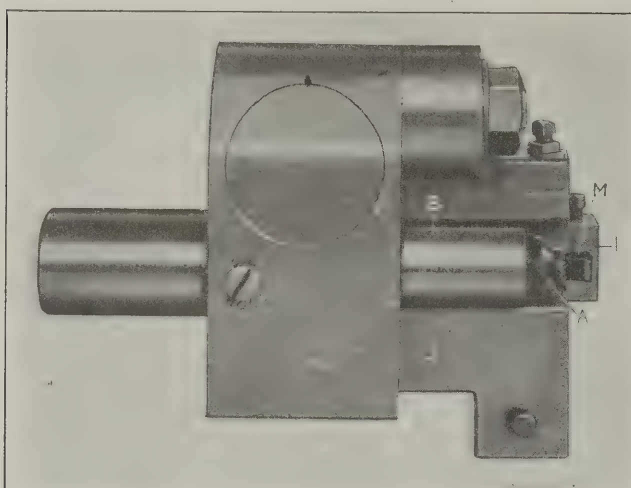


Fig. 1. Oil Groove Cutting Tool showing Driver and Cutter

being longitudinally traversed is at the same time fed into the work to the desired depth by means of a rising block held on the cross-slide.

Operation of the Oil Groove Cutting Tool

The oil groove cutting tool shown in Figs. 1, 2, 3 and 4 is operated in the following manner: After the end of the work

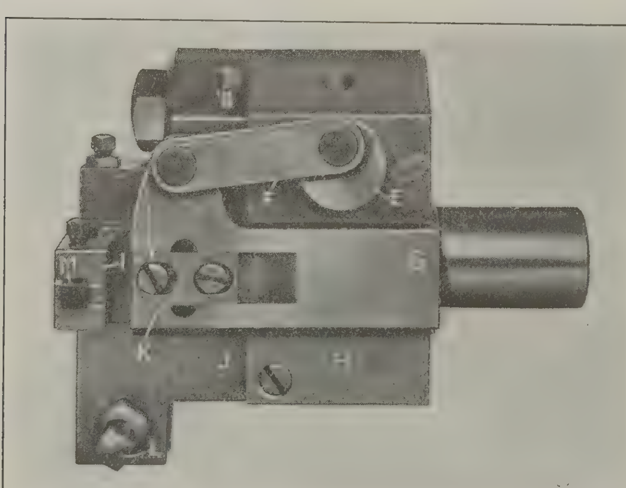

Fig. 2. Rear View of Oil Groove Cutting Tool showing Crank-Tool-slide, etc.

has been knurled, the turret is advanced, bringing the driver *A* into contact with the knurled end of the work. The rotating motion of the work is transmitted by driver *A* to spindle *B*, the latter being connected to the driver by a pin *C* fitting in an elongated hole in the spindle. The spindle *B* is provided with helical teeth that mesh with the helical gear *D*, held on a shaft *E* to which link *F* is eccentrically connected. The other end of link *F* is pivoted to the crank-slide *G*, which fits in a V-groove cut in the main body *H*. The tool-slide *I*, which fits in a V-groove in the swinging member *J* is connected to the crank-slide *G* by a tongued block *K* held by two screws in a slot cut in the crank-slide.

When the driver *A* is in contact with the work, the front cross-slide is advanced and the rising block coming in contact

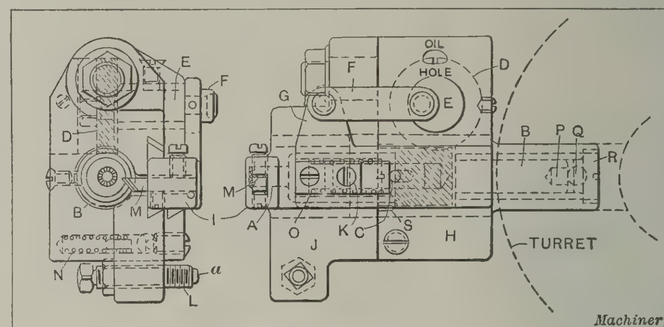

Fig. 3. End and Side Elevations of Oil Groove Cutting Tool

with the end *a* of the set-screw *L* forces in the swinging member *J* carrying the turning tool *M*. While this is taking place, the turning tool is being traversed back and forth by means of the crank mechanism, and thus produces the helical groove in the work. Upon the completion of the oil groove, the cross-slide drops back, and the coil spring *N* returns the swinging member to its former position; and when the turret drops back, the coil spring *O* returns the driver *A* to its "out" position.

Construction of the Oil Groove Cutting Tool

This tool embodies some features in its design which could be incorporated in other turret tools of the generating type,

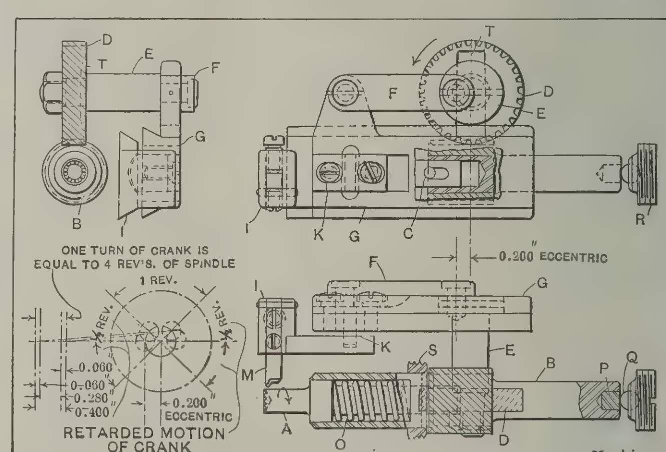

Fig. 4. Diagram showing Operation of the Oil Groove Cutting Tool

so that a description of its construction might be of value. Referring to Figs. 3 and 4, it will be seen that the driver *A* is countersunk and knurled on the end, and is provided with a shoulder against which the spring *O* abuts. The driver is prevented from coming out of the spindle *B* by a pin *C*, driven into the former and fitting in an elongated hole in the spindle. This pin also acts as a stop to prevent further movement of the driver *A*, when it has once come in contact with the work.

The driving spindle *B* is made from machine steel, counterbored to receive the driver *A*, and provided with helically cut teeth. To take the thrust of the driver coming up against the work, the rear end of the spindle is provided with a hardened block *P*; this block bears against a ball *Q* held in the nut *R*, which is screwed into the shank of the holder. The spindle is retained in the main body *H* by a hollow-nut *S*, and runs in a phosphor-bronze bearing. The helical gear *D* is held on the end of the crank stud *E* which runs in a phosphor-bronze bearing, by a nut as shown, and is retained in the

* For a description of other tools on the generating principle, built by the Brown & Sharpe Mfg. Co., see the following articles: "Cutting Helical Gears on the Brown & Sharpe Automatic Screw Machines, April, 1909; and "Attachment for Cutting Helical Steel Gears," August, 1909.

† Associate Editor of MACHINERY.

correct relation to the eccentric by the slot T which fits the flattened sides of the stud.

As the swinging member carrying the tool-slide must have a slight movement across the face of the main holder, it is necessary that the two slides be flexibly connected. This is accomplished by inserting a block K, which is provided with a tongue to fit in the slot cut in the crank-slide G. The tongue extends down through an elongated slot in the slide, and fits in a corresponding slot in the tool-slide I. The slot in slide

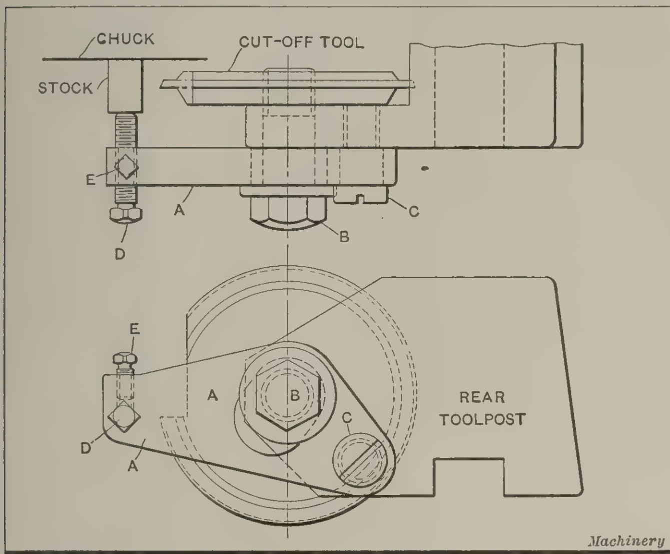

Fig. 5. Stop used on the Rear Cross-slide for Gaging the Stock to Length

G is greater in width than the tongue on the block K so that a slight adjustment for the tool-slide is provided. This adjustment makes it possible to start the cutting tool in the correct relation to the end of the work and the driver.

Obtaining the Throw of the Crank

Referring to the illustration Fig. 7, where a sample of the work is shown at A, it will be seen that the oil groove is to make one complete revolution in 0.282 inch for both forward

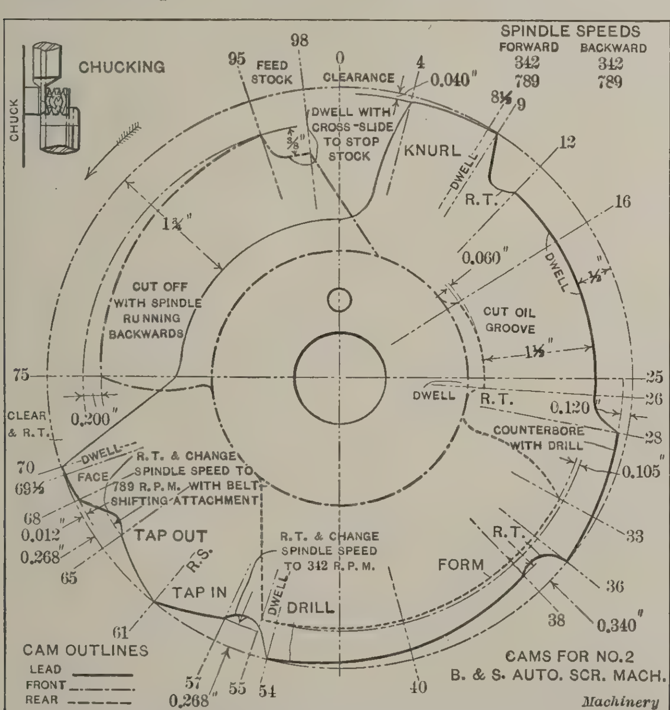

Fig. 6. Cams used in Making and Cutting the Oil Groove in the Needle Bar Connection Pin shown at A in Fig. 7

and return strokes, giving two revolutions in all. The path of the oil groove is more clearly shown in the initial illustration. Now it is evident that the speed at which the tool-slide travels must be less than that at which the work is rotating, or in other words, the work must make four revolutions when the crank is making one complete turn. The helical gears are therefore made in a ratio of 4 to 1.

As this tool is operated by a crank mechanism, it follows that the cutting tool is given a variable movement; that is, it starts up slowly, then increases in speed as it approaches the center, and decreases in speed as it reaches full throw, the same movement being repeated on the return stroke. To obtain the required throw of the eccentric, construct a square having sides equal in length to 0.282 inch, and circumscribe a circle about it. The radius r of this circle, see B, Fig. 7, will then equal the required amount of throw of the crank. The radius r is found by the following formula:

$$r = \frac{\frac{0.282}{2}}{\sin 45 \text{ deg.}} = \frac{0.141}{0.707} = 0.200 \text{ inch approximately.}$$

Referring to the diagram in the left-hand lower corner of Fig. 4, it will be seen that the first one-eighth revolution of

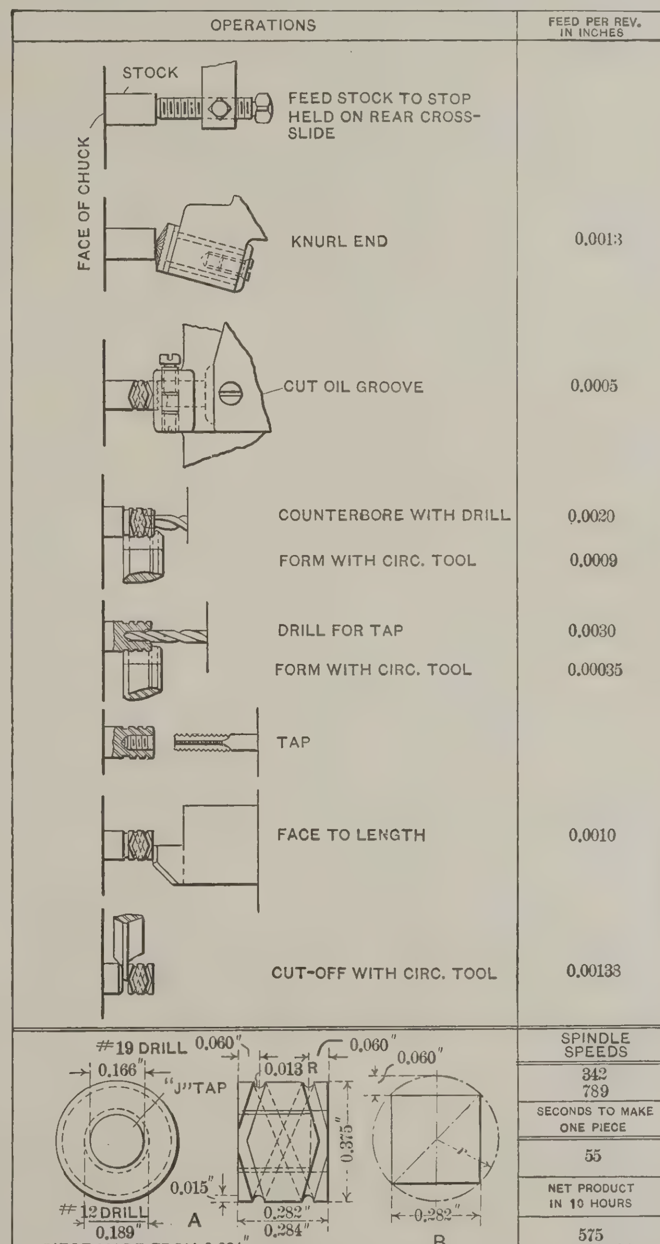

Fig. 7. Order of Operations and Feeds used in Making the Needle Bar Connection Pin

the crank, which equals one-half revolution of the work, gives a longitudinal movement to the tool of about 0.060 inch. The next revolution of the work (or one-quarter revolution of the crank) gives a movement of 0.280 inch, while the remaining forward movement gives a travel of approximately 0.060 inch. The same movement is given to the tool on the return of the crank, the complete travel of which is 0.400 inch. The groove produced by the tool when its motion is retarded is not required. Hence, when the piece is faced and cut off to 0.282 inch, it leaves an oil groove which makes two complete revolutions around the work. The two half revolutions of the groove on each end are removed by the facing tool held in the turret and the circular cut-off tool on the cross-slide.

The chart, Fig. 7, illustrates the tools used and the order in which they are applied. By a close inspection of this chart it will be seen that the turret is full of tools, so that it is necessary to provide some other means for gaging the stock to length. This is accomplished by fastening a block *A* to the rear toolpost as shown in Fig. 5. This block *A* is furnished with an elongated slot so that it can be swung up out of the way to remove the short piece of the bar left in the chuck when it is exhausted. The slot straddles the body diameter of the clamping screw *B*, which is used in holding the circular cut-off tool to the toolpost. The toolpost is drilled and tapped to receive the shoulder screw *C*, which acts as a fulcrum for the block *A*. In the forward end of the block *A* is held a screw *D* which acts as a stop for the stock. This screw is held when adjusted to the correct position by a set-screw *E* bearing upon a brass shoe, which prevents the thread on the screw *D* from being bruised.

Order of Operations

The order of operations followed in completing the needle bar connecting pin is shown in Fig. 7. The first operation is to feed the stock to the stop; then the rear cross-slide drops back and the knurling tool is brought in and knurls the end of the work. The turret is now revolved, bringing the oil groove cutting tool into operation which produces the oil groove. The turret dwells, holding the driver in contact with the work while the swinging memoer is being advanced by the rising block on the front cross-slide, which feeds the tool in to the correct depth. While this is taking place the tool-slide, of course, is driven back and forth across the face of the work by the crank mechanism.

After the oil groove is completed, the turret is again revolved and the drill is brought in to counterbore the front end of the work. The turret is then revolved to bring the tapping size drill in, which drills a hole completely through the work. While the drilling is being accomplished, the front cross-slide is advanced, bringing the circular form tool into operation, which turns down the work to the correct outside diameter. The cross-slide then backs out of the way and the turret is revolved, bringing the tap into operation. After the tapping is completed, the turret is again revolved and the work faced to the correct length by a facing tool held in the turret. After this, the rear cross-slide advances, holding the circular cut-off tool, which severs the completed piece from the bar.

The cams used in making this piece are shown in Fig. 6, where the uses of the various lobes are clearly indicated. It will be noticed that four one-hundredths of the cam surface is allowed between the points where the turret dwells with the oil grooving tool and the cross-slide begins to force the cutting tool into the work. This amount of clearance is necessary because of the relative positions of the lead and the cross-slide levers. The procedure to follow in designing a set of cams for performing operations accomplished by swing tools was illustrated and described in the article entitled "Internal Cutting Tools" which appeared in the November, 1910, number of MACHINERY.

* * *

A petrol-electric omnibus has been introduced in London and extensive tests have been made with it. It is fitted with a four-cylinder engine driving a dynamo which, in turn, supplies the driving current for the motors of the vehicle. The advantages of the design over the regular gasoline engine omnibus are said to be that considerable economy in the use of fuel is possible, that the control of the vehicle is made simpler and more effective, and that the arrangement increases the life of the engine, as the shocks from clutching and de-clutching, which are ordinarily so destructive, are eliminated.

* * *

A maker of twist drills investigated a complaint of a customer who had split several drills in drilling a drop forging. He found that the forging was made with a depression in the center where the hole was drilled, but the depression was of a lesser included angle than the standard drill angle of 118 degrees. The result was that the lips of the drill "hogged in" without having a support for the point. Splitting was inevitable. Changing the angle of the drill to conform to the angle in the forging stopped the trouble.

THE PROBLEM OF FOUR TANGENT CIRCLES*

By WILLIAM W. JOHNSON†

The problem of four tangent circles is as follows: Given three circles and the distances between their centers, to find the radius of a circle which is tangent to the three given circles.

This problem sometimes is met with in practical mechanics. For example, it may be required to find the diameter of a gear which will mesh with three given gears, the diameters

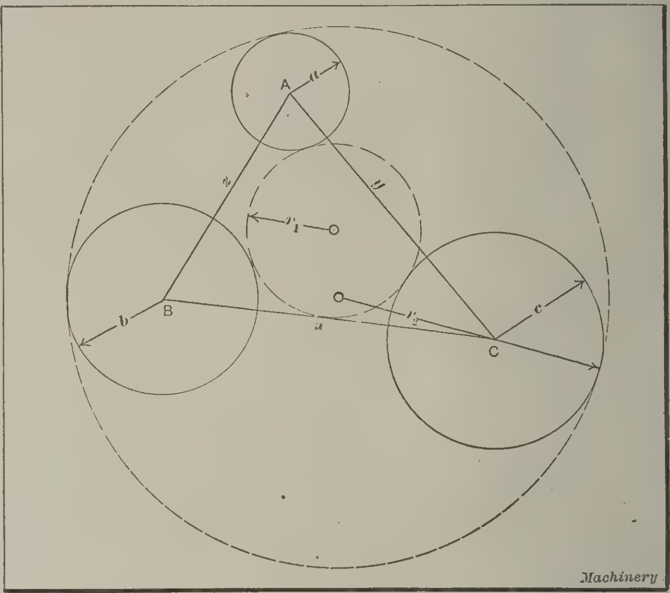

Fig. 1. Circle making Internal Contact with all Three Given Circles, and Circle making External Contact with all Three Circles

and the distances between the centers of which are given. The purpose of this article is to show how general formulas may be derived for calculating the diameter of a circle which is tangent to three given circles. There are not less than eight circles which meet the requirements: One, making internal contact with all three circles (see Fig. 1); one, making external contact with all three circles (see Fig. 1); three, making external contact with two circles and internal contact

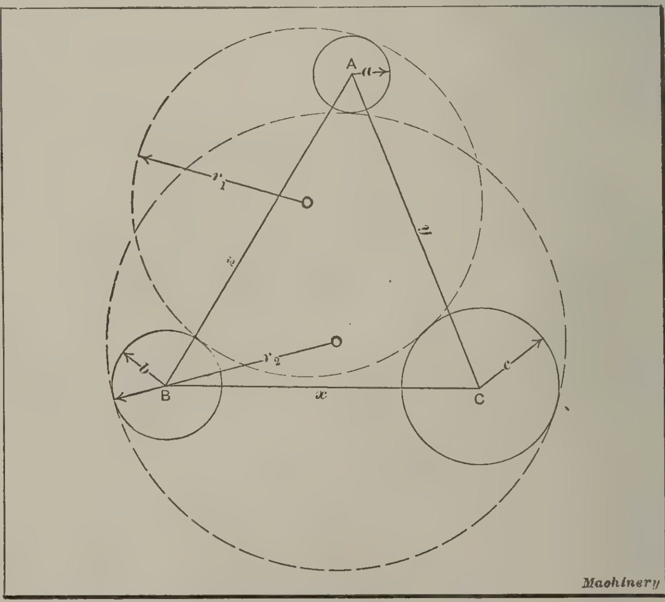

Fig. 2. Circles making Internal Contact with One or Two of the Given Circles

with one circle (see Fig. 2); three, making external contact with one circle and internal contact with two circles (see Fig. 2).

Referring to Fig. 3, let *A*, *B*, and *C* be the centers of the three given circles whose radii are *a*, *b* and *c*, respectively,

* See MACHINERY, March, 1906, How and Why columns, and May, 1906, engineering edition, "The Problem of Touching Circles."
† Address: 1313 East 88th St., Cleveland, Ohio.

and let $BC = x$, $AC = y$ and $AB = z$; find r. We can get an equation of the second degree as follows:

Let $AO = p$, $BO = q$, $CO = s$, and angle $AOB = \theta$, angle $BOC = \phi$, and angle $COA = \psi$. Then, $\theta + \phi + \psi = 360°$; $\theta = 360° - (\phi + \psi)$, and $\cos\theta = \cos(\phi + \psi) = \cos\phi\cos\psi - \sin\phi\sin\psi$, or $\cos\theta - \cos\phi\cos\psi = -\sin\phi\sin\psi$.

Squaring both sides we get:

$$\cos^2\theta - 2\cos\theta\cos\phi\cos\psi + \cos^2\phi\cos^2\psi = \sin^2\phi\sin^2\psi$$
$$= (1 - \cos^2\phi)(1 - \cos^2\psi) = 1 - \cos^2\phi - \cos^2\psi + \cos^2\phi\cos^2\psi.$$

Hence, $\cos^2\theta + \cos^2\phi + \cos^2\psi - 2\cos\theta\cos\phi\cos\psi = 1. \quad (1)$

From the cosine formulas in trigonometry we get:

$$\cos\theta = \frac{p^2 + q^2 - z^2}{2pq} = 1 + \frac{(p-q)^2 - z^2}{2pq}$$

$$\cos\phi = \frac{q^2 + s^2 - x^2}{2qs} = 1 + \frac{(q-s)^2 - x^2}{2qs}$$

$$\cos\psi = \frac{s^2 + p^2 - y^2}{2sp} = 1 + \frac{(s-p)^2 - y^2}{2sp}$$

Put, in the numerators, $p = r + a$, $q = r + b$, and $s = r + c$; then:

$$1 + \frac{(p-q)^2 - z^2}{2pq} = 1 + \frac{(a-b)^2 - z^2}{2pq} = 1 + \frac{A}{2pq}$$

$$1 + \frac{(q-s)^2 - x^2}{2qs} = 1 + \frac{(b-c)^2 - x^2}{2qs} = 1 + \frac{B}{2qs}$$

$$1 + \frac{(s-p)^2 - y^2}{2sp} = 1 + \frac{(c-a)^2 - y^2}{2sp} = 1 + \frac{C}{2sp}$$

Substituting these values in Equation (1), we get

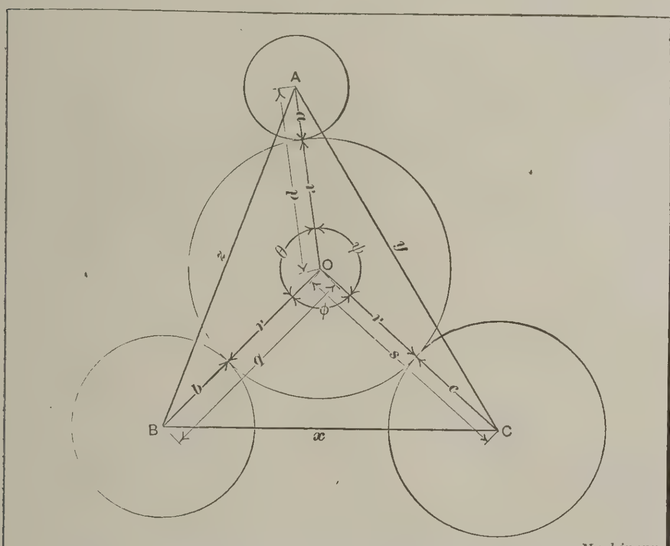

Fig. 3. Diagram for the Analytical Solution of the Problem

$$A^2s^2 + B^2p^2 + C^2q^2 - 2ABsp - 2BCpq - 2CAqs - ABC = 0. \quad (2)$$

Putting $p = r + a$, $q = r + b$, and $s = r + c$, in Equation (2), we get:

$$r^2[A^2 + B^2 + C^2 - 2AB - 2BC - 2CA] + 2r[A^2c + B^2a + C^2b - AB(a + c) - BC(a + b) - CA(b + c)] + [A^2c^2 + B^2a^2 + C^2b^2 - 2ABca - 2BCab - 2CAbc - ABC] = 0. \quad (3)$$

This is the general equation, from which two values for r are always found; one applies to the internal and one to the external circle, Fig. 1.

When $p = r - a$, $q = r + b$, and $s = r + c$ an equation for two other values of r, which apply to Fig. 2, is obtained. When $p = r + a$, $q = r - b$, and $s = r + c$ an equation for two other values is found, and when $p = r + a$, $q = r + b$ and $s = r - c$, an equation for the last two values of r, Fig. 2, is obtained.

By following the same procedure as in the foregoing, and substituting the values for p, q, and s just given, we get as the general equation for the conditions in Fig. 2 ($p = r - a$):

$$r^2[A^2 + B^2 + C^2 - 2AB - 2BC - 2CA] + 2r[A^2c - B^2a + C^2b - AB(c - a) - BC(b - a) - CA(b + c)] + [A^2c^2 + B^2a^2 + C^2b^2 + 2ABca + 2BCab - 2CAbc - ABC] = 0. \quad (4)$$

The other two formulas may be obtained by changing the letters in cyclical order, *i. e.*, changing a to b, b to c, c to a, and x to y, y to z, and z to x. Care must be taken in using the formulas to substitute the values exactly as they appear in the figure. For instance, x is the length of the side opposite the circle of radius a, etc.

Application of the Formulas

In Fig. 1 let $a = 3$; $b = 5$; $c = 6$; $x = 12$; $y = 13$; $z = 10$. Using Formula (3):

$$A = (a - b)^2 - z^2 = -96$$
$$B = (b - c)^2 - x^2 = -143$$
$$C = (c - a)^2 - y^2 = -160$$

Coefficient of $r^2 = A^2 + B^2 + C^2 - 2AB - 2BC - 2CA = -48{,}671$.

Coefficient of $2r = A^2c + B^2a + C^2b - AB(a + c) - BC(a + b) - CA(b + c) = -230{,}909$.

Absolute term $= A^2c^2 + B^2a^2 + C^2b^2 - 2ABca - 2BCab - 2CAbc - ABC = 1{,}250{,}089$.

This gives the quadratic equation

$$48{,}671\ r^2 + 2\ (230{,}909)\ r - 1{,}250{,}089 = 0$$

Solving for r we find:

$$r_1 = 2.1978, \text{ and } r_2 = -11.6864.$$

In Fig. 2 let $a = 1$; $b = 2$; $c = 3$; $x = 7$; $y = 6$; $z = 5$. Using Formula (4):

$$A = (a + b)^2 - z^2 = -16$$
$$B = (b - c)^2 - x^2 = -48$$
$$C = (a + c)^2 - y^2 = -20$$

Coefficient of $r^2 = A^2 + B^2 + C^2 - 2AB - 2BC - 2CA = -1136$.

Coefficient of $2r = A^2c - B^2a + C^2b - AB(c - a) - BC(b - a) - CA(b + c) = -4832$.

Absolute term $= A^2c^2 + B^2a^2 + C^2b^2 + 2ABca + 2BCab - 2CAbc - ABC = 26{,}176$.

This gives the quadratic equation:

$$1136r^2 + 2(4832)r - 26{,}176 = 0.$$

Dividing by 16, reduces to:

$$71r^2 + 2(302)r - 1636 = 0.$$

Solving for r, we find:

$$r_1 = 2.1601 \text{ and } r_2 = -10.6671.$$

* * *

DOUBLE-CUTTING PLANERS

A planer for cutting on both the forward and return stroke has been developed by Joshua Buckton & Co., Leeds, England, and was described in a paper read by Mr. J. Hartley Wicksteed at a recent meeting of the Institution of Mechanical Engineers. Many attempts have been made in the past to adapt the planer to double-stroke cutting, but the objection has always been made that with an equal speed of the planer table on both the forward and return strokes, the absence of a quick return motion on the idle stroke in such cases where the work does not permit of the use of both tools, on account of lack of clearance at the end of the stroke, discounts the advantages gained on work where double-cutting could be employed. This objection is overcome in the double-cutting Buckton planer by adopting for the drive a variable speed motor and using a small auxiliary motor for such operations as feeding and traversing the tools. A special advantage of the Buckton arrangement is, therefore, that it is flexible, so that either the forward and return strokes can be made at a uniform speed, or the return stroke can be made at an increased rate of speed when required. Another design has also been introduced with belt drive to the planer, by means of which the same flexibility as regards the rate of speed of the return stroke can be obtained. The method of holding the double-cutting tools is to fasten them back to back and exactly in line.

* * *

In painting or otherwise coloring the walls of any workroom, this question naturally arises: What color reflects the most and what the least light? Here are the data, based on recent experiments in Germany. Dark blue reflects 6½ per cent of the light falling upon it; dark green about 10 per cent; pale red a little more than 16 per cent; dark yellow, 20 per cent; pale blue, 30 per cent; pale yellow, 40 per cent; pale green, 46½ per cent; pale orange, nearly 55 per cent; *pale white, 70 per cent.* Glossiness and varnish increase the amount of light reflected.—*Detroit-Fenestra.*

THE CINCINNATI METHOD OF INDUSTRIAL EDUCATION—A FRIENDLY CRITICISM*

By JAMES A. PRATT†

The writer recently visited Cincinnati with the purpose of becoming acquainted with the work done there along the lines of industrial education. An opportunity was afforded to visit four very well equipped plants, attention at these visits being given solely to the mechanical engineering and machinist's shop courses there provided in connection with studies at the Cincinnati University or the apprentice continuation school. In each case the writer made his purpose clearly known, and requested the privilege of talking with the students.

The Course for the Students of Mechanical Engineering

In order to obtain an idea of the practical shop knowledge assimilated by the students, a number of questions of the character indicated below were put to them.

What is the advantage of the floating collet as used in small tool design?

In assigning work to the boring mills, what general division would you make between that going to the horizontal mill and that going to the vertical?

What factors would you consider in deciding whether a casting should be made from a full pattern or swept up?

Assuming that you were running a certain mixture, which had previously given satisfaction, in the cupola, and you unexpectedly found your casting coming hard, what would be your line of procedure to determine the cause of the difficulty?

These are questions which with proper shop teaching in engineering, students should be able to answer. Out of five men, however, but one was able to give passable answers to questions of this kind. This man was in the fifth year of the course, and yet, on certain phases of shop work, he could answer no questions, as many subjects had never been taken up at all. According to his own statement, this young man has never been asked, throughout the five years of his course, to make a shop report of any kind to a college authority.

The work done by the engineering students in the shop is in no way different from that given to the ordinary mechanic. It is evident that great breadth of view and ability would result if a man studying to become an engineer could at the same time be trained to be a thorough mechanic in at least one of the trades, while he was given a fair degree of familiarity with all the other trades bearing on his profession. Such a plan, however, could not be carried into effect in much less than seven years entirely devoted to understudy work, not including the three or four years of preparatory work required, and few persons are willing to spend this length of time in training, especially as it is not absolutely necessary for the engineer to be a skilled mechanic.

Since, therefore, some details of the shop work must be dropped from the course of training, which should these be? Logically it would appear that those details which develop dexterity to a greater degree than they impart knowledge of tools and processes, could be eliminated with the least danger. What the student requires most, in order to tell in the future when a man, or a gang of men, is working efficiently, is to understand the purpose and efficient operation of various machines. Outside of this the shop work of the engineering student should have in view the development of his ability to solve engineering shop problems, rather than to train him to be a skilled mechanic. However, the writer was told by a person in authority at one of the shops visited that no attempt was made to give the engineering students any other class of work than was given a boy who was learning a trade.

The manufacturer is surely not to blame for this condition. He is not running an educational institution, and his position was presented clearly by the statement of one manufacturer who said that the manufacturers were glad to have the boys get anything that they could out of the scheme, but no special shop arrangement would be permitted for the benefit of the engineering students. From a business point of view this position is not open to criticism, nor can those in charge of the plants be expected to act otherwise. There is, however, a reason for discussion when the claim is made by educators, that the scheme, as worked out, is a full and satisfactory substitute for proper college shop training. Such a claim is made by those responsible for this method of training in Cincinnati. It is admitted by the writer that there is a great deal of college shop work which does not give the student any better view of actual shop work, nor perhaps as good, as that obtained by the Cincinnati students, but such conditions exist only because of incompetence or indifference on the part of the educators, and this neglect cannot be excused. In any event, the training as obtained by the students in Cincinnati—so far as the work was shown to the writer—does not give a sufficiently broad training, because the student must do the work wanted in the plant regardless of whether it benefits him or not, and, further, some of the plants do not maintain all the departments in which training is usually considered essential to the engineer.

The Coordinator

In visiting the plants it was expected that the coordinator would be met with and an opportunity afforded to talk over this matter with him. The writer had expected that he made frequent calls on the boys while at work. In the first shop visited, however, a man having such duties as ascribed to the coordinator was not known, and the most precise statement obtainable was that a man came around once in awhile, and if a student was kept too long on one job he tried to get him changed. The students interviewed said that there was no connection between the work in the shop and the studies in the college. In theory the coordinator may be clearly defined and his purpose fixed, but as far as ascertainable, the practical results of his work are not effective, since he has no authority over the students or their work in the shop. It is, therefore, open to question whether the cooperative plan is an efficient substitute for proper college shop work, especially since even under the best conditions there is much that is necessary for an efficient training which is not presented.

In three of the four plants visited, it was stated that the students, under the cooperative system, were not to work except in the machine shop, no pattern shop, foundry nor forge shop training having been arranged for. The reason for this was that these plants did not have such departments, work of this character being done for them by outside firms. In another case an engineering student stated that upon authoritative advice he was omitting training in the pattern shop and foundry, because these branches were unnecessary as a part of a mechanical engineer's course.

Apprenticing Engineers

Literally, an attempt is made in Cincinnati to apply the apprenticeship method of teaching engineering. This plan would be satisfactory if the shop work were supervised in such a way that the student covered the proper field in a correct manner, and providing only a small number of students were to be handled. As soon as a large number are placed under such a plan, the training is likely to be insufficient, because there is not enough of the proper kind of work in any one plant to meet the student's needs. The point where there is a surplus of students to permit proper training has evidently been reached in Cincinnati, if it be true, as it is stated, that there are two courses available to students, one under which he can agree to a contract at a certain wage rate, according to which contract the company must place him in all of its departments, and one under a later form of contract where there is no agreement on the part of the employer to afford experience to a student in more than one department of a shop; but in this case a higher wage scale is offered. The writer did not see the latter contract, but was told that such a course was taken by many. This method permits of the entry of a larger number of students to the course, but it does not give them an efficient training.

There are certain excellent features of the engineering shop work as practiced in Cincinnati, one of which is the association with the workmen; but the most important feature of all—that the training of the student should be carried on without curtailment until the requirements of the course are met with in full—is being neglected. There is no department of a technical school which may be used so effectively as the shop in developing executive ability, provided the shop course is properly managed; and the factor of the development

* For previous articles on the Cincinnati plan of industrial education, see "Industrial Education—The Cincinnati Plan," November, 1909, and "Cooperative Industrial Education," October, 1908.

† Director of Williamson Free School P. O., Delaware Co., Pa.

of executive ability should be kept well in mind by all who are training young engineers. Yet this feature is entirely lacking in the method applied in Cincinnati.

Summary

Summing up the points in favor of the Cincinnati plan and the points that are against it, we find the following favorable conditions embodied in the method.

1. The student has an opportunity to see a shop arranged for commercial production. During noon hours and, perhaps, at other times when not engaged, he may go about, ask questions, and observe for himself, thus gathering much valuable information.
2. The student has an opportunity to see modern tools installed and running in an efficient manner, and observe the operation of all classes of shop devices.
3. He gets used to factory routine.
4. He learns his place as a factor in the productive plan, and finishes his college course with a balanced estimate of his knowledge and usefulness.
5. He develops dexterity.

The unfavorable points, as the writer sees them, are as follows:

1. The student does not obtain a full understanding of the possibilities and the wide application of any one tool.
2. The ability to discriminate between methods of production, and their bearing upon economy, is not developed.
3. The underlying reasons for using jigs and fixtures and similar labor-saving devices are not made thoroughly clear.
4. There is a lack of general familiarity with elementary shop processes with which the engineer must necessarily come in contact.
5. The student cannot be placed to advantage in the various shops by the college authorities who are responsible for his training.
6. His executive capacities are not developed.
7. Necessary branches of the work are dropped from the course at will.
8. The trend is toward training a mechanic for the shop rather than an engineer.
9. There is insufficient supervision of the shop work by the college authorities, or else the supervision is ineffective.
10. A large number of students do not get the proper training and the opportunities which may be available are for a few.
11. The feature of alternating between shop and school (the Cincinnati system being based upon the plan of the student working one week in the shop and then the next week in the college, and so on) is detrimental to the student's work in both branches, because of the frequent extended interruptions, first in one department and then in the other.

The Trade Course

The previous discussion has dealt with the engineering work only, no thought having been given to the training of mechanics, as the method of teaching for the two classes should be entirely different. Boys learning a trade have four hours a week off to go to school, and are paid apprentice wages for this time. In the apprentice school the problems given are related to the shop. The writer did not have an opportunity to see a class in session, but talked with some of the boys, and apparently this work consists of a series of shop talks with related problems. The subject matter of these shop talks appears to be good, though limited in its scope. They are delivered by persons who know their business, which by the way, is a very important feature. The apprentice classes meet in a separate school building devoted to this work alone. This school feature, however, is the only feature which is in any way different from the apprentice course available almost anywhere in the country to a boy who enters a machine shop.

One must not regard shop talks and the solution of problems as the whole of trade teaching. They are important and necessary adjuncts, but the real teaching of the trade is done on the shop floor by a man who makes it his business to see that the apprentice understands what he is doing; at the same time he is given such a range of experience that he may enter any shop as an all-around man. This involves the ability to operate all the principal machine tools, as well as familiarity with floor work; as principal machine tools are classed the lathe, planer, shaper, slotter, milling machine, boring mill, and grinding machine.

Now it depends on the position which one takes relative to trade teaching, whether the manufacturer is morally responsible for teaching a trade such as outlined above or not. If no claim is made to public attention or funds, any manufacturer may give any kind of training that a boy is willing to accept, or may be compelled by force of circumstances to accept, and there is no fault to find. The manufacturer has a right to make the apprenticeship he offers meet his own requirements for the benefit of his plant, and take care that the working personnel may not become depleted. This is what the men in charge of the shops in Cincinnati claimed to be doing and nothing more. No person in authority with whom the writer talked claimed to be training all-around men. "Three branches is all we give, at most," someone said, "and all the boys do not get these." One man in charge at one of the shops stated very clearly that there was no claim towards doing anything in this matter of trade training that is not done in almost every community, except that in the continuation school an effort was made to give the boy a proper view of his trade.

While thus the writer was not given any erroneous impression of the nature of the training afforded boys under the Cincinnati arrangement by those in charge of the shops, yet is it claimed by the educational authorities in presenting the cooperative plan of work in Cincinnati that the boy has an excellent chance to learn a trade, and this is the one point where the system is open to criticism—when it is claimed before the public that a course based on the needs of the apprentice is offered, and that his needs are the prime consideration. Persons connected with the school work in Cincinnati, however, have no control over the shop work and no assurance that the boy shall apply any of the matter taught at school in practice. In fact, the school work seems to be merely a scheme to keep the boy interested in what he is doing in the shop, in a vague way, rather than having direct application to his work. No one on the shop floor gives the apprentice any special attention. The instruction he gets is mere chance, and is not a certainty for every boy.

Therefore, in view of the fact that, at best, but a limited course is offered, and that even such a course is frequently curtailed, it hardly appears that the cooperative plan is a good way to teach a trade, nor even a desirable way in view of the fact that there are better ways open at a low cost to any community. This way is the trade school pure and simple. Worcester, Bridgeport, and New Britain, as well as some other communities have tried this method and seem to be satisfied with it. To say that such a school is too expensive is to admit that one does not understand the operation of a plant on a business basis, because all the trades taught at a school can be made to contribute to its support in the making of its own equipment.

This article should not appear without an acknowledgment of the courtesies extended the writer at the various plants, and an appreciation of the frank and open way in which each of those in authority at these plants answered all questions and assisted in the obtaining of the required information.

* * *

When steel balls are used for burnishing small metal articles by tumbling, it is important that a liberal amount of steel balls be used. There is a strong tendency, particularly among the smaller manufacturers, to attempt to economize on the balls and use too few. The result is, according to the *Brass World*, that not only is it difficult to obtain a good burnished surface on the goods in a reasonable time, but sometimes the appearance of the articles is such that the manufacturer will condemn the ball burnishing process. If too small a quantity of balls is used, they do not come in contact with the surface of the work being burnished as often as is necessary, and hence the process is slower than it would otherwise be. Also, if a small quantity of balls is used, the surfaces of the articles being burnished come in contact with one another instead of with the balls, and abrasion takes place instead of burnishing. In establishments doing some excellent work by the use of steel balls it is customary to use about twice the quantity of steel balls as compared with the quantity of the work in the barrel.

When the New York, New Haven & Hartford railroad shall have completed the electrification of its lines all the way to New Haven, as recently decided upon, it will have a mileage of about 150 miles under electric operation, or a trackage of about 600 miles. It is expected that these lines will be electrified before the end of 1913. This electrification marks the greatest undertaking along these lines as yet definitely proposed.

IMPROVED DESIGN OF HYDRAULIC ACCUMULATOR

By ALEX. W. BEGGS*

In the December number of MACHINERY an illustrated description on designing a hydraulic accumulator appeared. The writer has no fault to find with this article, or the calculations as given for the design presented, but he takes exception to the design or type itself. The design shown is con-

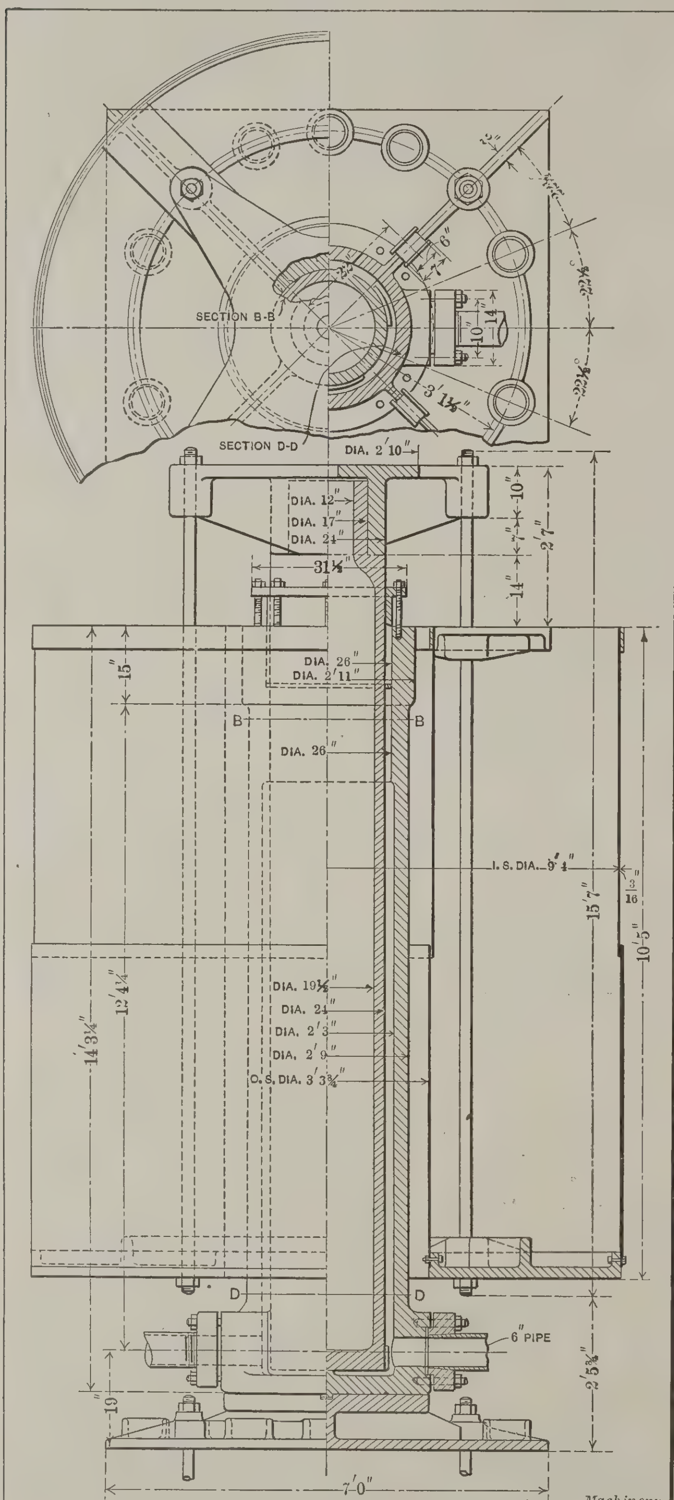

Fig. 1. Improved Design of Hydraulic Accumulator

sidered out of date, being what one might call "upside down." Furthermore, the author of the article states that it is better to make the plunger small in diameter and the stroke long, thus saving in the number and size of cast-iron weights required. The latter statement is, of course, correct, but it makes a more costly machine to build. Castings 23 feet long are difficult to make in the foundry, and to handle in the machine shop, and few shops have lathes that will take castings of that length. In addition, there is the guide frame to build and to fasten to the building, and the overhead room required. It is also troublesome for the man who has to crawl in under the accumulator to pack the gland on the plunger.

If it is necessary to save on the cast-iron weights, a tank can be used which can be filled with any kind of cheap scrap. The accompanying illustration shows a 24-inch accumulator for 600 pounds pressure, of which several have been built. It is self-contained, and as the packing of the gland is at the top, it can be easily reached. It is the practice in some plants employing hydraulic power, to use about 600 pounds pressure for general work. If a higher pressure is required an intensifier is used.

All the principal points of the design are indicated in the illustration, and it is not necessary to elaborate on them. One point in the design may, however, be worth while calling attention to. As will be seen in the engraving Fig. 2, the plunger is provided with four lugs, 9 inches wide, on the lower end. Four similar lugs are also provided on the inside of the upper end of the cylinder. If the plunger is placed in the cylinder and then given one-eighth of a turn, this will bring the lugs exactly in line with each other, and when the plunger is extended to its full stroke, the lugs will come in contact with each other and prevent further movement of the plunger. The plunger is prevented from turning back by a 1½-inch bolt

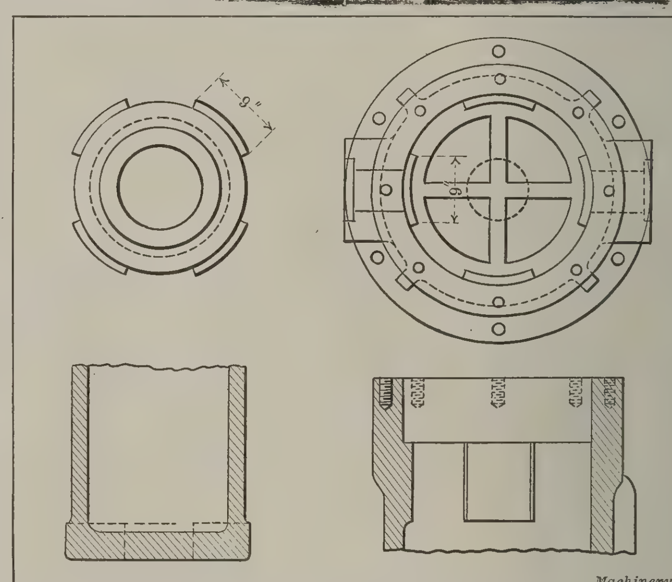

Fig. 2. End Views of Cylinder and Plunger, and Sections of Upper End of Cylinder and Lower End of Plunger, showing Safety Lugs

at the upper end, which passes through both the yoke and plunger. The yoke is prevented from turning by the flanged guide wheels on the bottom of the tank.

BRITISH STANDARD DEFINITIONS OF YIELD POINT AND ELASTIC LIMIT

The Engineering Standards main committee has agreed upon the following definitions for yield point and elastic limit. The elastic limit is the point at which the extensions cease to be proportional to the loads. In a stress-strain diagram plotted to a large scale it is the point where the diagram ceases to be a straight line and becomes curved. The elastic limit can only be determined by the skillful use of very delicate instruments and by the measurement of the extensions for small successive increments of load. It is impossible to determine it in ordinary commercial testing.

The yield point is the point where the extension of the bar increases without increase of load. Practically, the yield point is the load per square inch at which a distinctly visible increase occurs in the distance between gage points on the test piece, observed by using dividers; or at which, when the load is increased at a moderately fast rate there is a distinct drop of the testing machine lever, or, in hydraulic machines, of the gage finger. A steel test piece at the yield point shows rapidly a large increase of extension, amounting to more than one two-hundredth of the gage length. The point is strongly marked in a stress-strain diagram.

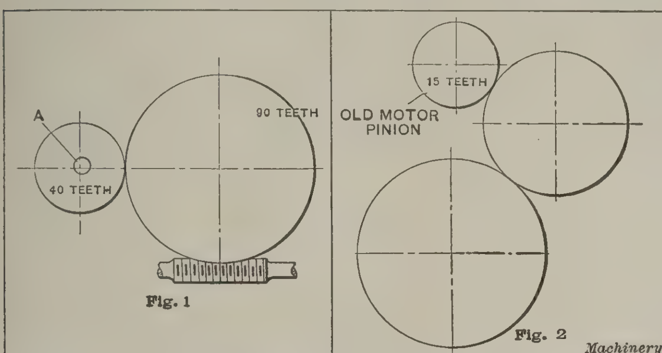
SHOP PROBLEMS INVOLVING GEAR AND PULLEY SPEEDS*

By J. H. CARVER†

In the following article are given a number of problems involving gear and pulley speeds. The problems are of a type likely to occur in ordinary shop practice, and their solutions are submitted with the hope that they will be of interest and value to those who may meet with similar instances, where the methods here given might be employed.

In the first place, assume that we have two gears with fixed center distance and a given ratio, which are to be replaced by two gears of a different ratio. Let R be this new ratio;



Figs. 1 and 2. Problems in Gear Ratios

and let the sum of the number of teeth in both the new and the old gears be $N + n = S$, where

N = the number of teeth in the large new gear,

n = the number of teeth in the small new gear.

R and S are known, and N and n are to be found. But, as $R = n \div N$, we have $NR = n$, or $NR - n = 0$. We have also $N + n = S$. Adding these two equations we have:

$$NR + N = S, \text{ or } N = \frac{S}{R+1} \qquad (1)$$

$$\text{From } R = n \div N, \text{ we have } n = NR. \qquad (2)$$

These formulas determine the number of teeth in the two new gears, which are of a different ratio but have the same center distance as the old gears.

As an example, assume that we have two gears on fixed studs, each having 60 teeth, and that these gears are to be replaced by two having a ratio of 4:11. Then, from the equations just given we have:

$$N = \frac{S}{R+1} = \frac{120}{(4 \div 11) + 1} = \frac{120 \times 11}{15} = 88 \text{ teeth.}$$

$$n = NR = 88 \times \frac{4}{11} = 32 \text{ teeth.}$$

In the arrangement of gearing shown in Fig. 1, shaft A is

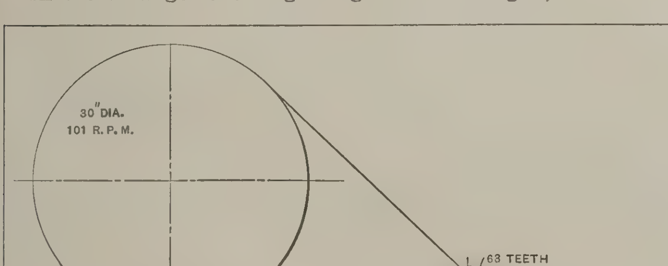


Fig. 3. Speed Reduction obtained by Gearing and Belting in Combination

turned by a worm- and spur-gear train. It is required to revolve shaft A thirty per cent faster by replacing the 40- and 90-tooth gears by other gears of proper ratio and suitable for the fixed center distance.

$$\text{Old gear ratio} = \frac{40}{90}. \quad \text{New gear ratio} = \frac{40}{90} + \left(\frac{30}{100} \times \frac{40}{90}\right) = \frac{52}{90}$$

$$\text{Hence, } N = \frac{S}{R+1} = \frac{130}{(52 \div 90) + 1} = 82.3,$$

or say 82 teeth, which is the nearest whole number. Further

$$n = NR = 82 \times \frac{52}{90} = 48, \text{ approximately.}$$

Hence, two gears of 82 and 48 teeth, respectively, making $S = 130$ teeth, as it should be, will give an increase of speed to shaft A of practically 30 per cent.

It is sometimes desired to change the size of the motor because of the increased duty of a motor-driven machine. For example, a 30-inch engine lathe is provided with a 2½ horsepower variable speed motor running at 700–1400 R.P.M., and it is desired to replace it with a 5 horsepower motor running at 500–1500 R.P.M. The speeds of the lathe spindle must cover at least the same range as before. The arrangement of the gears near the motor is shown in Fig. 2. The only change necessary would be in the motor pinion. The number of teeth N in this pinion is found from the proportion:

$$\frac{N}{15} = \frac{650}{500}, \text{ or } N = \frac{15 \times 650}{500} = 20 \text{ teeth, approximately.}$$

The value 650 is used in place of 700 because both slower and faster new speeds can thereby be provided for.

It often happens when belting from the motor to the pulley on a motor-driven machine, that the desired slow speed cannot be obtained by belting directly to the regular motor

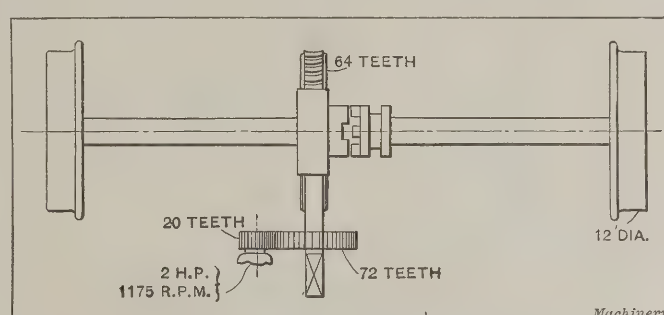

Fig. 4. A Simple Problem in Gear Ratios

pulley. In this case the motor may be geared as illustrated in Fig. 3. A bracket carrying a shaft is mounted on the motor frame. This shaft has a gear on one end meshing with a pinion on the motor shaft, and a driving pulley on the opposite end to which the pulley on the machine to be driven is belted.

A punch-press, for example, has a balance wheel 30 inches in diameter, as indicated in Fig. 3, and is driven by a two-horsepower constant-speed motor running at 1175 R.P.M. The required speed of the balance wheel is 100 revolutions. It will be found that by the arrangement shown a speed of

$$\frac{1175 \times 27 \times 6}{63 \times 30} = 100.7 \text{ R.P.M.}$$

will be obtained, which is near enough for practical requirements.

An inclined hydraulic press, whose back yoke is mounted on wheels and designed to be moved by an individual motor at a speed of 16 feet per minute, is arranged in the manner indicated in Fig. 4. A two-horsepower constant-speed motor is used, running at a speed of 1175 R.P.M. The wheels on which the yoke is mounted are 12 inches in diameter, or 3.14 feet in circumference. Hence, the number of revolutions necessary for a speed of 16 feet per minute equals $\frac{16}{3.14} = 5.1$ revolutions. Further, the speed of the worm $= 64 \times 5.1 =$ 326.4 R.P.M. Assume that we choose a 20-tooth gear on the motor shaft. How many teeth should the gear on the worm-shaft, meshing with this 20-tooth gear, have? Denoting the

* For a treatise dealing more completely with the principles involved in the problems presented in the present article, see MACHINERY'S Reference Books No. 18, "Shop Arithmetic for the Machinist," and No. 52, "Advanced Shop Arithmetic for the Machinist."

† Address: 761 Eastern Ave., Schenectady, N. Y.

number of teeth to be found by T, we find this number as follows:

$$T = \frac{20 \times 1175}{326.4} = 72 \text{ teeth.}$$

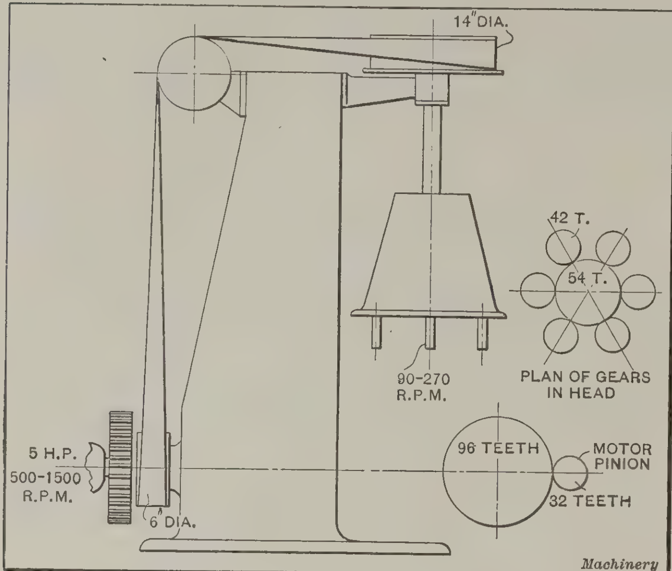

Fig. 5. Drive of a Six-spindle Drill Press

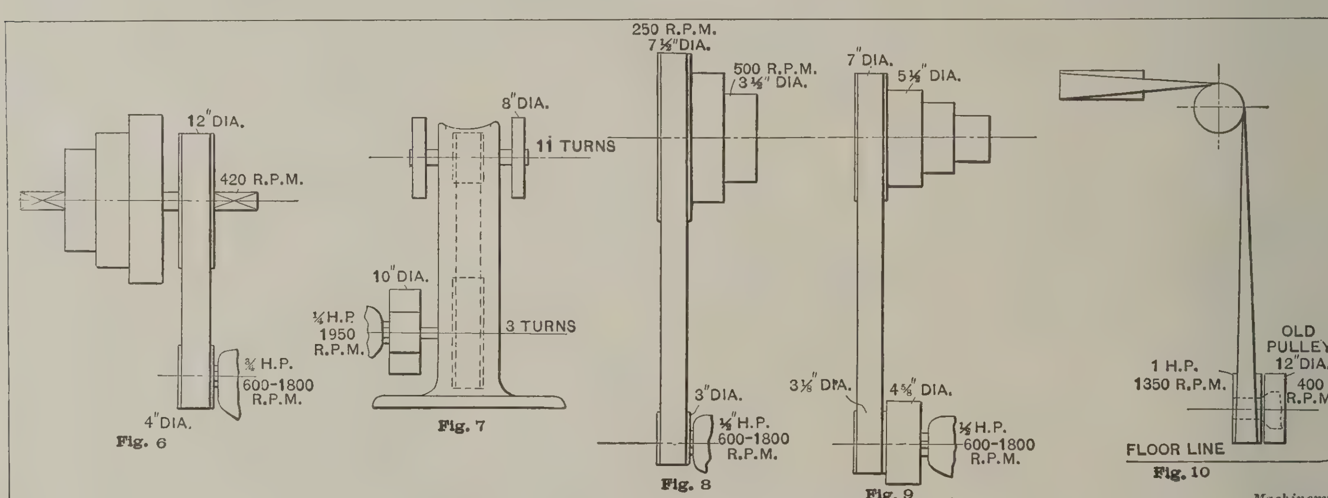
In Fig. 5 is shown a diagram of gears and pulleys used on a six-spindle multiple drill. A 32-tooth pinion on the motor meshes with a 96-tooth gear, as shown. A five-horsepower motor, 500–1500 R.P.M., was used. The drill speeds neces-



Figs. 6 to 10. Miscellaneous Examples of Belt Drives

sary were 90–270 R.P.M. The number of teeth in the motor pinion was found as follows:

$$\frac{96 \times 14 \times 42 \times 90}{6 \times 54 \times 500} = 32 \text{ teeth, approximately.}$$

A three-spindle sensitive drill was to be equipped with a ¾-horsepower variable speed motor, running at 600–1800 R.P.M. It has been found that ¼ horsepower per spindle is ample for driving sensitive drills. In the old belt-drive arrangement, the drive was to a 12-inch pulley, driving the cone-shaft at 420 R.P.M., as indicated in Fig. 6. The motor is belted to the same pulley, as shown. The diameter of the pulley on the motor is found as follows:

$$\frac{12 \times 200}{600} = 4 \text{ inches diameter.}$$

The value 200 is used instead of 420 in order to give a slower speed for the lowest motor speed than that obtainable by the belting arrangement. The average motor speed will then give the required speed to the cone shaft.

A grinder using an 8-inch emery wheel is to be driven as shown in Fig. 7, by a ¼-horsepower motor running at 1950 R.P.M. The emery wheel is run at 2100 R.P.M. The pulleys shown dotted are enclosed, and it is difficult to measure their diameters so as to determine the proper size for the motor pulley. By turning the emery wheel spindle, however, it can be found that eleven turns of the emery wheel correspond to three turns of the 10-inch pulley belted to the motor pulley. Hence, the speed of the 10-inch pulley equals $\frac{3 \times 2100}{11} = 573$ R.P.M., and the size of the required motor pulley will be $\frac{10 \times 573}{1950} = 3$ inches, approximately.

When changing the style of drive on a machine tool from belt to motor drive, it often happens that a cone pulley must be belted to the motor pulley. In the case of many lathes, profiling machines, drill presses, shapers, slotters, milling machines and special tools, the ratio of the speeds obtainable through the cone pulley may run from 3 to 1, according to whether the belt is on the smallest or largest step of the pulley. In such a case a 3 to 1 variable speed motor with the proper diameter of pulley to give the desired slow speed when belted to the large step of the cone will also give the corresponding high speed. As an example, assume that a turret lathe runs at 250 R.P.M. with the belt on the largest step, and at 500 R.P.M. with the belt on the smallest step, as indicated in Fig. 8. This lathe is to be belted directly from the motor pulley to the largest cone step. A 3-inch motor pulley gives a greater speed range than the old speeds, when using a ½-horsepower motor running at 600–1800 R.P.M.

In the case of higher ratios of machine cone pulleys, where the motors obtainable do not cover the desired speeds, a two-step motor pulley will meet the requirements. For example, a speed lathe, the cone of which together with the two-step cone of the motor is shown in Fig. 9, is driven by a ½-horsepower motor running at 600–1800 R.P.M. The lathe originally ran at 200–1500 R.P.M. With the motor pulley shown the speeds are 270–810 R.P.M. with the belt on the large step of the lathe pulley, and 500–1500 R.P.M. with the belt on the next smaller step.

A drill press was belted in the manner shown in Fig. 10. The 12-inch tight and loose pulleys shown were to be removed and replaced by a motor with pulley. The pulleys ran at 400 R.P.M. The motor was 1 horsepower, running at 1350 R.P.M. The peripheral speeds of the 12-inch pulley and the required motor pulley must be the same, if the drill press speed is to remain unchanged. Therefore, when the speed is increased, the diameter will be proportionately decreased, and

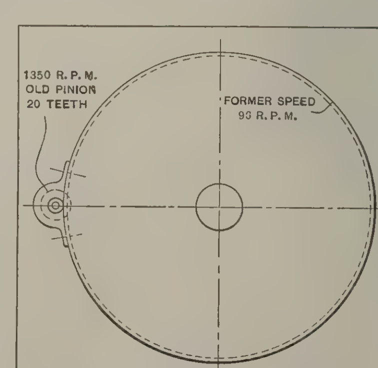


Fig. 11. A Problem in Gear Ratios

hence, the diameter D of the required motor pulley will be found as follows:

$$\frac{D}{12} = \frac{400}{1350}, \text{ or } D = \frac{12 \times 400}{1350} = 3.55,$$

or, say, 3½ inches, which is near enough for all practical purposes.

Fig. 11 shows a diagrammatical view of a punch press arrangement, the balance wheel being driven by a ½-horsepower motor running at 1350 R.P.M. The motor pinion has 20 teeth meshing with teeth in the balance wheel. The wheel runs at 96 R.P.M. It is desired to change to a 2-horsepower motor running at 1175 R.P.M., and at the same time increase the speed of the balance wheel to 110 R.P.M. The balance wheel is enclosed, making it difficult to measure or count the number of its teeth. By the calculations in the following, the necessary number of teeth in the new motor pinion is determined without reference to the balance wheel. If N is the number of teeth required, then

$$\frac{N}{20} = \frac{1350}{1175}, \text{ or } N = 23 \text{ teeth, approximately}$$

if 96 turns per minute, only, were required; but when 110 R.P.M. are required, we would have:

$$\frac{N}{23} = \frac{110}{96}, \text{ or } N = 26 \text{ teeth.}$$

* * *

An electrically operated blueprinting machine, used for making the blueprints for the municipal departments of St. Louis, Mo., produced 15,900 blueprints last year. According to the *Engineering Record*, the cost per square foot, including labor, material, and depreciation of the machine, was 1.5 cent for blueprints, 3.4 cents for brown-prints, 5.4 cents for black-prints, and 6.4 cents for blue-cloth-prints.

AUTOMATIC DIE-CASTING MACHINES*

By E. F. LAKE†

Nearly all die-casting machines in use at the present time are operated by hand, that is, a number of levers are pulled back and forth to perform the different operations of closing the mold, moving the plunger to force the metal into the mold, cutting off the sprue, opening the mold, and ejecting the castings. Nearly all of these machines require two men to operate them, and in some cases it requires five men to operate two machines. With these hand-operated machines a large quantity of castings can be manufactured in a day, and many have not considered it necessary to design and build more expensive machines. Some manufacturers, however, have built completely automatic machines for their own use, in order to save the labor cost of the hand-operated machines.

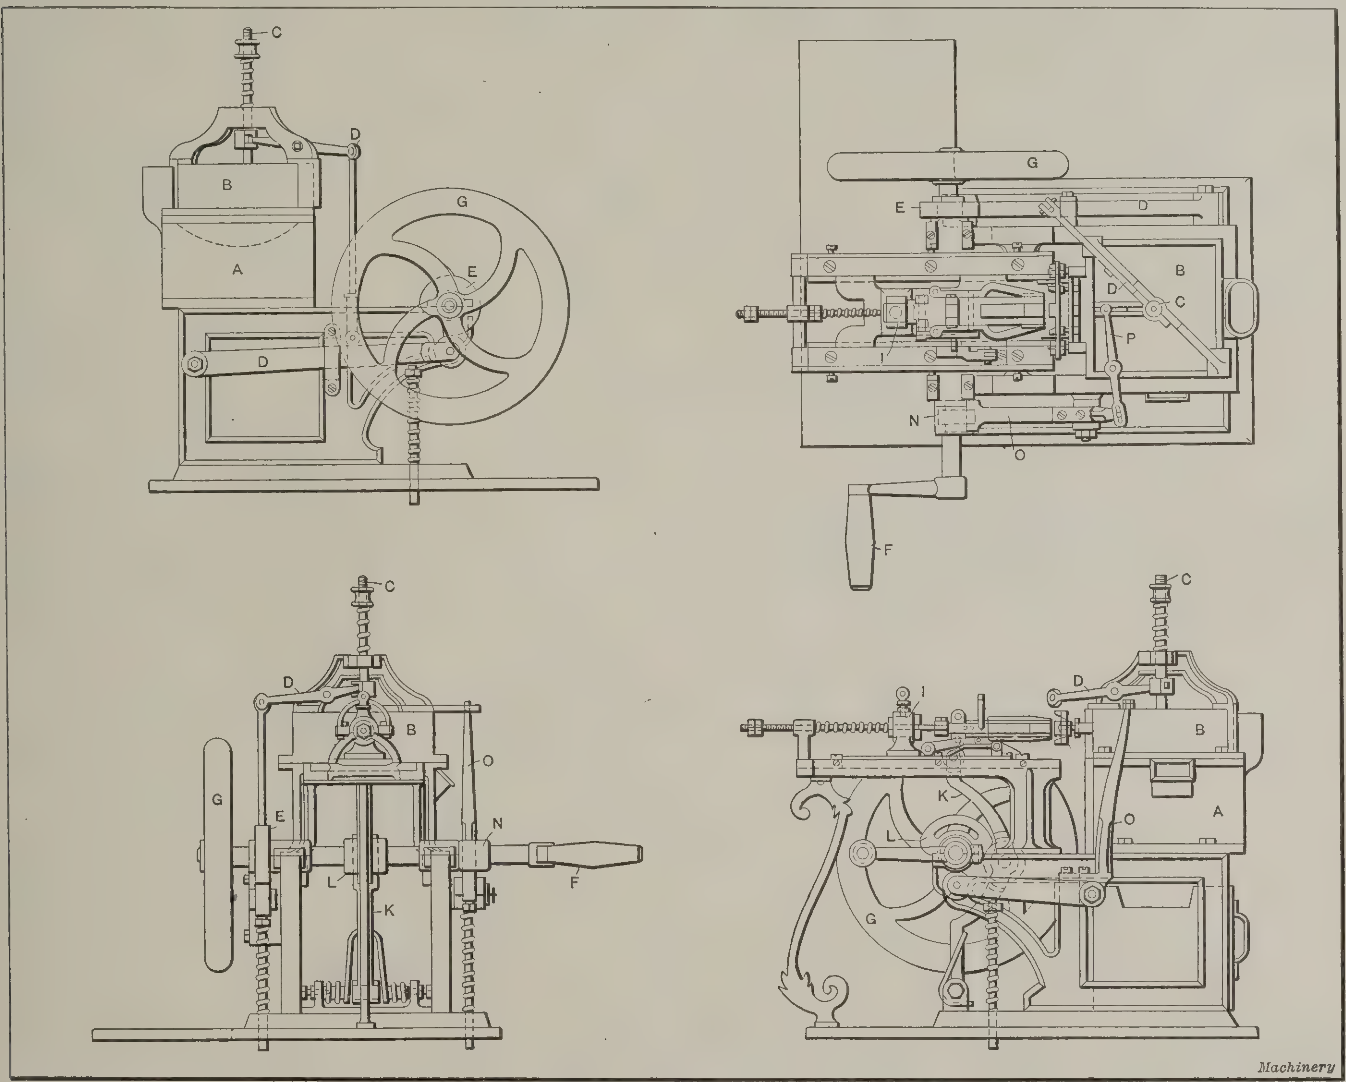

Fig. 1. First Automatic Die-casting Machine

These automatic machines are very successful, and are producing die-castings at a very low cost.

Automatic machines for casting type have been in use for more than sixty years, and these are, in reality, die-casting machines, although only used for the particular purpose of manufacturing type. Like all other die-casting machines, the automatics were devised from ideas and principles adopted in the type-casting machines, and are, in fact, largely improvements of these. The first attempt at applying such machines to the manufacture of castings, other than type, is shown in Fig. 1. This machine was patented by M. Dimock in 1875 for the manufacture of sewing machine bobbins. By turning crank F, all movements were produced that were necessary for the casting of a bobbin and throwing it out of the machine. By putting a pulley in place of the crank, it could be belt-driven and thus made completely automatic. In this machine,

* See MACHINERY, July, 1911, engineering edition, "The Design of Die-casting Machines—Alloys for Pressure Castings," and also the previous articles there referred to.

† Address: 184 Ave. B., corner 47th St., Bayonne, N. J.

A is the furnace and *B* the melting pot located over the furnace, in which the metal is melted and held, ready for casting; *C* is the upper end of the pump or plunger that forces the metal into the mold. This plunger is raised and lowered by levers *D*, which in turn are moved by cam *E* located on the driving shaft, which passes through the machine from crank *F* to the flywheel *G*. The mold and the apparatus for opening and closing it and ejecting the casting are located on a

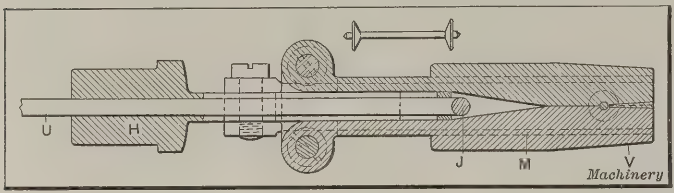

Fig. 2. Die-mold and the Bobbin cast

framework just above this shaft. The die-mold receives its metal from a nozzle in the side of the melting pot.

The cross-section of the die-mold, with shank *H* on which it is pivoted, is shown enlarged in Fig. 2; the bobbin which is cast in it is shown above the mold. Shank *H* fits into cross-head *I*, and is, by means of this cross-head, pulled back from the spout so that it can be opened. The two halves of mold *M* are opened like an alligator's jaw by turning bar *J*, which is long enough for this purpose and is located on the end of shaft *U* that passes through shank *H* and carriage *I*. The cast bobbin is then thrown out and the mold closed, ready for another casting. The cross-head and mold are moved back and forth by lever *K*, one end of which is pivoted to the frame at the bottom of the machine, while the other end works in a slot in the cross-head. Lever *K* is operated by cam *L* which is located on the center of the main shaft. When mold *M* is moved up to the nozzle of the machine, the tapered end at *V* enters a socket, thus holding the mold firmly closed. As soon as the mold assumes this position, a cam located on the main shaft at *N* operates hinged lever *O*, and this, in turn, moves lever *P*, which opens a valve that allows the molten metal to be injected into the die-mold. This valve operates in practically the same manner as valve *T* in Fig. 3 and valve *L* in Fig. 5, to be described later. In the meantime, plunger *C* has been raised to the top and as soon as the metal cut-off valve opens, the plunger is forced down and fills the mold with metal.

While this machine was simple in design, it worked fairly well, and many castings were made with it. The springs which gave the levers their return motion, however, were not positive enough, and on later machines cams were added for this work. A sprue cutter, such as is now used, was not provided, and hence the sprue had to be broken off from each casting. These were about the only faults that could be found, and the principles here adopted were developed to a point that enabled automatic die-casting machines to cast pieces very intricate in shape. Movements were devised for pulling out pins, located in the die-molds, as well as other loose pieces that might form any size or shape of hole in the casting.

In 1902, Mr. C. H. Veeder patented the machine shown in Fig. 3. On this he was granted patents on nineteen combinations claims, but it will be seen that, although the machine is greatly improved in its design, the basic principles on which it operates are practically the same as those of the machine patented in 1875. The furnace is located at *A*, the melting pot at *B*, and the upper end of the plunger at *C*, as in the former machine. Lever *D* is operated by cam *E* and moves rod *Q* and lever *R*, which latter causes plunger *S* to travel up and down and squirt the molten metal into the die-mold. Another cam moves pivoted lever *O*, which is connected with the valve rod, and opens and closes valve *T* in identically the same manner as did the earlier machine; in fact, the shape of lever *O* is almost the same. This, however, is a design that has been successfully used for years on type-casting machines and is difficult to improve upon.

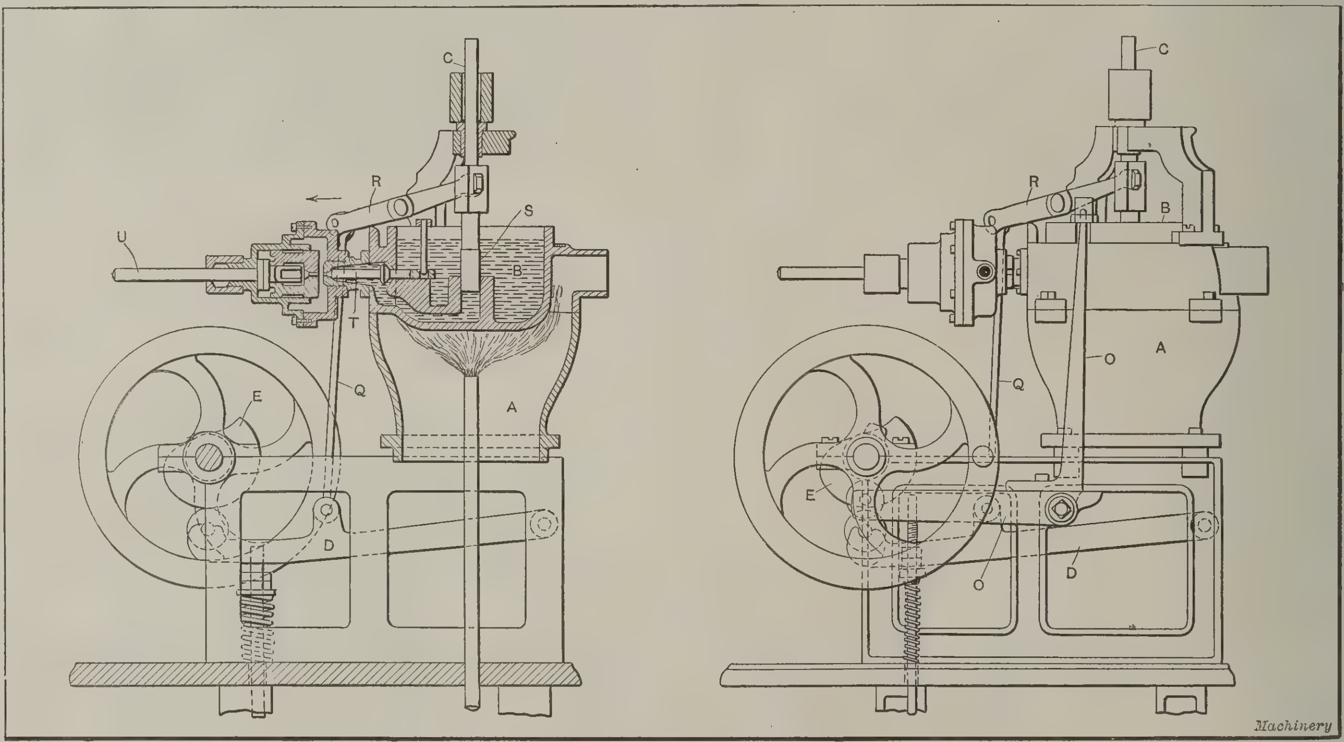

Fig. 3. Modern Die-casting Machine

The manner of parting the mold to remove the casting is altogether different. Instead of opening it like an alligator's jaw, as in the earlier type of machine, a part of the mold is moved back, away from the machine, and the casting is thus allowed to fall out. The mechanism that opens and closes the mold is not shown in Fig. 3, but it is done with a very similar supporting frame and cross-head to that which draws the mold away from the nozzle in the Dimock machine in Fig. 1; but, instead of using rod *U* to turn bar *J* and thus open the mold, as in the Dimock machine, rod *U* is used to form a core in the casting and after the casting has been made, rod *U* is pulled back to free the casting from the mold. This machine has been used for several years, but has also been improved upon. It has been made entirely automatic by putting a pulley in place of the crank wheel.

While in most automatic machines cams have been used to control nearly all of the movements, in others springs and gears have been used in combination with cams. Such a machine is shown in Fig. 4. In this a cam *E* is used to control the motion of the pump plunger and a large spring is used to hold the lever against this cam. The mold is moved

up to the spout and away from it by a crank on the end of the shaft that holds the cam. This shaft is driven by a gear N that meshes with a pinion L driven by a worm-wheel K and worm J; the worm, in turn, is driven by a pulley F and belt. A stationary cam is used to control the motion of a knife which cuts off the sprues and a brush that brushes off the knife. With the exception of the spring for holding the lever that operates the plunger against the cam, this machine works successfully. A spring in this location is liable to fail, owing to the plunger's sticking in the cylinder, due to dross in the molten metal; no metal would then be forced into the mold.

This machine was especially designed for casting electric storage battery grids, but can well be used for making many shapes of castings for machine parts. These grids are thin strips of metal, crossing each other at right angles, the strips being joined together at each intersection; they thus contain a number of square openings, and resemble wire netting, except that the strips are not round. As in the other die-casting machines, A is the furnace, B the melting pot over the furnace, C the plunger rod, and D the lever that operates the plunger. A roller attached to lever D rides on cam E, to guide the up and down motion of plunger G; spring I holds lever D against cam E. It would doubtless be better to use another cam to perform the work of this spring and thus make the upward motion of the plunger as positive as is the downward motion. Cam E is so shaped and timed in its motion as to cause the plunger G to move down only when the mold is closed tightly against the nozzle and ready to receive the metal. To reduce the air pressure in the mold against the plunger's action and insure that all parts are filled with the incoming metal, an air pipe Y, with pump, is often connected to the mold. This automatically pumps out the air and creates a vacuum in the cavity of the mold that shapes the casting, just before the molten metal is injected into it by the plunger.

The mold is operated by a mechanism that is as simple, positive and handy as that of any die-casting machine made. Mold M is located on rocker arm H, which is connected by rod P and spring Q to crank R. Thus, while cam E is controlling the operation of plunger G, crank R is controlling the movements of the mold. Mold M is thus brought up to the nozzle and held there while plunger G descends and squirts the metal into it. Plunger G is then raised for another stroke, while mold M is rocking back away from the nozzle. For the grid casting made in this machine many gates are used, and while the rocker is carrying the mold back to the end of its stroke, knife S travels across the face of the mold and cuts off the sprues. A brush then travels across the face of knife S and brushes off any chips that may have accumulated. These motions are controlled by cam U, which is bolted to the side of the frame.

On many kinds of castings for machines or instruments, the shape is such that this knife and brush could not be used for the sprue cutter, but it is easy to take off this mechanism and attach others that would perform the necessary operations, and which might be even simpler in design. The distance through which rocker arm H travels can be adjusted by shortening or lengthening rod P by the nuts provided. The mold can thus always be kept tightly against the nozzle, and also go back far enough to eject any casting. When rocker arm H reaches the end of its backward stroke, arm V strikes block W and this operates the mechanism that ejects the casting from the mold. To insure no jar, flat spring X is provided for rocker arm H to strike against.

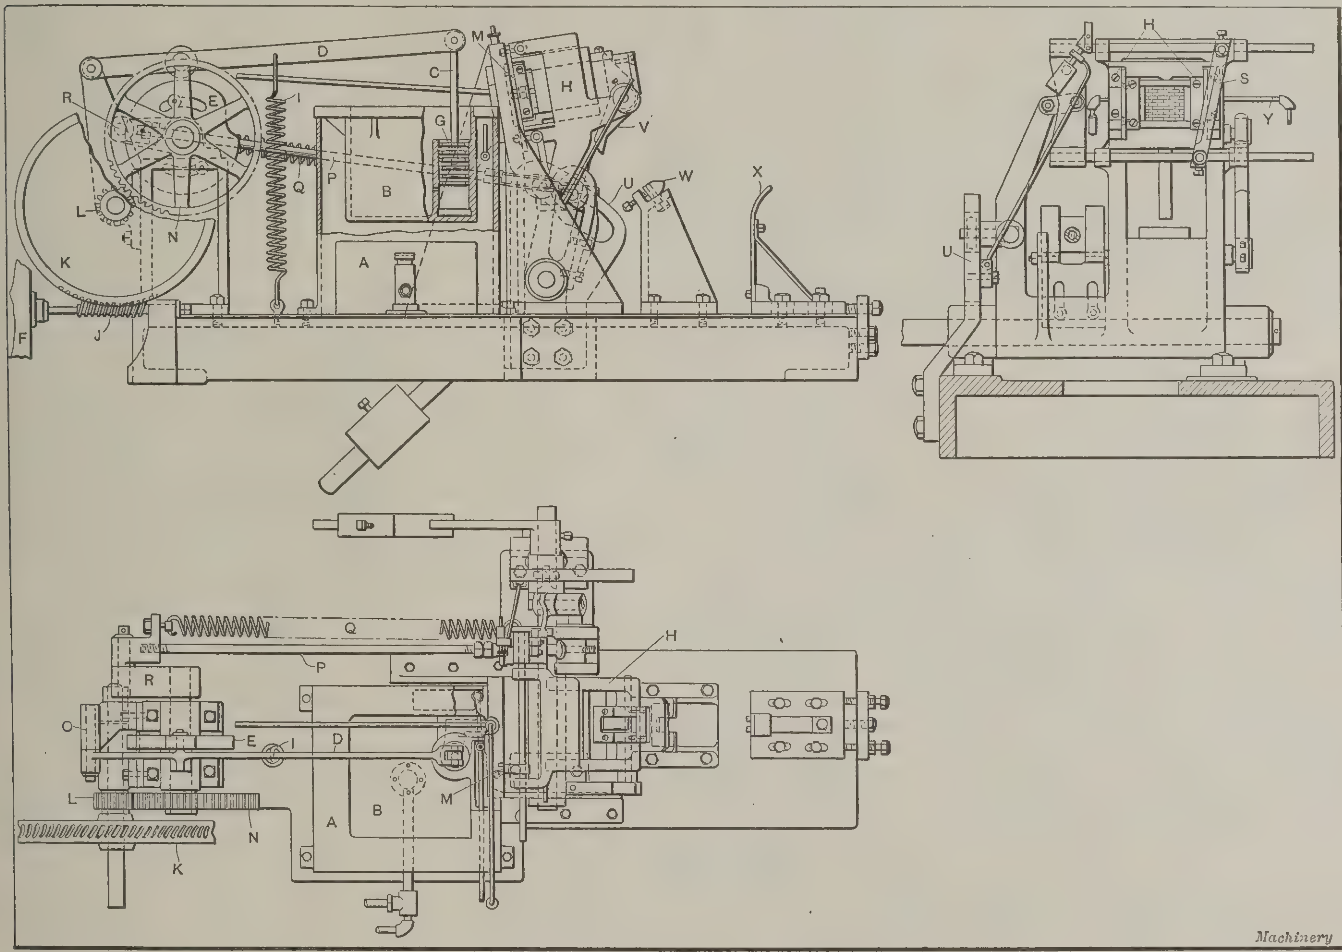

Fig. 4. Another Modern Type of Automatic Die-casting Machine

One of the most complete automatic die-casting machines built is shown in Fig. 5. This machine was patented by Mr. C. H. Veeder and is a vast improvement over the machine shown in Fig. 3. It is supplied with two melting pots and is completely automatic. All that the attendant has to do is to keep the secondary melting pot filled with metal and carry away the finished castings. With each casting that is made, the metal lowers in the melting pot and the secondary melting pot is used for the purpose of keeping the primary melting pot filled. In this machine the air is exhausted from the mold with an air pump before forcing the metal into it, thus insuring the filling of every crevice. The machine differs from nearly all other types in that it has provision for a

powerful, positive pressure for forcing the metal into the mold, in addition to the vacuum. Thus, the formation of gas bubbles or air pockets in the cavity that forms the castings is overcome and deformed castings are not produced. The percentage of bad castings has, therefore, been reduced to a minimum.

In this machine also, A is the furnace; B the melting pots; C the plunger; D the lever that moves the plunger up and down; E the cam that causes the movements of this lever; F the pulley that drives the machine; H the carriage that holds and operates the mold; and M the mold.

A single shaft J, driven by pulley F, controls all the movements. Cams are located on the central portion of this shaft and cranks on the two ends to give the machine all of its movements. No gears are used. A double-action valve is used to control the injection of the metal into the mold, and to cut off the sprue. This valve is shown at L. Before plunger C starts moving downward, arm N is moved away from valve L and the flow of metal due to the downward

This is a weak point of the machine, as the pressure that forces the molten metal into the mold is exerted against this spring, unless a locking device is attached to the mold, and this requires additional mechanism. Another cam could more easily be used to close the mold and hold it against the pressure of plunger C. While the mold is opening, bar S is moving to the left through carriage H to eject the casting from the mold. The movement of bar S is controlled by a series of levers moved by cam T. While the mold is closed, vacuum tanks U are automatically connected with it and draw out all of the air. A vacuum is constantly maintained in these tanks by an air pump.

With all of these movements properly timed, die castings are made as fast as the metal will solidify, and can be ejected from the mold without deforming the castings. Most die-casting machines do not apply as much pressure to the plunger, but depend on the suction created by the vacuum to draw the metal into the mold. This does not produce castings

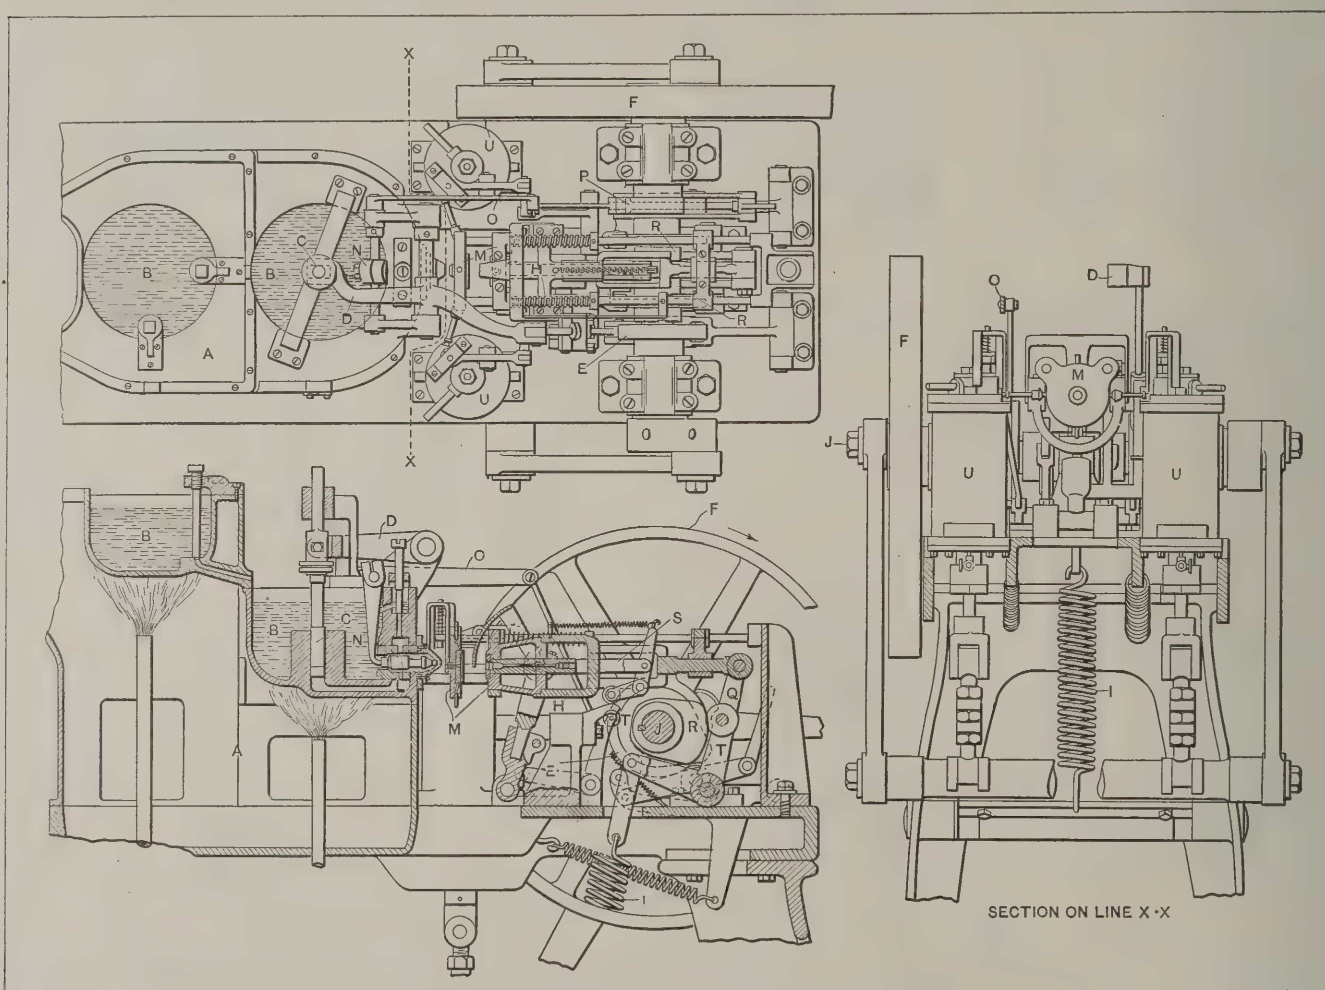

Fig. 5. The Latest Type of Automatic Die-casting Machine

motion of plunger C causes valve L to move to the left and close the opening between the passage in which this valve is located and the melting pot. Thus, all of the pressure exerted by the plunger is used to force the molten metal from this valve chamber into the mold. When the die-mold has been filled, arm N pushes against valve L and causes it to close up the nozzle opening through which the metal flows into the die-mold, and, at the same time, valve L cuts off the sprue of the casting. Arm N is moved by lever O, which, in turn, derives its motion from cam P.

Carriage H, which holds the mold and controls its movements, is operated by a series of levers that are moved by two cams. Lever Q, with its connecting levers is moved by cam R, and this pulls carriage H to the right to open the die-mold as shown in the lower left-hand view of Fig. 5. By the action of cam R, lever Q afterwards moves carriage H to the left, thus closing the mold and holding it tightly against the nozzle while it is being filled with the casting metal. Spring I holds the roller of lever Q against cam R.

with as fine and dense a grain as when a high pressure is applied, and they are more liable to have porous and spongy places. The high pressure, combined with the vacuum in the mold, also makes the casting correspond exactly to the contour of the cavity cut in the mold. One die-mold can be taken out and another, for a different casting, inserted in its place with very little labor. Thus the machine can be made to operate on several kinds of castings in a day's run.

These and other reasons make it one of the most economical machines built, as the cost of the castings has been reduced to little more than the cost of the metals for making the alloys, the gas that keeps the metal molten, interest on original investment, and the expense necessary to keep the machine in repair. Automatic type-casting machines cast one type at a time, at the rate of 240 per minute. This speed is largely due to the fact that cold water is forced through a water-jacket that surrounds the type cavity in the mold; as many as 240 per hour would be a high figure for die-castings for machine or instrument parts, as these are nearly always

more intricate in design and have a larger volume of metal to be cooled. Many times, however, more than one casting can be made in a mold. When the mold is water-jacketed, and the machine completely automatic, the output of perfect castings will be many times that of hand-operated machines, and at a very low labor cost.

The formation of coarse crystals is an inherent trait of all metals when they are slowly cooled from the liquid state. This coarse crystallization is more pronounced in some metals than in others, and the alloys from which die-castings are made are composed of the metals that form the coarsest crystals, when so cooled. The most notable example of this crystalline formation is antimony, while zinc is another metal that has a very flaky crystalline structure. This formation of coarse crystals can be overcome to a large extent if the metals are chilled and suddenly solidified from the molten state, when casting them into shape. This is done in the machine shown in Fig. 5 by circulating a stream of cold water through a water jacket formed around the cavity in the mold that forms the casting. While the vacuum created in the cavity of the mold and the pressure used to force the metal in have a tendency to reduce the coarse grain and crystallization, the rapid cooling and solidification that is caused by the current of cold water still further aids in refining the grain.

The action is similar to that which takes place when hardening steel. In this case, the grain is refined by heating cold metal to the desired temperature, and the fine grain is retained by instantly quenching in a liquid, and thus suddenly cooling the metal. If it were allowed to cool slowly, the grain crystals would return to the coarse size of the unheated steel; or if heated to too high a temperature, a coarse grain would be formed that could only be refined by the pressure or hammering applied during forging operations. In the die-casting alloys, this fine grain is produced by melting, and the quicker it can be cooled down from the molten state, the finer will be the grain of the metal in the castings. It is not a difficult matter to surround the casting cavity in all die-molds with a water-jacket. This, of course, will not only give the metal a more dense, homogeneous grain, but will also solidify the castings much more quickly and enable many more castings to be made per hour than can be made in a machine where the mold is not water-jacketed.

* * *

The manufacture of tungsten lamps has been a difficult and expensive matter because of the characteristics of tungsten. Up to a few months ago it was impossible to draw tungsten into wire as the common ductile metals are drawn, but it had to be squirted while in the so-called "colloidal" state to form the required filaments. The other elements mixed with the powdered tungsten had to be driven off by heat, thus leaving a very brittle wire, exceedingly difficult to mount in the lamp and easily broken by shock. Now, thanks to improved methods of treatment, it is possible to draw the pure metal into wire of great tenuity, diameters of 0.003 inch or less being readily produced. The metal is drawn through diamond dies into lengths of 600 or 700 feet and can be wound on spools without danger of breakage. The success of the research has made the tungsten lamp as practicable as the old carbon filament lamp which it is rapidly displacing because of its much greater efficiency.

* * *

A reader suggests that the boss who refuses to help a man acquire knowledge of those things in which he is weak for fear that he might get the boss's job some day, is not up-to-date. The modern foreman strives to surround himself with intelligent men, realizing that the higher the grade of average intelligence of men, the better will *he* stand with his employers. The intelligent foreman should cooperate in the training of an understudy who will be able at a moment's notice to take charge of his department. The late R. T. Crane of Crane & Co., absolutely required that every man occupying a responsible position have an alternate who knew all his duties and how to execute them. Did this mean that the foremen were likely to lose their jobs at any moment's notice? No, on the other hand the tenure of position was much more secure there than in the common run of factories.

THE EVOLUTION AND PRESENT DEVELOPMENT OF THE TURBINE-PUMP*†

At the present time the use of the turbine-pump has become so extended that it is difficult to find services to which it cannot be advantageously applied. It will no doubt, therefore, be a matter of interest to trace the evolution and development of machines of this design, and this, perhaps, cannot be better done than by considering in particular one type only. As a description of the commercial application of the steam-turbine is a history of the Parsons machine, so that of the turbine-pump can be adequately portrayed by an account of the evolution of the Osborne Reynolds pump.

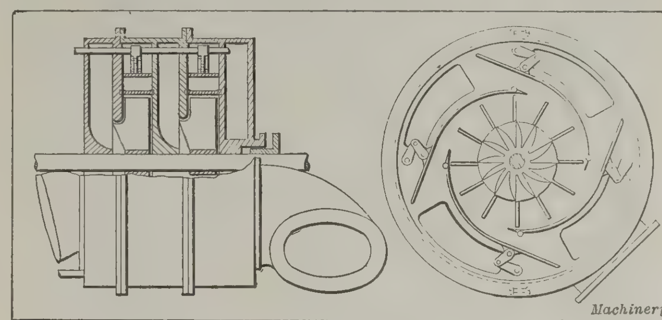

Fig. 1. Reynolds Turbine-pump, 1875

Centrifugal pumps were in the past accepted by engineers as suitable appliances for easily and cheaply (as to first cost) raising water to low heads. It was not realized that they were capable of dealing with any but low heads; in fact, this view became a canon of ordinary engineering practice, creating a tradition which took many years to remove. It is singular that, though the water-turbine with its guide-vanes was a matter of common knowledge at the time, no attempt appears to have been made to reverse its action with the prospect of obtaining a similar high efficiency and increase of head, for the purpose of raising water. There was, however, one exception in the invention of Prof. Osborne Reynolds'. It is the object of the present article to trace and discuss the development of this invention.

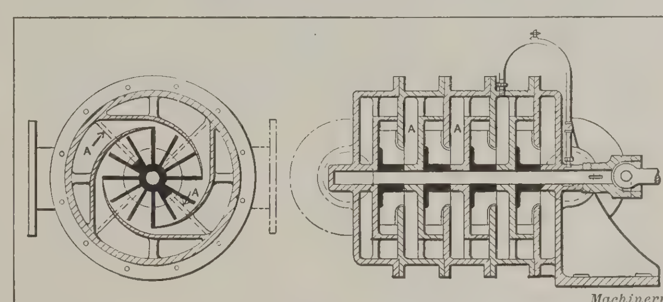

Fig. 2. Reynolds Pump, 1887

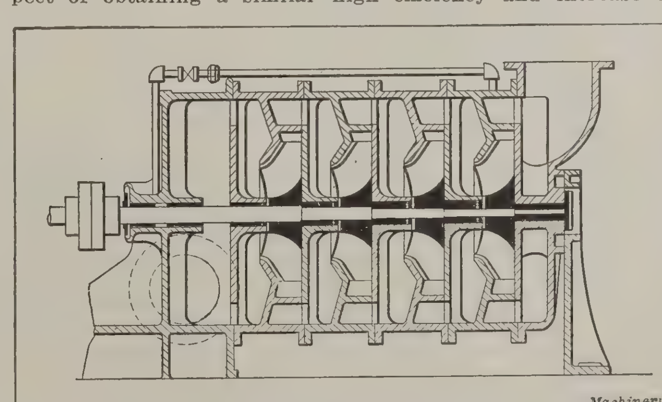

Fig. 3. Mather-Reynolds Pump, 1895

* Abstract of paper by Dr. Edward Hopkinson and Mr. Alan E. L. Chorlton, of Manchester, England, read before the Institution of Mechanical Engineers, January 19, 1912.

† For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: "Self-contained Turbine Pumping Engine," April, 1910; "Turbine Pump Motor Drive," and "Electric Drive of Turbine Pumps," December, 1909, engineering edition; "Centrifugal Pumps," June, 1909, engineering edition; "Centrifugal Pumps," February, 1909, engineering edition. See also the note published in connection with the last mentioned of these articles.

In 1875 Prof. Osborne Reynolds invented a turbine-pump of the series type, fitted with guide-vanes, as shown in Fig. 1. Comparison of this figure with illustrations following show how the essential features of his original proposition have been adopted in subsequent practice. In this pump the impeller delivered its water to tangent guide-vanes, as shown, and the similarity to an inward-flow turbine of the Thomson type is noticeable, for, as in that machine, the mouths of the guide-channels could be regulated to raise the efficiency of the pump for smaller outputs, a device however seldom adopted in later practice.

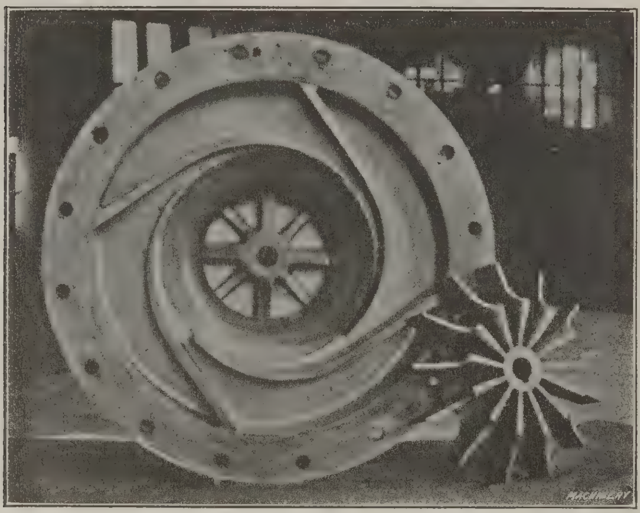

Fig. 4. Impeller and Guide-passages of Mather-Reynolds Pump

Nothing of any commercial value appears to have been done with the invention for many years; in fact, the first pump of which records and tests are available was constructed in 1887 by the firm of Mather & Platt for the engineering laboratory of the Owens College, Manchester. This pump, shown in cross and longitudinal section in Fig. 2, had four impellers in series and gave at 1500 revolutions per minute a total head of 148 feet or 37 feet per chamber. The average efficiency recorded in the tests made by Prof. Reynolds was 58.5 per cent, a high result, in proportion to its small size, for a pump made twenty-five years ago. The readings were taken from a dynamometer fixed between the pump and the belt-pulley, and, as no method of damping the indicating finger seems to have been employed, they may be liable to some error. Thus the maximum efficiency obtained, *viz.*, 70 per cent, appears open to some doubt. The guide-vanes, after leaving the wheel in a curve, reached the inner periphery of the outer shell of the chamber at an angle. The water having had its velocity of whirl converted into pressure-head in these passages, had then to pass sideways at right angles into radial-return passages formed in the back portion of the chamber and marked *A* in Fig. 2. In these passages the water was guided and prevented from rotating by radial vanes. The water on reaching the center passed into the eye of the second impeller, and so on until it was finally delivered at the pump outlet at the head pressure required. It will be observed that the impeller was of the open type with radial vanes.

The tests of Prof. Reynolds proved the capability of the pump to perform many duties, previously thought impossible by centrifugal pumps, and in 1893 the firm of Mather & Platt took up its commercial manufacture. The mechanical construction of a standard Mather-Reynolds pump as built in 1895 is illustrated in longitudinal section in Fig. 3. The impeller and guide-passages are also shown in Fig. 4. The pump consists of four chambers working in series. At one end, these are secured by bolts against the circular flange of a frame carrying the driving pulley or shaft coupling, this having the suction branch and entrance to the first chamber cast with it. At the other end the delivery chamber forms the final cover, and has the delivery pipe cast on the upper part connecting to the annular space into which the last set of guide-passages deliver, and at this end a suitable stay is attached to support the pump from the floor. The chambers are secured to each other by bolts through external flanges, each chamber being recessed and spigoted so as to preserve the correct alignment of the whole. This forms an inexpensive design, and permits of accurate manufacture. It allows of

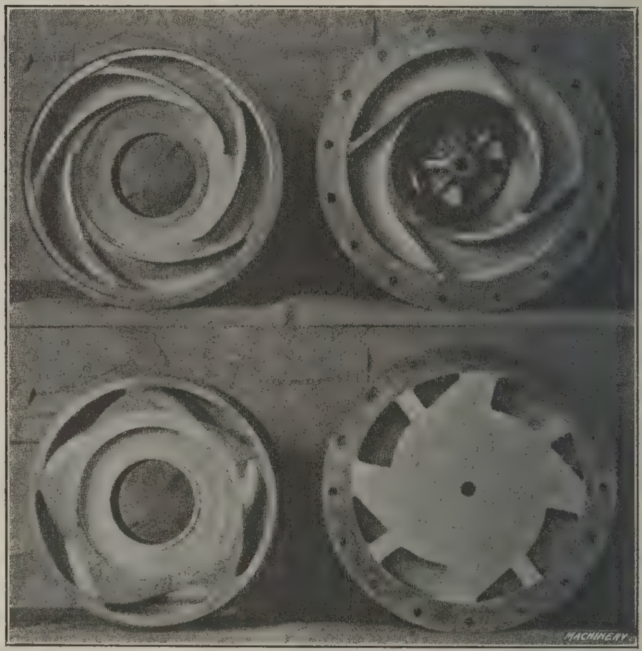

Fig. 5. Comparison between Guide-vanes in Pump of 1895 and Modern Pump

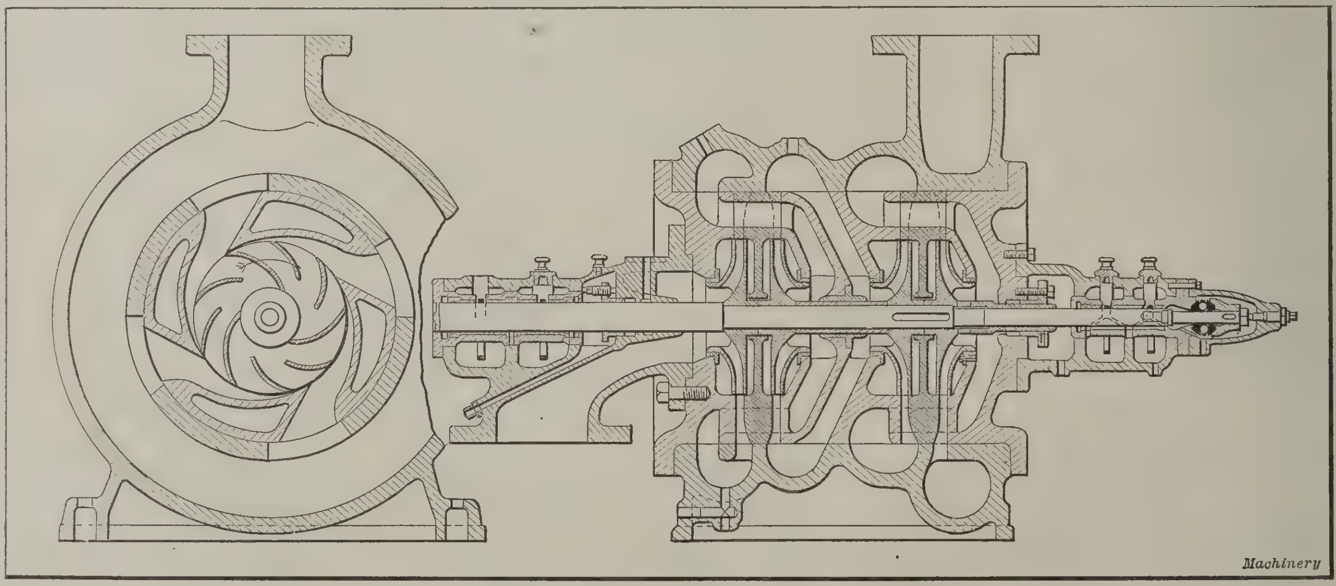

Fig. 6. Four-chamber High-lift Centrifugal Pump of Sulzer's Design

chambers being added or subtracted for higher or lower heads. Each chamber is distinct in itself, and has on one side the guide-vanes, receiving the discharge from the impeller, and on the other the return passage to the eye of the next impeller. This return passage is walled by a diaphragm integral with the casting. The water leaving the impeller, guided by the

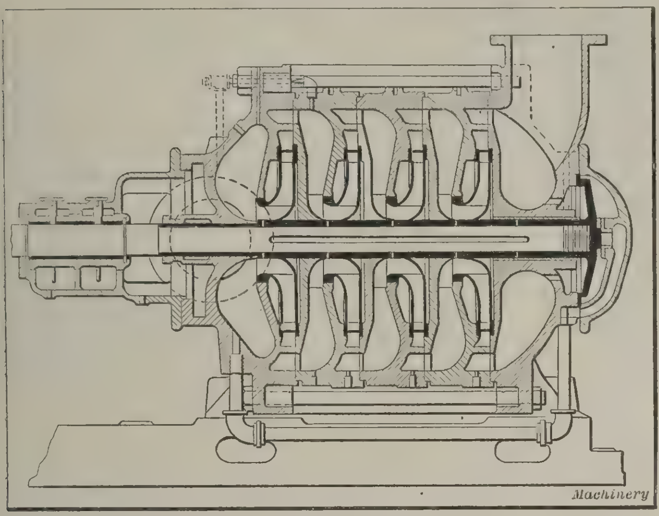

Fig. 7. Modern Four-chamber Pump

delivery vanes, passes to the next chamber and is there guided to the eye of the following impeller.

In comparing such a pump with a modern one (see Fig. 5) it will be found that it is in the form of its impeller and its delivery-casing that the original Mather-Reynolds pump differed most from the present design. The impeller, as shown in Fig. 4, is of the open type (not shrouded), with radial vanes, the roots of which are carried across the openings of the eye into the boss, necessitating the use of a modified form of Francis entrance. This form was probably adopted in order to secure sufficient strength to drive the vanes, necessitating their being carried through full width to the boss on the pump-shaft, and not starting level with the outer diameter of the eye as now. The impeller was turned all over, and revolved a close fit in its casing, which was turned to a corresponding form. This prevented leakage and loss of efficiency by the return of the water from the tip to the suction along the impeller sides.

In the 1895 pumps the speeds of the water through the impeller and passages were comparatively low, and large areas were therefore necessary. Each wheel being of the open type was nearly balanced as to end-thrust in itself, and so with the moderate heads pumped against, troubles with lateral end-thrust were not experienced. There is no doubt, however, that end-thrust did occur, and this caused the impellers to rub on the sides of their casings with consequent friction, the wear causing leakage and loss of efficiency, the varying conditions of which make the true comparison of various tests difficult. This, however, did not cause any serious trouble in practice on account of the large areas on which the end-thrust was taken, and the low head per chamber.

Considering the guide-vanes, it will be seen that in the 1895 pump these are shorter, or rather open out more quickly than in a modern pump. (See Fig. 5.) They are obviously less efficient if judged from the analogy of a Venturi tube, which must have a certain length if serious loss is not to be occasioned by converting velocity into pressure.

A considerable number of pumps of the 1895 form were constructed for installations in this country and abroad. Meanwhile Messrs. Sulzer Bros., of Winterthur, had commenced the manufacture of multiple turbine-pumps about 1896, and had evolved various modifications in the Osborne Reynolds design, whereby both the efficiency and the lifting capacity were considerably improved. They had established in 1898

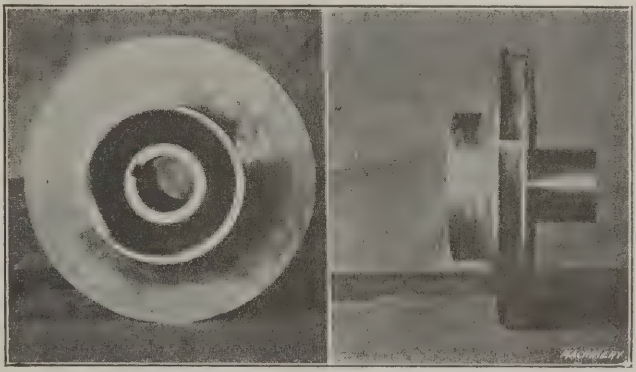

Fig. 8. Impeller of Pump in Fig. 7

an interesting and novel installation of these improved pumps at the Spanish mines of Horcajo, which attracted considerable attention. Two years later an agreement was concluded between Messrs. Sulzer Bros. and Messrs. Mather & Platt, providing for an interchange of future improvements.

A four-chamber pump of the Sulzer design is shown in longitudinal and cross sections in Fig. 6. Comparing this with the 1895 design, three important differences are noticeable. Firstly, the body casting of the pump is constructed in one piece, with the intermediate pieces, guide-vanes, and impellers put in from one end. Secondly, the impellers are shrouded and have backward-curved vanes. Thirdly, the impellers are arranged back to back to compensate for the increased lateral end-pressure set up by the higher heads worked against. This arrangement of the impellers involved the use of somewhat tortuous pas-

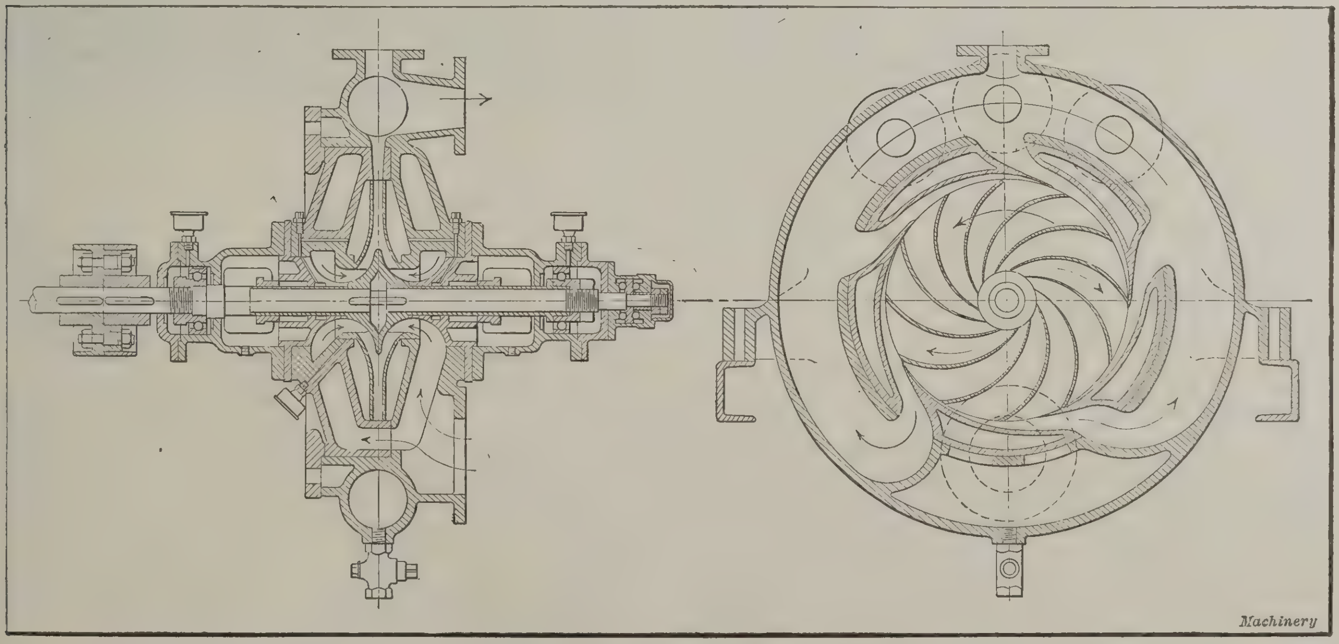

Fig. 9. Single-chamber High-lift Turbine-pump

sages in the pump to bring the discharge of the first impeller to the eye of the second, and so on. Moreover, these passages passing several joints increased the probability of internal leakage from one stage to another. The agreement between Sulzer Bros. and Mather & Platt came to an end by mutual consent in 1904, and after that date each firm further developed their pumps on their own lines.

Proceeding now to the discussion of later designs, a four-chamber pump is shown in longitudinal section in Fig. 7, its guide-vanes being shown in Fig. 5, to the left in the lower view, and its impeller in Fig. 8. It will be seen that constructionally this pump differs principally in that the extended suction-end is shortened, and is similar to the delivery-end. This enables various classes of drives—motor, belt, or steam-turbine—to be better negotiated with a standard pattern. Successive chambers, instead of being secured to their neighbors by bolts and flanges, are held together by long bolts extending the entire length of the pump body and held only at the two ends (suction and delivery).

The impeller is of the shrouded type, having vanes bent well backwards and the guide-passages are longer and more correctly divergent, while the return-way to the eye of the next impeller is of a curved form and more in line and continuous with the receptive ports, thus preventing the abrupt right-angle turn through the casing obtaining in the Reynolds pump. The losses in the Reynolds impeller through side friction in its casing are obviated, and any leakage from the periphery back to the suction is prevented or greatly minimized by the outer circumference of the impeller eye running in neck bushes with a very small radial clearance, amounting to less than 0.005 inch. The importance of preventing this leakage is very great if high efficiency is to be secured. The impeller is turned all over on the outside, to reduce loss by skin friction, and with the same object it is usual to use as many wheels as the circumstances will otherwise allow.

An interesting application of the turbine-pump for fire-prevention purposes, as fitted to petrol automobile fire engines, is shown in Fig. 9. The capacity varies usually from 350 to 1000 gallons per minute, against a head of 250 to 300 feet. The pump has a single chamber and is designed to fit on the back part of the chassis of an automobile, and to be driven by an extended shaft from the engine. The regularity of the flow of water delivered renders the holding of the hose-jets much easier and the action of the turbine-pump allows the shutting off of any particular jet, or of all the jets, without any tendency to burst the hose-pipes, as may be the case with a reciprocating pump. Further, the pump is much lighter than a corresponding pump of reciprocating type, and takes up considerably less space. The difficulties incident to starting with a heavy suction can be met by the provision of a small auxiliary pump which exhausts the suction pipe, thus causing the water to fill the turbine-pump. As soon as the turbine-pump has developed its head pressure, the auxiliary pump can be put out of action, and the turbine-pump will continue to work with suction lifts up to at least 80 per cent of the height of the barometric water column.

"PRESSURE OF COAL ON STORAGE BIN WALLS"—CORRECTION

The formulas for the pressure of anthracite and bituminous coal given in the February number on page 432, engineering edition, second column, should read as follows:

$$P = \frac{w \times 1.454\, h^2}{2} \tan^2 31°\ 30' \text{ for anthracite coal, and}$$

$$P = \frac{w \times 1.574\, h^2}{2} \tan^2 27°\ 30' \text{ for bituminous coal in which}$$

form they agree with the formula

$$P = \frac{wh^2}{2} \tan^2 \alpha$$

The third and concluding installment of "The Forms of Lathe Beds," by Mr. Joseph G. Horner, will appear in the April number.

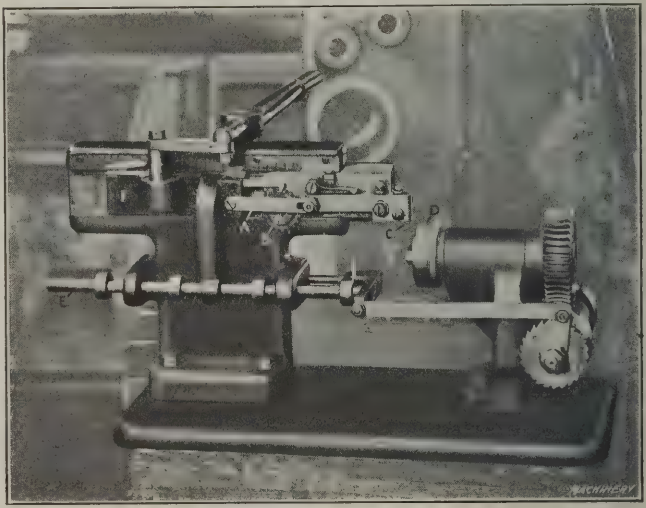
CLEVELAND GRADUATING MACHINE

The halftone shows a simple and effective graduating machine made by the Cleveland Machine Tool Works, Cleveland, Ohio, and used in the manufacture of the Cleveland horizontal boring machines, to graduate the collars of feed and adjusting screws.

The machine comprises a work spindle (at the right in the illustration) driven by a worm and worm-wheel, the collar to be graduated showing at *D;* and a slide at the left which is in two parts, consisting of the part *F* and the tool-slide proper on which the marking tool is mounted. Both slides work in the same guides. The slide *F* is worked by the hand lever at the top, and *F* has an arm projecting downward loosely fitting the horizontal rod *E* on which are four collars. The outer collars limit the travel of the slide, and the position of the middle pair of collars determines the swing of the ratchet indexing lever on the end of the worm.

The form of graduation most used is markings in groups of five, every fifth graduation being denoted by a longer line than those indicating the intermediate graduations. The means by which the variation in length of lines is effected constitute the chief novelty of the machine.

The tool that cuts the lines is fixed just at the left of *C* in the tool-holder. In advance of the cutting tool at *C* is an adjustable hardened stop which limits the depth of the line. This stop is pressed against the collar to be graduated, by the flat spring seen above, so that any irregularities in the work



Cleveland Graduating Machine

do not affect the depth of the line. As stated before, the tool-holder is mounted on a slide moving between the same guides as the slide *F*. It is connected to *F* by the link *A* which is slotted at the right end. Behind the link is a ratchet wheel *B* having every fifth tooth longer than the intermediate teeth. This wheel is mounted on the slide carrying the tool-holder, and is turned one tooth at each stroke of the operating handle by the pawl shown above it. The tool-slide is pushed to the right by a pin in *F*, concealed by *A*, which strikes the end of the ratchet teeth in *B;* and it is pulled to the left by the link *A*. The lost motion or dwell of the slide, due to the slotted link connection, operates the ratchet. The action is as follows:

Suppose that the first four graduations are the short lines. Then the tool is pushed to the right for the minimum length of line. On the fifth stroke, however, the ratchet has turned so that the driving pin strikes on top of the long tooth, and thus the tool slide is pushed to the right an amount greater than the previous four strokes by the difference in height of the long and short ratchet teeth.

Of course the machine is not limited to a fixed order of graduations. Other graduations can be made by using ratchets to suit the required combination of long and short lines.

* * *

The output of steel from electric furnaces during 1910 amounted to almost 112,000 tons in Germany, the United States and Austria-Hungary. There are at the present time in use, or being built, not less than 118 electric furnaces of all types.

THE NEW PLANT OF THE CINCINNATI MILLING MACHINE CO.*

Some years ago, when the Cincinnati Milling Machine Co.'s business had grown beyond the capacity of the old plant, Mr. Fred A. Geier, president of the company, conceived the idea of organizing a factory colony grouped about a central power plant. Three other companies that were in need of better facilities joined at once in this project, and the outcome of the idea is the factory colony at Oakley, situated forty minutes by trolley from the business center of Cincinnati. Seven plants are now located there. In the present article the new plant of the Cincinnati Milling Machine Co., as built in this location during the last three years, will be described. In many respects this plant is one of the most remarkable factory buildings in the country. It is apparent to the observer that a great deal of thought has been expended to secure, as nearly as possible, ideal shop conditions with regard to mechanical arrangement, light, heat, ventilation and sanitation. It is no exaggeration to call these works a model plant, constructed and equipped for the highest efficiency.

General Arrangement and Character of Plant

A bird's-eye view of the entire plant is shown in Fig. 1, while Fig. 2 shows an outline plan of the buildings, indicating their relation to each other and to the railway tracks, etc. The total floor space of the whole plant is 275,000 square feet; the machine shop proper is 585 feet long, and the three-story building facing south has a length of 380 feet. A general idea of the size and arrangement of the machine shop may be obtained from the interior view Fig. 3.

Fig. 1. The New Plant of the Cincinnati Milling Machine Co., at Oakley, Cincinnati

The first section of the machine shop was erected in 1909 and 1910, and was operated in connection with the old plant until the three-story section was completed in the fall of 1911. The machine shop proper is a single-story brick and steel building, 16 feet high under the trusses, and 26 feet under the peak. A 60-foot section along the eastern side of the building is 21 feet under the trusses, and is traversed by 5-ton traveling cranes. The roof is of concrete and steel, covered with Carey roofing. It is supported by hollow cast-iron columns of small diameter, thus avoiding that sense of obstruction which is sometimes present in shops using built-up steel columns. The hollow columns also serve as downspouts. The roof trusses are provided with gusset plates to facilitate the placing of countershafts and crane-ways in either direction.

The floor is of reinforced concrete, 8 inches thick, so that individual foundations for the machines, except in the case of the largest planers, are unnecessary. The heavy concrete floor also provides for that stability in the assembling and testing departments which is essential for satisfactory working conditions. That part of the shop which is occupied by the planers has a floor 16 inches thick, to carry the weight of the smaller planers and the masses of heavy material in process of manufacture which are grouped about them. In preparing the ground for the concrete floors the sod was thoroughly removed and the surface was rolled with a 10-ton roller, after which it was leveled and rolled a second time. A covering of tar felt was then placed over the entire surface, and the concrete was placed directly on this covering. The reinforcement consists of 1/4-inch twisted bars laid at right angles with each other and spaced 12 inches apart, the bars being wired together at all intersections. This kind of floor proved so satisfactory during more than a year's use in the first part of the building that it was adopted without hesitation for the addition recently completed.

The three-story south front of the building is of reinforced concrete construction faced with brick. The first floor is a continuation of the one-story shop. The upper floors, each covering an area of 380 by 60 feet, provide quarters for the various offices and space for those departments which should preferably be separated from the main machine shop. Thus the third floor contains the general offices, and the engineering and clerical departments. This floor was selected for the offices because of the desirability of having them on the floor highest above the ground level on account of being more quiet, cleaner and better ventilated. Access to the office is by means of an elevator. The western end of the third floor contains an auditorium, having a seating capacity of 600 people, and is also provided with a kitchen and dining rooms. The floors of all the offices, as well as the floor in the main entrance to the building, are laid with ceramic tiling with a 6-inch sanitary base of green tile.

Immediately adjoining the engineering department on the east is the toolmaking department, this arrangement bringing the latter into close touch with the tool-designing department. In general, as indicated in Fig. 2, the principle of placing all related departments adjacent to each other has been adhered to, and this principle has been carried out in the offices to the same extent as in the manufacturing departments.

The second floor is devoted to stock-rooms for the finished parts, and also to the assembling of cutter grinders, and milling machine attachments. This is the only manufacturing done outside of the main machine shop floor. One portion of the second floor was also especially set aside to provide a place where the dividing heads could be assembled, as experience had shown that this precision work could be done more satisfactorily in an isolated department.

The Shop Departments

When the factory colony at Oakley was decided upon, the Cincinnati Milling Machine Co. retained seventeen acres for

* For descriptions of other of the new plants located in the Oakley factory colony, see MACHINERY, July, 1911, engineering edition, "Cincinnati-Bickford Tool Co.'s Plant at Oakley, Cincinnati"; March, 1911, engineering edition, "Interesting Tools and Methods of Cincinnati Shops—The Cincinnati Planer Co."; June, 1910, "The New Cincinnati Planer Plant," and "Opening of New Plant of Triumph Electric Co. and Triumph Ice Machine Co."

foundry and machine shop purposes. The first building erected was the foundry, which is run as a separate organization known as the Modern Foundry Co., but owned by the stockholders of the Cincinnati Milling Machine Co. This foundry has a daily melting capacity of 30 tons of iron for machine-steel castings, all of which, including the largest milling machine column castings, are made on molding machines. As shown, the foundry is located to the north of the machine shop, with which it is connected by an industrial track. A depressed railway siding connects with this industrial track over which all the raw materials enter the north end of the machine shop.

As indicated in Fig. 2, the various departments are located with relation to each other in accordance with the sequence of operations. Hence the automatic screw machines and turret lathes are placed at the extreme north end, these machines performing the first operations on bar stock and on small castings, drop forgings, etc. On one side of these departments are racks upon which are stored all the bar steel adjacent to the machines. The machine equipment, in general, is highly specialized, and many machines are especially fitted up for certain work which is never done on any machine except the one so equipped. There are also many special machines which have been designed and installed mainly to improve the quality of the work. Some extremely large bar work is done on automatic machines, the largest automatics taking bars up to 6¾ inches in diameter. Individual motor drives are largely used, the motors being mounted directly on the machines. In some cases, however, this arrangement has not been found desirable, and the motors are then mounted in the ceiling directly over the machines.

Adjoining the automatic machines are the engine lathes, arranged in four rows, the two center rows being placed close together, back to back, with an ample aisle space between each of these and the outer rows. Next to the lathe department is the grinding department, and adjacent to this are the thread milling and screw chasing machines. Here all short screw threads are milled, while long lead-screws are made on automatic thread chasing machines. Next to the thread millers are the gear cutters, the equipment including a Gleason bevel gear generator, and two special tooth-rounding machines. The latter have been designed and built by the

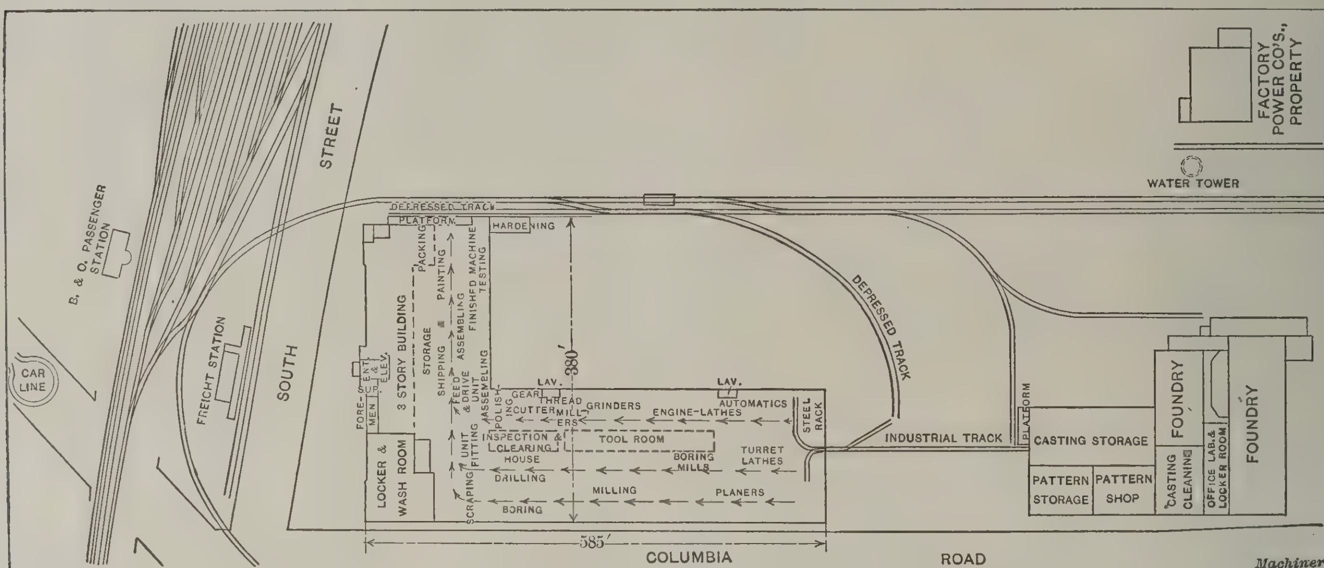


Fig. 2. General Plan of New Plant

Fig. 3. General Interior View of Machine Shop

company to meet its own special requirements. Special testing devices are provided, on which all gears are tested on fixed centers placed at the correct theoretical distance apart. The gears must show a proper bearing and must revolve freely without pinching or backlash when testing. The 20-degree pressure-angle form of tooth has been adopted because of its greater strength, and the cutters for each gear are especially developed for the correct number of teeth for that gear. The cutters are made in pairs for the two gears that work together. Proper running clearances between the gears are provided in the completed machine by arranging their final center distances a few thousandths inch farther apart than the theoretical distance.

Fig. 4. A View in the Tool-room

Tool-room—Inspection and Routing Department

The tool-room, as indicated in Fig. 2, is located as nearly as possible in the central section of the main manufacturing department, and comprises a floor space of 28 by 200 feet. A general view of this department is shown in Fig. 4. All jigs, tools, and fixtures, except some very large ones, are kept in this department, and may be withdrawn only on the presentation of workmen's checks and a shop order, the latter showing the part number and the operation for which the jig is wanted. A carefully planned system is used for taking care of the tools, and an arrangement is introduced which economizes space and gives easy access to all the shelves on which the tools are stored. This tool-room is distinctly a storage and distributing room, no toolmaking or repairing being done here, except that all cutting tools are sharpened here immediately upon their return from the manufacturing departments, and before being again placed on the shelves. Every tool, jig and fixture is inspected after having been used, and, if in need of repairs, is sent immediately to the toolmaking department. Because of the large size of this tool-room, there are three windows, one of which serves the drilling, fitting, and gear-cutting departments, one, the screw-cutting, grinding and engine lathe departments, and the third, the turret lathe, milling and planing departments.

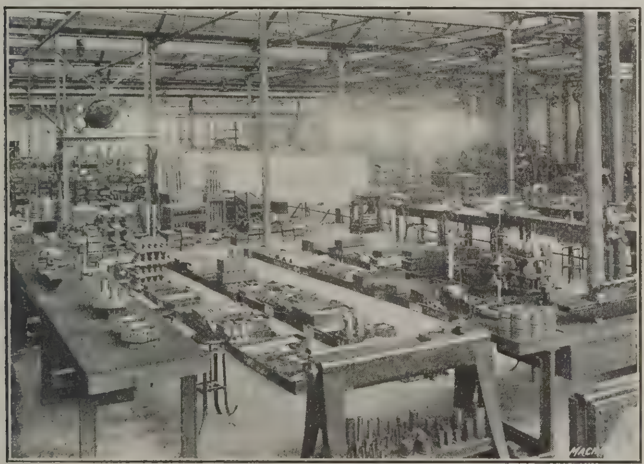

Fig. 5. Inspection and Routing Department

Immediately adjacent to the tool-room is the inspection department shown in Fig. 5. Here all the parts are inspected after each machining operation, the necessary gages, indicators, etc., being conveniently provided. All hardened gears, clutches and similar parts are tested with the scleroscope, definite standards of hardness having been determined upon for each part. The routing department is also located here. The large charts shown in the center of Fig. 5 contain a record of every piece passing through the shop, indicating which department it is in and, therefore, which operation is being performed on it, and also the date when each succeeding operation must be finished. In this way absolute control is kept over the movements of every individual piece and operation.

After having passed the final inspection, the finished parts are delivered to the stock-room shown in Fig. 6, where they are placed on shelves and await withdrawal for assembling.

Fig. 6. Stock-room for Finished Parts

An accurate record of receipts, withdrawals, and balance on hand of each individual part is carefully kept on the bin-slips attached to each shelf, a number of which are shown in the illustration. As already mentioned, this stock-room occupies part of the second floor of the three-story building. It is located close to the elevator, which is immediately adjacent to the assembling department on the machine shop floor. The remainder of the second floor, as also mentioned, is devoted to the assembling of cutter-grinders and milling machine attachments. This department is illustrated in Fig. 7. In this view are also shown some of the details of construction of the concrete building. The cast-iron-lined bolt-slots in the bottoms of the girders for suspending the countershafts, and those at the tops of the columns for attaching crane runways, are of special interest.

Fig. 7. Department for Assembling Cutter Grinders and Milling Machine Attachments

Planing, Milling and Boring Departments

All the large castings when entering the north end of the building are carried by the industrial track to the planing department, Fig. 8. The planers are all driven by individual motors. A number of them have 40-foot beds, the largest of them being the 72-inch by 72-inch by 40-foot planer, shown in

the background at the extreme right. The planers are all provided with a variable cutting stroke and a constant return stroke of 100 feet per minute. After leaving the planer department, the castings pass on to the drilling, milling and boring departments, as required.

A section of the milling department is shown in Fig. 9. The machines are grouped according to size and with regard to the nature of the work done on them. All of the larger machines are provided with individual motor drives and are located under the traveling cranes. A row of vertical milling machines along the wall is served by jib cranes, and similarly a row of large horizontal machines placed on the other side of the main aisle are also served by jib cranes. The space between these machines is entirely clear and available for handling the work. The machines face the jib cranes to facilitate swinging the large castings onto and off the machines. The smaller machines are belt-driven and are arranged in two parallel rows, but in this case they are placed back to back instead of facing each other. The radial drills, which are chiefly employed on large castings handled by jib cranes, are shown in the center of Fig. 3, under the traveling cranes.

Fig. 8. The Planing Department

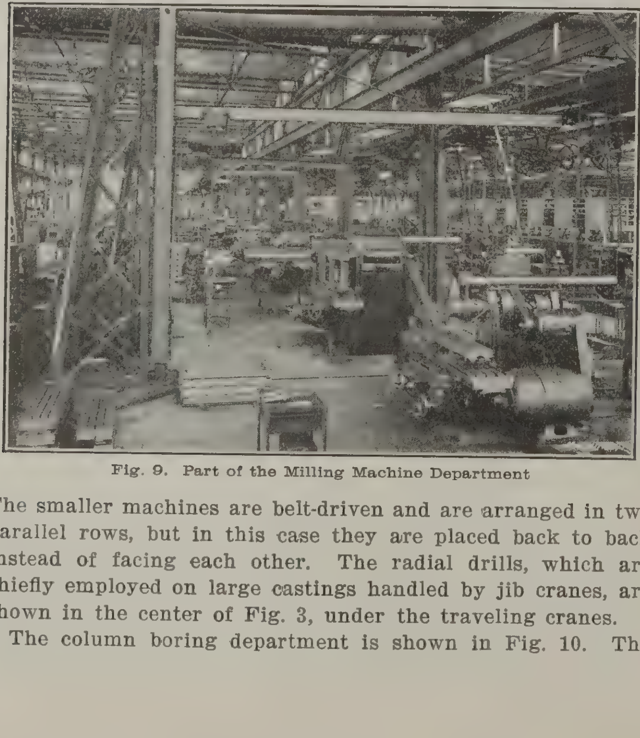

Fig. 9. Part of the Milling Machine Department

The column boring department is shown in Fig. 10. The faces of the columns are first rough scraped, and then the columns are placed in a specially designed machine which bores the spindle hole and the supporting or over-arm hole simultaneously. This machine is shown in the center of the illustration. The boring bars are in a vertical position. They may be operated simultaneously or independently, and either for boring or facing. The correct distance between the holes and their parallelism is taken care of entirely by the guides of the boring bars. The guides for the outer bar are removable and are provided in proper sizes for each size of column. The holding device on the bed of the machine locates the column central with the boring bars, which are connected with the driving spindles by a bayonet lock, facilitating quick and easy release, and providing sufficient play to allow the bars to revolve freely, regardless of the lack of alignment with the driving spindles.

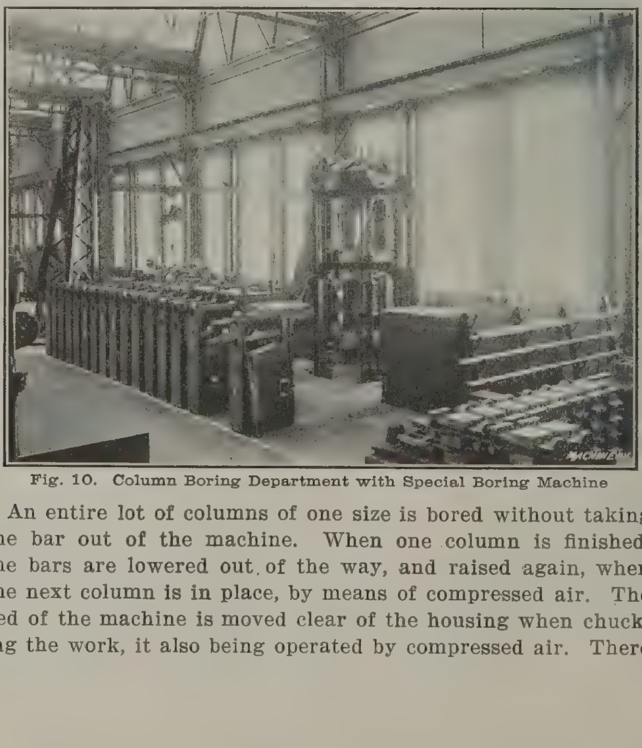

Fig. 10. Column Boring Department with Special Boring Machine

An entire lot of columns of one size is bored without taking the bar out of the machine. When one column is finished, the bars are lowered out of the way, and raised again, when the next column is in place, by means of compressed air. The bed of the machine is moved clear of the housing when chucking the work, it also being operated by compressed air. There

are two sets of operating levers, and the operator is provided with an elevator, the framework of which is shown in the front of the machine, for changing his position readily.

The chief consideration which led to the building of this machine was to obtain the highest possible accuracy rather than quantity of output. After the columns have been bored they are tested for accuracy by an inspector located in this department. The column in the foreground shows a testing instrument in place for examining the accuracy of the spindle holes with regard to their being at right angles with the

Fig. 11. Department for Assembling and Testing Feed and Drive Boxes

column face in both the vertical and horizontal direction. Further tests are made for parallelism, diameter, distance between over-arm and spindle holes, etc. A record of these tests accompanies each column to the fitting department. This inspection does not take the place of the final accuracy test to which the finished machine is afterwards subjected.

Scraping and Assembling

The large machine parts, such as columns, saddles, etc., next arrive at the scraping department shown in the foreground of Fig. 3. All the scraping is done to surface plates and master

Fig. 12. A Corner of the Department for Assembling Dividing Heads

gages. In this department there are a number of interesting devices, as, for example, a swiveling arrangement for holding the tables for the scraping operation, enabling the workman to always bring the surface worked upon into a horizontal position. Another interesting device is the so-called "scraping machine" at the left of Fig. 3, between the first two jib cranes. This is a hydraulic cylinder fitted with reversing valves which give the piston a continuous reciprocating movement. This device is used for sliding large parts on each other, to determine the accuracy of their bearings. The device is arranged to swivel, and it may be elevated by hydraulic means to suit the height of the different parts. The column scraping is done under the framework at the right of the picture, the framework forming a number of parallel runways for hoists.

Fig. 3 also shows the extent to which crane service and hoists are provided. The main traversing cranes are of five-ton capacity with 60-foot span. These cranes serve all the planers at the far end of the building and transport material from one department to the other. The individual machines, other than the planers, are served by self-contained jib cranes. The steel work of the jib crane is fastened to and supported by a large cast-iron base. The mast rests on a ball thrust bearing, consisting of a single ball of large diameter. These cranes are not a permanent part of the building, but are bolted to the floor and can be placed in some other part of the shop at any time that it may be desirable to do so.

The assembling department for feed and drive boxes is shown in Fig. 11. In the foreground is shown the testing stands on which each feed box and each drive box is given a running and endurance test under conditions which duplicate those under which it will operate when placed on the machine. In the immediate foreground is shown the driving clutch pulley testing stand on which the units entering into the single-pulley high-power machines are given a running and load test. This stand is provided with a prony brake and an ammeter which indicates the load applied under each test.

Fig. 13. The Hardening Room

Fig. 12 shows a corner of the dividing-head department. As already mentioned this department is purposely isolated, because of the precision work required. On completion, each dividing head is subjected to the most rigid accuracy tests, and a copy of each test is filed. The dividing-head worm-wheels are hobbed on a machine especially designed for this one operation. The worm-wheels hobbed in this machine will index work 8 inches in diameter with an average accuracy of 0.00025 inch of accumulative error in any one quarter of the circumference.

Fig. 14. The Toolmaking Department

The carbonizing and hardening department is shown in Fig. 13. In addition to the clutches and other small parts, a large number of the gears entering into the milling machines manufactured are hardened. The hardening department is equipped with gas furnaces and lead baths. Temperatures are determined by a pyrometer mounted on a track over the furnaces. The pressure blower is motor-driven, and a gas engine is also installed for emergency service, so as to provide for the necessary continuous carbonizing. Two oil tanks immersed in running water are placed in the floor. They are provided with steel covers for closing them when not in use.

Since the toolmaking department does not make any part

used in the products of the shop, there would be no advantage in having it located with the manufacturing departments. On the other hand, there is an advantage in having it located by itself, and, therefore, it has been placed on the third floor so as to be close to the tool-designing and engineering departments. This department, a view of which is shown in Fig. 14, is equipped with all the machine tools necessary for toolmaking, including a cylindrical grinder, an internal grinder, and a surface grinder, so that there will be no need to call on any of the manufacturing departments for assistance, except in the case of an unusually large planer job for a heavy fixture. No shapers are employed, all the work of a character for which shapers could be used being done on milling machines.

Fig. 15. Department for Testing the Completed Machines

As the new model milling machines built by the company are constructed entirely according to the unit system, the final assembling consists merely in assembling such units as feed boxes, drive boxes, driving clutch pulleys, etc., into one complete machine. After the machines have been assembled by successive groups of men, each attaching one class of units, they arrive at the final testing department shown in Fig. 15. Here each machine is given a thorough test for accuracy of alignment, and a running test under belt for a specified length of time. Each machine must also do a specified amount of milling. A permanent record is kept of all these tests.

Adjacent to the testing department are the shipping and

Fig. 16. The Packing Department

packing departments, the latter of which is shown in Fig. 16. There are two shipping doors leading to the shipping platform. The one in the center of the illustration is provided with a vestibule for the protection of this part of the shop during severe weather. They are closed by steel drop doors and are entirely surrounded by circulation pipes of the hot water heating system. The railway cars come up to the shipping platform on a depressed track so that the floors of the cars are level with the platform. Three cars may be loaded at one time.

Washrooms, Sanitation, etc.

The employes' entrance on the Columbia road side (see Fig. 2) leads directly into the service room where ventilated steel individual lockers are provided for all the men. The wash basins are of the individual type with hot and cold water, and there is one basin for every three men. Hot water for this room and for the shower baths is obtained from instantaneous heaters, one of which is shown in Fig. 17.

The sanitary arrangements are of the very best. The toilet rooms are marble lined, and all metal work is nickel-plated, these materials having been selected in order to keep everything in a sanitary condition. The shower baths for the use of the employes are also built of marble, each compartment being divided into two sections, with a bath in the rear and a dressing room in the front. Sanitary drinking fountains are provided at intervals throughout the shop.

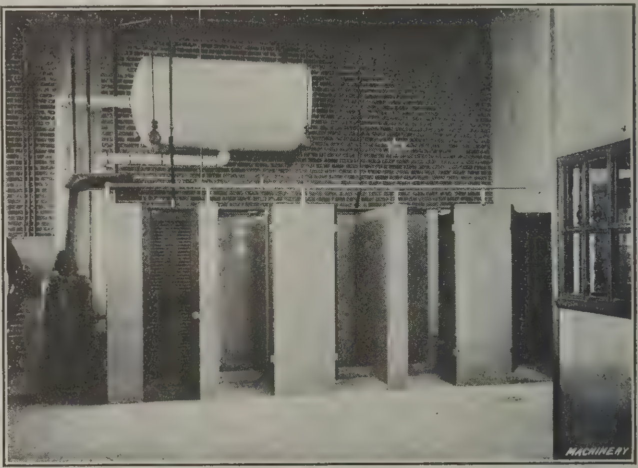

Fig. 17. The Shower Baths

The manufacturing departments are lighted by Cooper-Hewitt lamps which furnish sufficient illumination for all purposes without the use of individual lights, with the exception of a few special cases. The offices and engineering departments are lighted by the indirect system using tungsten lamps in clusters. This soft, diffused and evenly distributed light has proved as satisfactory as good daylight. The buildings are heated by the Evans-Almirall system of forced circulation hot water. In the single-story part of the building, the circulation pipes are placed on the lower chord of the trusses, immediately below the window space, as indicated in Fig. 16. This arrangement prevents drafts caused by descending cur-

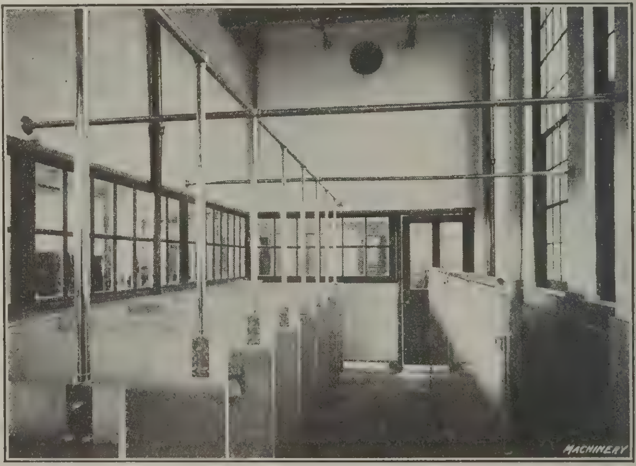

Fig. 18. One of the Marble-lined Toilet Rooms

rents of cold air from the roof windows, and has proved satisfactory during the extreme cold of the present winter. The provisions for ventilation have also proved sufficient during the extremely hot weather of the past summer. The arrangement of the roof windows permits the opening of the entire upper one-third of the sash, providing for 60 square feet of opening for each 500 square feet of floor space, the liberality of which is evident when compared with the usual arrangement of one 48-inch ventilator for every 100-foot length of roof, providing only 12 square feet of opening for each 2500 feet of floor space. The sash opening devices are operated from the floor, and in some cases as much as 100-foot lengths of sash are controlled from a single point.

APPLICATIONS FOR PNEUMATIC TOOLS

By A. M. M.

There are many classes of work now done by hand to which pneumatic tools can be applied with advantage. Many plants have developed special uses for these tools, a few of which are here presented.

A contractor engaged in erecting large electric generators had several thousand tubular rivets, 1½ inch in diameter, which were to be headed cold. This was a very slow and laborious job. The rivets were used to hold together the laminations of the stator, and were drilled at the ends to make them tubular and to facilitate heading. By means of a beading tool and a hand-hammer, they could be riveted up in the same manner that boiler tubes are beaded, but it was found that not more than two per hour could be headed by hand. After considerable experimenting a 9-inch pneumatic riveter was fitted with a special die for the work, and the time was reduced to five minutes per head, with less fatigue to the operator.

Fig. 1, showing the die and rivet end, illustrates the idea. A common riveting die was turned to fit the finished head, leaving a centering pin in the middle of the die. Two opposite sides of the die were then slabbed off on a milling machine, leaving the working edge about ⅜ inch thick. This edge was filed round, and the die hardened. A hole drilled through the die provided means for attaching a piece of ⅜-inch round steel wire as shown. This served as a handle to rotate the die. The operator could form a perfect head on the bolt by slowly rotating the die, and working down the edges as desired.

Hardening Riveting Dies

Many concerns have trouble with the breaking of riveting dies. One large company using about thirty riveters broke on an average ten dies per day. As these dies cost about $1.75 each, it will be seen that the total expense was considerable. The blacksmith hardened the dies only at the cup and shank, leaving the shoulder soft. He decided that as all the dies were breaking at the shoulder, he would leave that part as soft as possible. Many blacksmiths make the same mistake. The trouble, however, is that the tension set

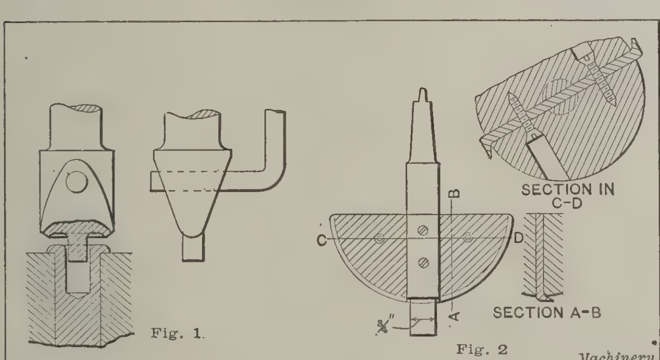

Fig. 1. A Pneumatic Beading Tool. Fig. 2. A Pneumatic Wood-cutting Tool

up by the uneven hardening causes the breakage. The following method of hardening was adopted, and the breakage fell to one die per week or less, instead of ten per day.

A die was first heated slowly and evenly to a temperature considerably higher than that required for the hardening. It was then allowed to cool for several minutes to insure that the interior of the die was as hot as the outside. It was then (at a dull red heat) quenched in oil. The blacksmith had previously prepared a ring or tube rolled up from a piece of ¾-inch plate. This tube was about 6 inches in inside diameter and 10 inches long. It was heated to a bright red heat, and the die held in the center of it to draw its temper evenly. When the right color was reached, the die was quenched in water. Dies hardened in this manner gave excellent results. A steel costing 12 cents per pound was used.

Driving Drift-bolts in Crib Work

A contractor was building crib work of hard fine timbers, 10 inches square. He had several thousand drift-bolts to drive. The bolts were 8 feet long, and 1 inch in diameter. He had several gangs of three men each working from a staging, driving with heavy sledges. The three men would drive one bolt, striking alternately. The work was progressing so slowly that he determined to try a pneumatic riveting hammer. He found that a heavy riveter, operated by one man, would do the work of two gangs (six men), and dispense with the heavy staging.

Use of Pneumatic Hammer in Broaching Operation

A machine shop had a large number of hexagon bushings whose inside surface had to be finished smooth and of accurate dimensions to make a close fit on a ¾-inch hexagon rod. A hexagon broach of the same dimensions as the rod was machined and the end squared off to a cutting edge. It was found very difficult to drive this tool through the bushing with a hand hammer, but it was easily and quickly accomplished by the rapid blows of a pneumatic hammer.

A Pneumatic Wood-cutting Tool

It often happens that wooden hatches or decks are fitted with I-bolts or handles which must lie flat with the surface.

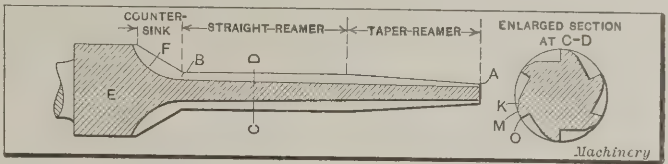

Fig. 3. Combined Reamer and Countersink

To make room for the fingers or a rope under the ring, the wood must be cut out in the form of a cup or depression. Often, on a large job, there will be several hundreds of these cups to hollow out of the flat surface. A carpenter with his gouge and mallet will take a couple of hours to finish one, but the cutter here described, fitted to a pneumatic machine, will do this work in a few minutes. The cutter blade is formed of ¼-inch tool steel plate, set into a slotted bar and brazed. After this operation is completed, a block of wood, turned in a wood lathe to the shape of the cup, is fitted to it as shown in Fig. 2. This block allows the cutter to project beyond its surface, and prevents it from taking too large a chip. The tool works best in one of the smaller machines of high speed. A ¾-inch guide hole is first bored to the required depth.

Special Reamers for Pneumatic Tools

In a plant handling structural or steel ship work, the reaming and countersinking of the thousands of rivet holes is a large item, and may represent a considerable percentage of the cost of construction. It is important that the reamer with which this work is done shall have certain properties. It must cut rapidly, without heating. It must clear itself when forced, without breaking. It must stand the abuse of unskilled labor. Two men with an ample supply of sharp correctly made reamers will ream several thousand holes per day, where they will only ream several hundred if obliged to work with reamers which do not cut properly. The following description and illustration, Fig. 3, shows how one of the large shipyards increased the efficiency of this operation several hundred per cent by giving careful attention to these points.

This yard had a million, more or less, ¾-inch rivet holes to be reamed and countersunk. The work was started with the ordinary pneumatic reamers and countersinks, making two separate operations. The tool-room, having only a small supply of these tools and having other troubles, was very "economical" in handing out reamers, and kept the men working with the tools long after they were too dull to cut properly. The consequence was that the men would keep a reamer turning in one hole for several minutes, and not only did it not work, but the reamers were burned. The men made no attempt to rush the work as this only resulted in burned reamers and a "call-down" from the tool-room.

The following system was adopted with an increase of about 500 per cent in the amount of work turned out. A special combination reamer and countersink was designed as shown in Fig. 3. Enough of these tools were provided to allow about four reamers per gang. The gangs were put on piecework

and one skilled operator in the tool-room was made responsible for keeping the reamers sharp. Each gang was given a can of tallow in which to lubricate the reamer as often as required. The gangs working on the flat decks were cut down to one

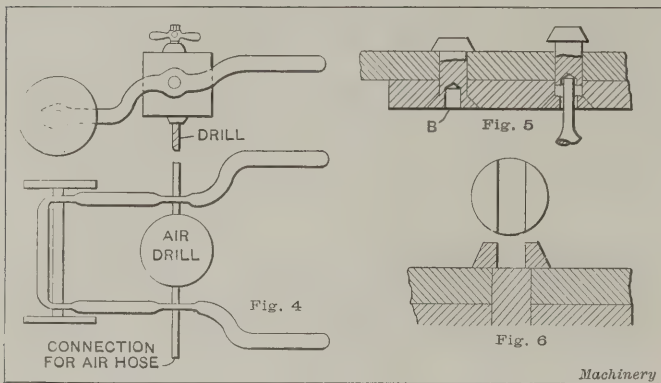

Fig. 4. A Substitute for the "Helper." Fig. 5. Method of Removing Rivets. Fig. 6. Method of Cutting-off Rivet Heads

man, and this man was provided with one of the "wheelbarrow" devices shown in Fig. 4, in place of his "helper." All extension shanks were inspected and those having damaged sockets were thrown out and replaced with new ones of tool steel with close-fitting sockets. Many of these shanks were found to be made of soft steel, and the socket which received the Morse taper shank was so cut out as to allow the reamer to jump out and turn in the socket. Many reamers were ruined by having the small ends of the shanks twisted off. All of these shanks should be carefully made of tool steel. The countersink-reamers insure that the countersink will be concentric with the reamed hole, and the whole job is done at one operation.

These reamers are turned out of solid stock ("22-cent" tool steel, box annealed) of the diameter of the countersink-portion E. In milling, a single straight cut is made from A to B, and the milling cutter is of a diameter to form the curve at F. This is not an ideal method, but it saves several resetting operations and is satisfactory in practice. Care is taken to grind off the back of the tooth to the proper angle at K. A cutting edge must be made with the clearance from M to O less than at K, and is the only portion ground in resharpening.

Easy Way of Cutting out Rivets

An easy way of cutting out rivets is as follows: First drill a hole as shown in Fig. 5 at B. Then use a backing-out punch made to fit a pneumatic riveting hammer. If a good backing is available, a pneumatic "jam hammer" can be used to advantage. For cutting off rivet heads proceed as in Fig. 6, using a pneumatic chipping hammer and "cape" chisel. First cut a slot through the head, making it like a slotted screw-head. The two sides can now be cut off without trouble.

* * *

Just so much of forms, rules and regulations as will insure that the right thing will be done in the right manner at the right time, is system. Whatever is more than that is red tape.

MAGAZINE ATTACHMENTS—2

APPLICATION TO THE BROWN & SHARPE AUTOMATIC SCREW MACHINES

By DOUGLAS T. HAMILTON*

Small pieces which have been partly completed in the punch press can be handled satisfactorily in a Brown & Sharpe automatic screw machine by the application of a magazine attachment. The type of attachment to use depends entirely on the shape and character of the work. In the February number, a few of the more simple attachments were illustrated and described. In this article is given a description of three attachments and their auxiliary mechanisms for handling parts blanked out in the punch press. Reference is made to Figs. 5 and 9, which appeared in the February number.

A Snake-shaped Attachment

Fig. 11 illustrates a snake-shaped slide which is used for handling the watch crowns shown at N and O in Fig. 9. The sectional views of this slide show the shape of the different crowns for which this attachment is used. Of course special slides were made for each different size. The slide shown in Fig. 11 is held in a bracket similar in construction to that shown at A in Fig. 12. The watch crowns are made from sheet metal, which is drawn up and formed around a solid

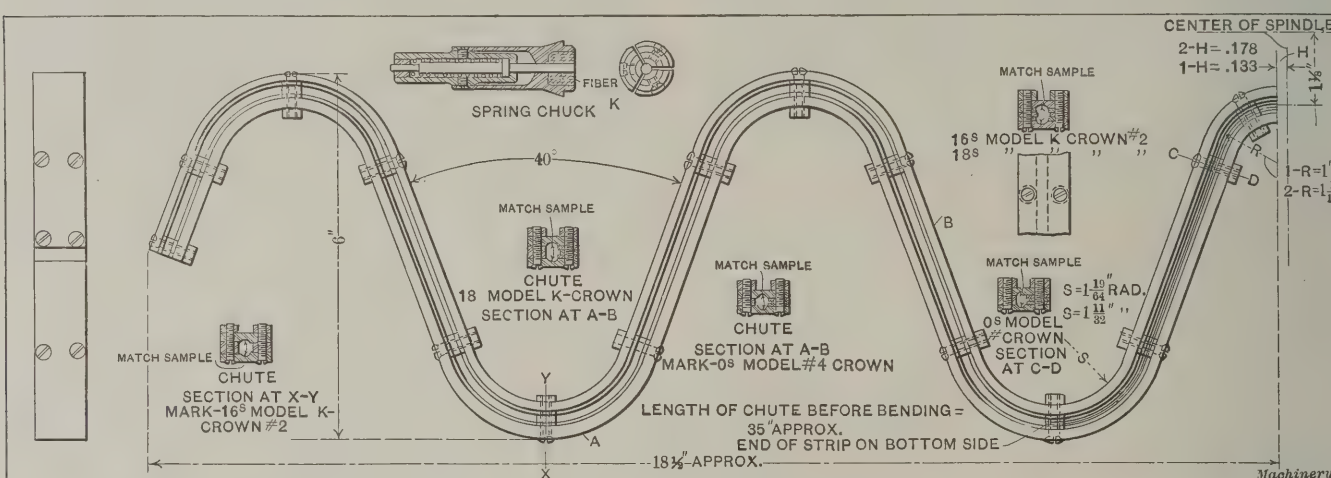

Fig. 11. Magazine Attachment for Handling Watch Crowns

center in the punch press. The knurling on the crown is also produced when it is being formed. The reason for making a crown in this manner is that it can be made from "rolled plate," the name given to a class of material used in

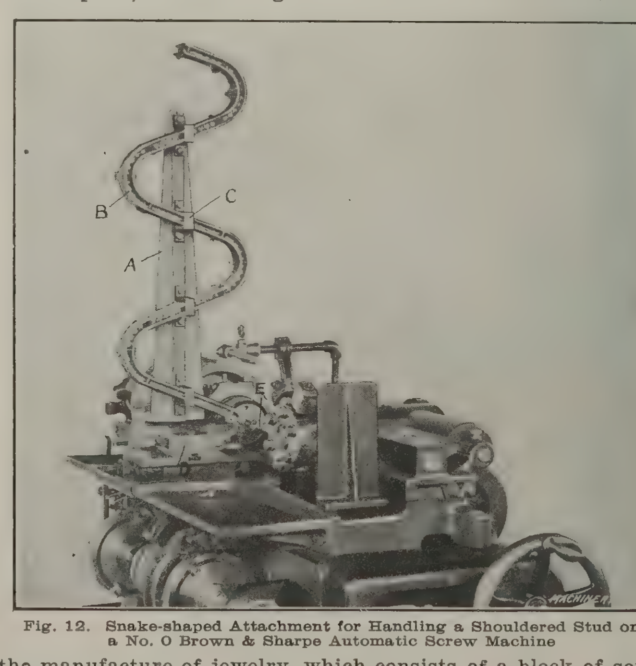

Fig. 12. Snake-shaped Attachment for Handling a Shouldered Stud on a No. 0 Brown & Sharpe Automatic Screw Machine

the manufacture of jewelry, which consists of a block of some composition, such as brass, to one side of which is soldered a thin sheet of gold; this block is then rolled out into sheets

* Associate Editor of MACHINERY.

of the desired thickness and cut up and formed in a punch press. This facilitates the production of an article which is much harder than gold, will not corrode, and wears well.

Referring to Fig. 11, this slide consists of two strips *A* and *B* held together by screws and separated by blocks. The strips are milled out to suit the work which is to be placed between them. There are two reasons for having the slide of this attachment made in this manner: First, being bent into the shape shown, it will hold a greater number of pieces in

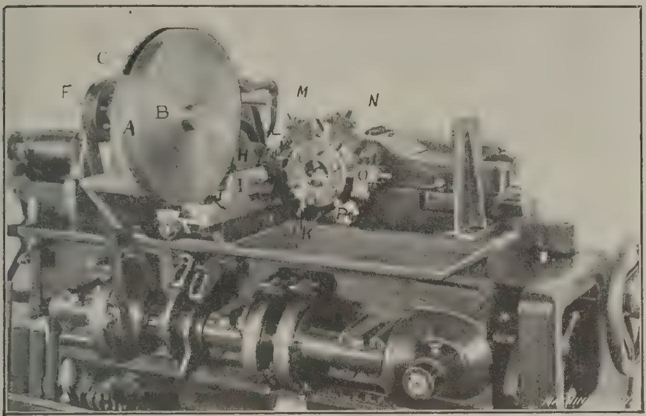

Fig. 13. Semi-automatic Magazine Attachment for Handling Blanks for Watch-spring Barrels on a No. 0 Brown & Sharpe Automatic Screw Machine

the same height, thus making it more accessible to the operator; second, it gives a practically vertical slide at the curved point, which assists in feeding the work to the machine. The work is carried from the slide to the machine by a carrier, a description of which will be given later. The chuck for holding these crowns is shown at *K* in Fig. 11; it consists of an ordinary spring collet, bored out in the front end to receive a fiber "bushing" which is cupped out to suit the crown. This fiber bushing allows the knurling on the crown to sink into it, thus holding it securely while being counterbored, drilled and tapped. Except for the addition of the fiber bushing this spring collet is similar to those previously described, being provided with a spring ejector.

In Fig. 12 is shown another snake-shaped attachment, which is used for handling a collar stud. The slide *B* is fastened to the bracket *A* by U-shaped braces *C*. The work is carried from the slide to the chuck by means of a carrier *D*, similar in construction to that shown in Fig. 5. The spring collet used for holding this piece is similar in construction to those previously shown, and the work is inserted by a spring plunger *E* held in the turret. Attachments of this type are bent to an included angle of 40 degrees, which has been found to give the best results for feeding the parts to the chuck.

Semi-automatic Magazine Attachment

The magazine attachment shown in Fig. 13 is used for feeding the blanks from which the barrels for watch springs are made, to the chuck. A watch spring barrel which has been completely machined is shown at *P* in Fig. 9, and also at *A* in Fig. 18. The teeth are cut on this barrel in an automatic gear cutter. This magazine attachment, which is fastened to the bracket on the No. 0 Brown & Sharpe automatic screw machine, consists of a rotating wheel held on a spindle and enclosed in the casing *A*.

The construction of this attachment is more clearly shown in Fig. 14, to which reference should now be made. The wheel *B* is recessed to form a pocket or magazine for the blanks, and is provided with slots in which the blanks fit. The blanks are inserted in the attachment through the slot *C*, which passes down into the pocket *D* of the rotating wheel. The wheel is driven from a pulley *E*, located on the front cam-shaft (see Fig. 13) by a belt running on the pulley *F* keyed to the wheel spindle. An idler pulley *G* is furnished to change the tension of the belt. As the pulleys *E* and *F* are of the same diameter, the wheel *B* rotates at the same speed as the front cam-shaft. The blanks, when carried around by the wheel *B*, drop into the slide *H* and from there into a pocket in the bushing held in the carrier *I*.

On account of the type of tools shown in Fig. 13, which are used in machining the spring barrel, and the shape of the carrier, it is necessary to increase the actual throw of the ordinary cross-slide, so that the carrier, when it drops back, will allow the tools in the turret to get at the work. The ordinary cross-slide is removed, and a slide *J*, which is shown more clearly in Fig. 15, is substituted. Referring to Fig. 15, it will be seen that slide *A* is provided with a dovetailed slot in its top face, in which the auxiliary slide *B* works. Attached to the machine by a shoulder screw *C*, fitting in an elongated hole in the bracket *F*, is a rack *D*, that meshes with a pinion *E* held to the lower slide *A* by a screw as shown. Pinion *E* meshes with teeth cut in the auxiliary or top slide *B*.

In operation, as the cam on the front cam-shaft advances the lower slide *A*, the pinion *E* is rotated, this action carrying forward the auxiliary slide *B*, and increasing the throw of the cross-slide. The rack *D* is formed into an L-shape in the rear end, and a set-screw, fitted into it and butting against

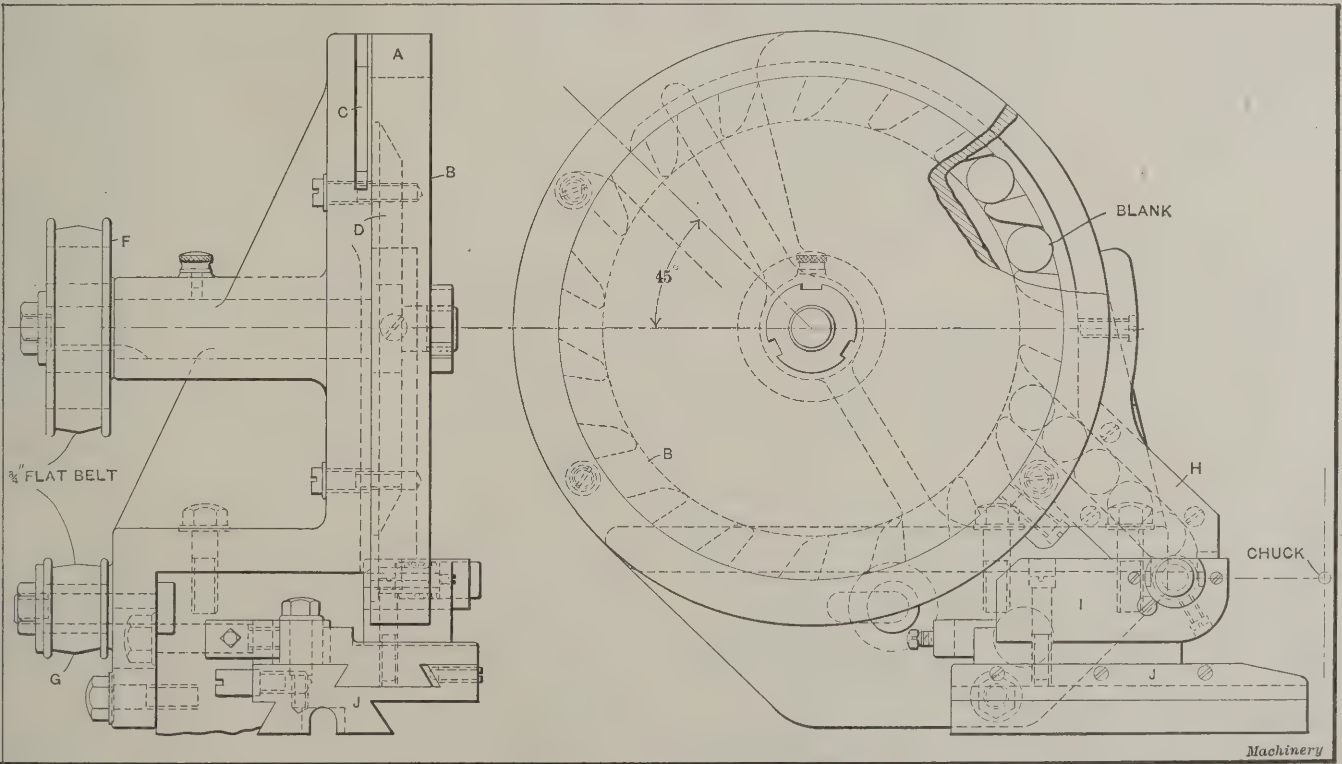

Fig. 14. Assembly Views of Magazine Attachment shown in Fig. 13

the bracket, is used for changing the position of the rack relative to the cross-slide.

The work carrier *I*, Fig. 13, which is shown more clearly in Fig. 16, consists of a block *A* counterbored to receive a bushing *B*; the bushing is also counterbored to receive a spring plunger *C* and cut out to fit the spring fingers *E*. The fingers are made from spring-tempered sheet steel, and fastened by flat-head screws to plugs *F*, which are held in drilled holes

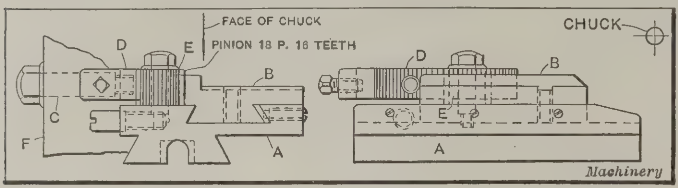

Fig. 15. Double-throw Front Cross-slide for the Magazine Attachment shown in Figs. 13 and 14

in the carrier block *A*, and retained by means of headless screws, as shown. The spring plunger *C* is retained in the bushing *B* by means of a pin driven into the bushing and fitting a terminated slot in the plunger. The bushing *B* is free to slide in the carrier block, and is held back by means of a coil spring *G* bearing against a pin driven into the bushing. The bushing is located in its "back" position by a headless screw acting as a stop for the pin which is driven into the bushing. It is also prevented from rotating by means of a screw *H* turned down on the end to fit a slot in the bushing.

In operation, as the blank comes down the slide, it is deposited in the bushing *B*. The cross-slide then advances and brings the blank in line with the hole in the chuck. When in this position the turret is advanced, and the stop *K* (see Fig. 13) pushes the spring plunger *C* forward, forcing the blank out from the fingers and depositing it in the chuck. It will

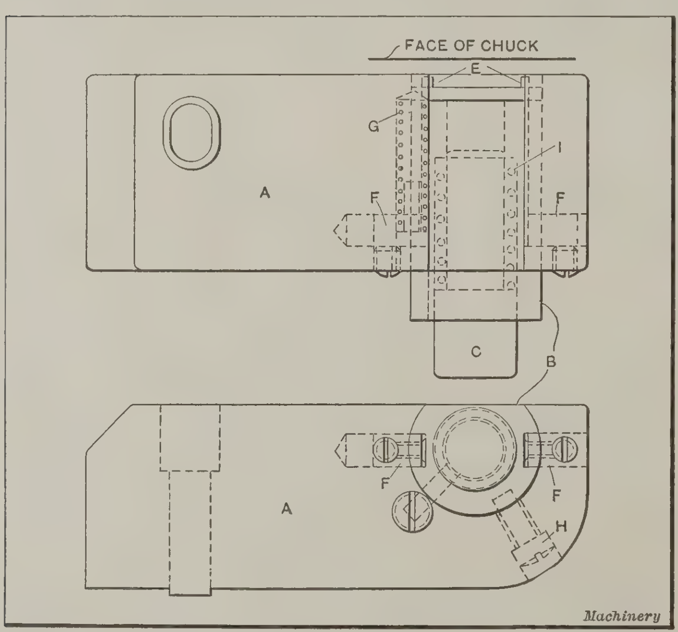

Fig. 16. Work-inserter used in Connection with the Magazine Attachment shown in Figs. 13 and 14

be noticed that the spring *I*, operating the spring plunger *C*, is made much heavier than the spring used for holding back the bushing *B*. The object of this is to insure that the bushing will be brought up close to the face of the chuck before the plunger forces the blank out of the spring fingers.

These spring barrels are difficult to hold, as can be seen by referring to Fig. 18. The part not cut down with the circular form tool is only 0.034 inch wide, which means that only about 0.025 inch can be used for gripping purposes, as it will require from 0.005 to 0.010 inch for clearance. It would be difficult to hold this blank rigidly and true in an ordinary counterbored spring chuck, owing to the fact that a recess would have to be made at the shoulder in the chuck which would reduce the gripping portion.

The manner in which these blanks are held is interesting and is clearly shown in Fig. 17. A special threaded cap *A* is made to fit over the nose of the spindle, and is provided with grooves in which a spider *B* is held to it by screws. This spider is made from tool steel, hardened and ground on both faces. The cap is also hardened and ground on the face bearing against the nose of the spindle and in the slots. The spring collet *C* projects past the face of the spider about 0.028 inch, and is cut out to fit the arms of the spider. The hole in the chuck is serrated to hold the blank more securely.

The tools used for performing the operations on this spring barrel are shown in Fig. 13, where *K* is the pusher which forces the piece out of the carrier into the chuck; *L*, a combination drill and countersink; *M*, a roughing recessing tool; *N*, a second roughing recessing tool; *O*, a finishing recessing tool; and *P*, a reamer holder. The cams used in making this blank are shown in Fig. 18 where the uses of the various lobes are clearly indicated. It might here be mentioned that the making of this spring barrel presents an unusual difficulty in

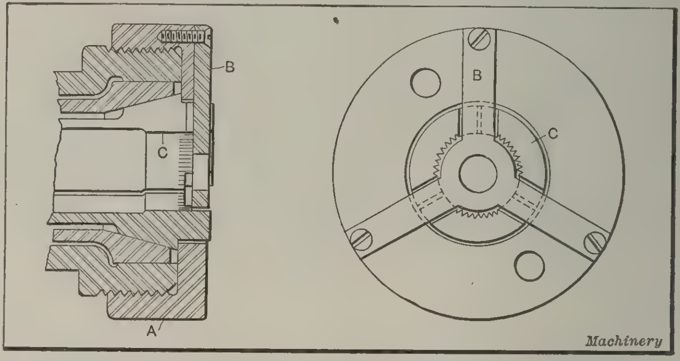

Fig. 17. Special Spring Collet used in Holding the Blank for the Watch-spring Barrel

producing a wall which will be of an even thickness and not cupped. This is accomplished by using a recessing tool for facing, instead of counterboring with a counterbore held in the turret. The application of recessing tools to work of this class was described in an article which appeared in the November, 1910, number of MACHINERY, entitled "Internal Cutting Tools." Here the proportion of the thickness of the wall to

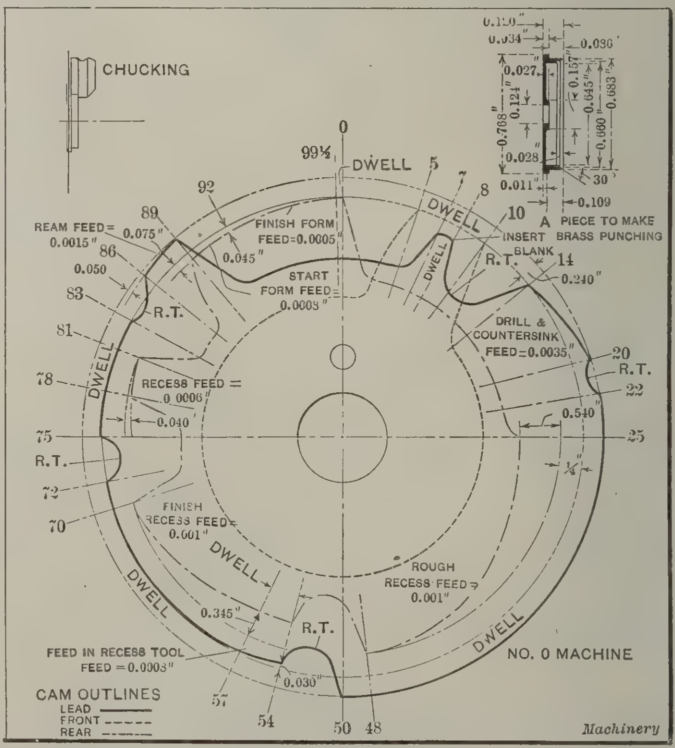

Fig. 18. Cross-slide and Turret Cams used in Producing the Watch-spring Barrel

the diameter, for facing operations, and the feeds to be used, were given.

The order of operations for piece *A*, Fig. 18, is as follows:

Order of Operations	Revolutions	Hundredths
Open chuck	24	2
Eject piece with feeding finger	30	2½
Clearance	6	½
Bring up carrier on front cross-slide	(48)	(4)
Hold carrier in line with chuck	60	5
Insert piece with inserting tool	(30)	(2½)
Dwell with inserting tool	(12)	(1)

Close chuck	(24)	(2)
Clearance	6	½
Revolve turret	42	3½
Drill and countersink, 0.240 inch rise at 0.0035 inch feed	72	6
Revolve turret	24	2
Clearance to place recessing tool in position	12	1
Advance rear cross-slide	24	2
Rough recess, 0.540 inch rise at 0.001 inch feed with L. H. swing tool	276	23
Clearance to drop back pusher on cross-slide	24	2
Revolve turret and clear	48	4
Advance recessing tool and feed in for cut 0.030 inch rise at 0.0008 inch feed	36	3
Dwell with rising block on cross-slide	(36)	(3)
Advance pusher on cross-slide, 0.345 inch rise at 0.001 inch feed	156	13
Clearance to drop back pusher on cross-slide	24	2
Revolve turret	36	3
Bring recessing tool into position	36	3
Advance pusher on cross-slide, 0.040 inch rise at 0.0006 inch feed	36	3
Clearance to drop back pusher on cross-slide	24	2
Revolve turret	36	3
Ream, 0.050 inch rise at 0.0015 inch feed	36	3
Start forming with circular tool, 0.030 inch rise at 0.0008 inch feed	36	3
Finish form, 0.045 inch rise at 0.0005 inch feed dwell 0.050	96	8
Total	1200	100

This article completes the extensive series, which have appeared in MACHINERY from June, 1909, up to the present time on the Brown & Sharpe automatic screw machines. Back numbers of MACHINERY containing all of these articles* cannot be supplied, but the complete series will be incorporated in MACHINERY's Reference Books, in the near future.

In bringing this series of articles to a close, the writer wishes to express his gratitude to the Brown & Sharpe Mfg. Co., who has very carefully gone over all manuscripts which were submitted. This company has also been very liberal in supplying us with drawings and photographs, for illustrating the machines, tools, and other equipments.

HOLDING WORK FOR GRINDING

The accompanying illustrations show three methods of holding work that are employed in the Stevens-Duryea factory in Chicopee Falls, Mass. Fig. 1 illustrates a chucking fixture for use in the bench grinding machine for holding small disks

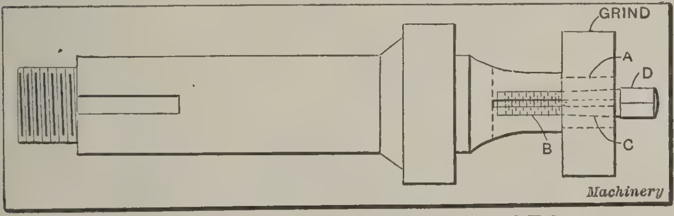

Fig. 1. Fixture for Holding Work by a Central Hole

that must be ground with their peripheries concentric with the central hole. This fixture consists of a shank that fits the spindle of the bench grinding machine. The outer end of the fixture has been turned at *A* to fit the bore of the hole of the piece to be ground. In the center of this turned portion a hole *B* is drilled and tapped. The outer end, *C*, is slightly tapered. Set-screw *D* is made with a tapered section to fit the tapered hole, and, after splitting the end of the fixture with two slots at right angles to each other, the fixture is ready for use. When the pieces that are to be ground are put in place and the set-screw *D* is tightened, the contact of the tapered section of the screw with the tapered hole within the piece to be ground, opens the fixture so that it grips the work tightly and it is certain that the grinding will be concentric with the central hole.

In Fig. 2 is illustrated another fixture for use in the bench grinding machine. The working end of this fixture consists of a part *A* recessed to accommodate the work *B*. The work is held in the fixture by means of two screws *C* and a washer *D*, after which the conical recess is ground in the edge. One

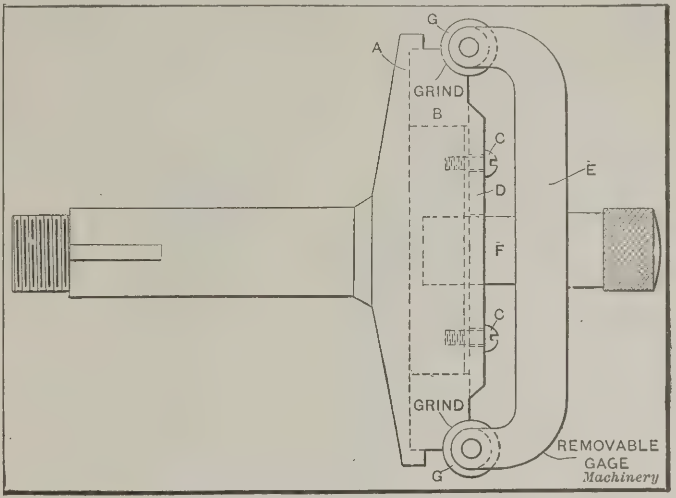

Fig. 2. Fixture for Holding Ball Races for Grinding, and Gage for Testing Work

of the interesting parts of this fixture and work is the method used in checking the grinding. This is done by means of gage *E*. The central plug *F* of gage *E* is made to fit a hole in the fixture, which is ground accurately to the same size as the stud. At the two extremities of gage *E* two steel disks *G* that have been beveled to a knife edge are mounted. By means of this fixture the shape of the ground portion may be checked as well as the overall diameter and the concentricity of the grinding with the bore.

A somewhat different proposition is illustrated in Figs. 3, 4, and 5. Fig. 3 illustrates the piece that must be ground. This piece, it will be noticed, has a hole crosswise of the cylindrical part. The problem is to grind this cylindrical part exactly true with the hole; that is to say, the distances from the center of this hole to the outside of the piece must be

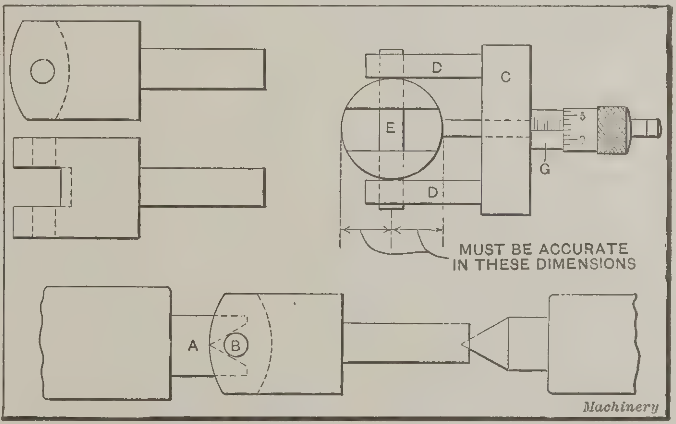

Fig. 3. Piece to be ground. Fig. 4. Method of Testing Accuracy of Grinding. Fig. 5. Method of Holding Work

exactly equal and accurate as to size. This point can be best illustrated by referring to Fig. 4, in which the dimensions that must be accurate are noted. The method used in holding this work for grinding is illustrated in Fig. 5 and consists essentially of a stud *A* whose end is milled with a V-slot that is exactly in the center of the stud. The other end of the work is held in the usual manner by the tail center of the grinding machine. Fig. 4 illustrates the method used in checking the accuracy of this grinding. This gaging fixture consists of a bar *C*, having two arms *D* that are drilled and reamed to receive the pin *E*, which, in turn, may be slipped through the holes of the piece and the holes of these arms *D*. The measuring part of the gage consists of a micrometer head *G* that is mounted in the center of bar *C*. By means of this micrometer head the distances from the center of the hole to the outside of the work in either direction may be readily and accurately measured. C. L. L.

* The titles and dates of publication of the complete series of articles on the Brown & Sharpe automatic screw machines are: "Magazine Attachments—1," February, 1912; "Milling Cross-Drilling and Burring Attachments—1-2-3-4," September to December, 1911; "Thread Rolling," August, 1911, engineering edition; "Knurls and Knurling Operations," July, 1911; "External Cutting Tools—1-2-3-4-5," January (except May) to June, 1911; "Internal Cutting Tools—1-2-3," September to November, 1910; "Designing Screw Machine Tools and Cams," August, 1910; "Threading Operations—1-2," June to July, 1910; "Circular Form and Cut-off Tools—1-2," March to April, 1910; "Knurls and Knurling Operations—1-2," June to July, 1909, engineering edition.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

A THREE-SPINDLE DRILLING ATTACHMENT

As the demand for the product of a manufacturing concern increases, new tools must be designed to increase the output. The company with which I am employed makes a large number of cast-brass rings of different diameters and thicknesses.

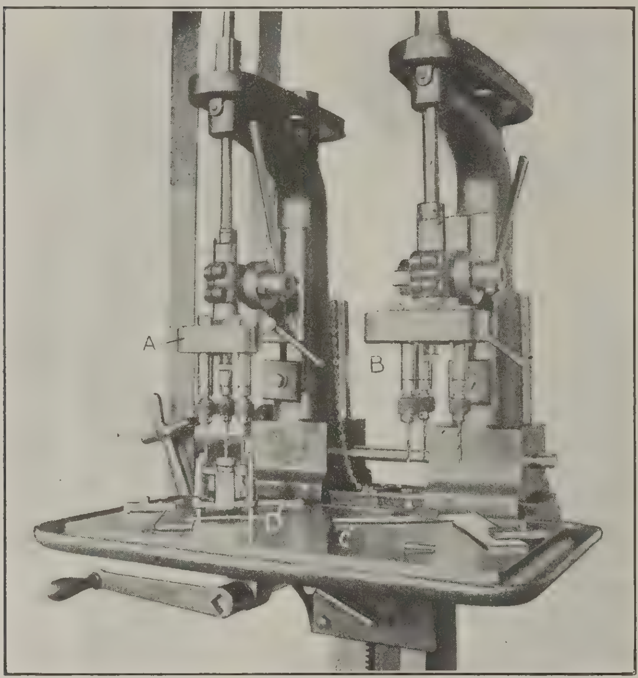

Fig. 1. Drill Press equipped with Two Three-spindle Drilling Attachments

These are attached to plates with three fillister-head screws. The three-spindle drilling attachments, shown in Fig. 1, were made by the writer to drill the three holes in these plates and the three tapped holes in the sides of the brass rings. The diameter of the hole circle is larger on one side of the ring than on the other, thus requiring two drilling attachments.

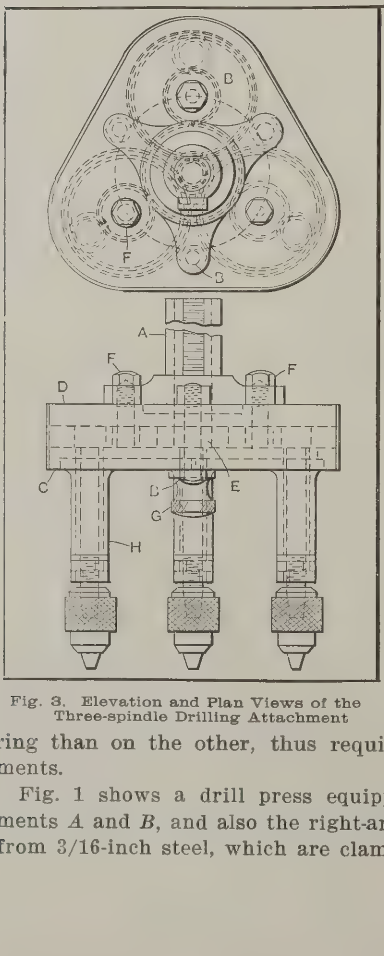

Fig. 3. Elevation and Plan Views of the Three-spindle Drilling Attachment

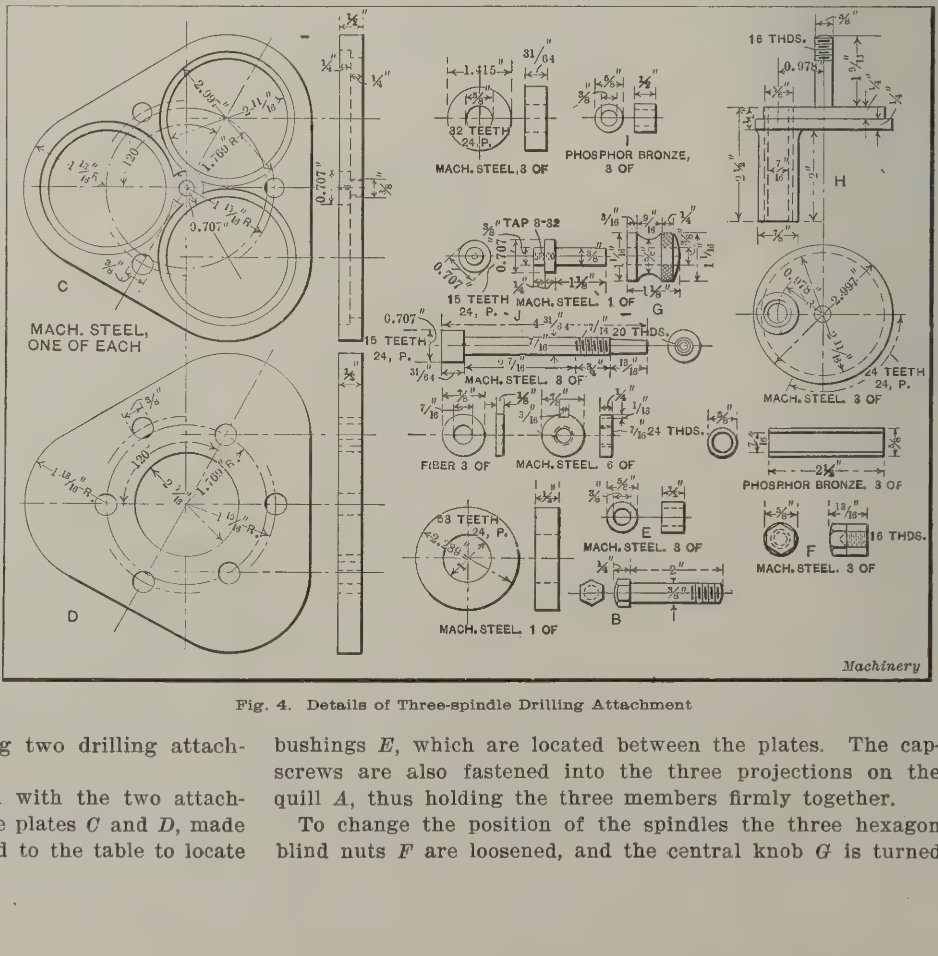

Fig. 4. Details of Three-spindle Drilling Attachment

Fig. 1 shows a drill press equipped with the two attachments *A* and *B*, and also the right-angle plates *C* and *D*, made from 3/16-inch steel, which are clamped to the table to locate the bushings in the drill jig quickly in line with the drills. The attachment *A* will drill three equally spaced holes in any circle from 2 5/8 inches in diameter up to and including 4 7/16 inches in diameter, while the attachment *B* will handle hole circles varying from 3 3/16 inches up to and including 5 1/2 inches in diameter.

At *A* in Fig. 2 is shown a view of one of these attachments looking directly at the chucks, and by close inspection it will be seen that teeth are cut on part of the circumference of the spindle members. There are 24 teeth, 24 pitch, cut in each spindle member in such a position that when the central knob *B* is revolved, the spindles are moved in toward the center of the attachment. The chuck spindle gear has 15 teeth and just clears the driving gear having 53 teeth, which is fastened

Fig. 2. Views looking directly on the Chuck and Gears

to the drill press spindle. The arrangement of the gears can be seen at *C* in Fig. 2, and also in Fig. 3. All gears are cut 24 pitch.

The feed or spindle quills were removed from the drill press, and a special type attached to the fixture as shown at *A* in Fig. 3; then the two drilling attachments *A* and *B* shown in Fig. 1 were put in place, making the machine a permanent multi-spindle drill press. The attachments are made of steel except the quill *A*, Fig. 3, which is made of brass; provision is made to save the expensive parts from excessive wear by making the bushings in the chuck spindle member and the intermediate gear of phosphor-bronze. The 3/8-inch cap-screws *B* pass through the two plates *C* and *D* and the 1/2-inch steel bushings *E*, which are located between the plates. The cap-screws are also fastened into the three projections on the quill *A*, thus holding the three members firmly together.

To change the position of the spindles the three hexagon blind nuts *F* are loosened, and the central knob *G* is turned

in the required direction, moving the spindles H to the proper diameter, so that the drills will line up with the bushings in the drill jig. When the nuts F are tightened, the spindle member is drawn up against a shoulder in the bottom plate C, and the phosphor-bronze bushings I, see Fig. 4, in the intermediate gear are drawn up against the top-plate D, thereby locking each spindle firmly.

The details of this three-spindle drilling attachment are shown in Fig. 4, similar parts in Figs. 3 and 4 bearing the same reference letters. The central knob G is forced onto the ⅜-inch end of the stud J after the teeth are cut, and is held in place in the bottom of the plate C by a tight fitting screw and washer, which projects into a recess turned in the driving gear on the main spindle. The construction of the other parts are clearly indicated in Fig. 4 so that further references are not necessary.

The fact that three of these drilling attachments have been made speaks well for their efficiency. Besides using these attachments for drilling three holes they are also used for drilling two holes where the distance between centers or the distance across the chord with a 6-inch hole circle comes within the range of the attachments. The capacity of the chucks is from the smallest size drill up to and including a No. 1 drill. The spindles rotate at 1400 R.P.M., and provision is made for oiling the spindles by drilling oil holes in the top plate D and tapping it for flat-head screws. Oil grooves are also cut in the drilling spindles, so they are furnished at all times with a copious supply of lubricant. The gears also are well lubricated.

Dorchester, Mass. ALBERT C. SAWYER

TWISTING IRON ON THE BULLDOZER

When it is desired to twist one or both ends of a rectangular bar which is considerably wider than it is thick, the twisting can be done on a bulldozer without the aid of any complicated mechanism. The twisting device may also be used in connection with a former, for bending the bar in the direction of its greatest width. The method employed is illustrated in Fig. 1.

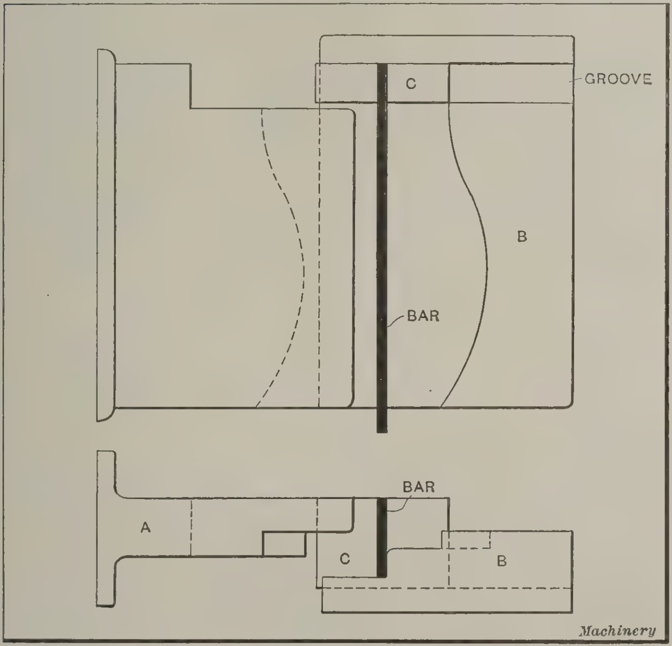

Fig. 1. Formers for Twisting Iron on the Bulldozer

The casting A is attached to the crosshead of a bulldozer, and corresponds to the movable die in the ordinary former, while the casting B corresponds to the stationary die. It will be seen that if the bar, which is shown standing on edge, is firmly held in this position at one end, it will be twisted when the dies come together. To hold the end of the bar in position, a block C is used, provided with a slot to fit the bar. It is evident that this block C must move forward with the movable die; otherwise the bar would be distorted at the point of the bend. This is easily done by cutting a groove in the stationary die, into which the block will slide. The curved lines on the formers represent the shape to which the bar is to be bent.

In Fig. 2 is shown some of the work which may be accomplished by formers of this kind. C shows a bar which is both twisted and bent, and B shows a bar twisted at both ends. Should it be desired to bring the twisted end on either side of the center of the straight portion of the bar, and have

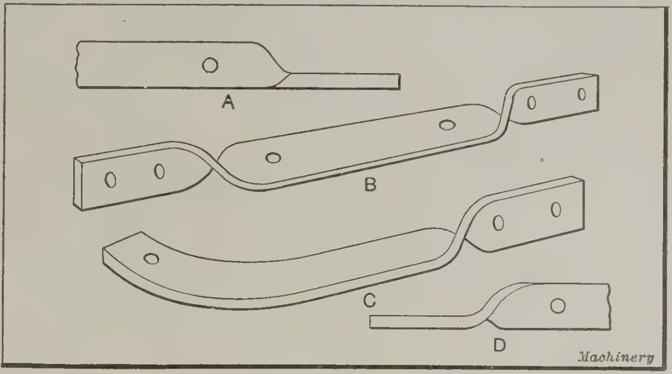

Fig. 2. Examples of Twisted Iron Bars

the flat surfaces at right angles to each other, as shown at A and D, this is easily done by lengthening or shortening the projection on the movable die, which bears against the block.

By the additional provision of a link connecting the block C to the movable die A, Fig. 1, the block can be brought back to the first position with the backward stroke of the machine. If the block is short, it will be necessary to use a guide or some other means of preventing it from tipping up as the bar twists.

W. L. B.

DIAGRAM OF EFFICIENCIES OF WORMS AND SCREWS

The accompanying diagram shows at a glance the percentage of efficiency of worms and screws when the ratio between the lead of the screw or worm thread and the pitch diameter is known. The inexperienced designer is apt to overlook the question of efficiency, but unless this is considered, it is possible that an apparently ample leverage will be so reduced by the inefficiency of the screw that hand adjustment will be difficult or power adjustment subject to severe wear. The diagram given is similar to one published in a book entitled "Worm and Spiral Gearing," by Frederick A. Halsey, but is easier to apply on account of the introduction of the factor of the ratio of lead to pitch diameter in place of the angle of the thread.

It will be seen that two curves are given, one for the efficiency of the worm alone and one for the efficiency of worm and step. The first curve is used in cases where the end thrust is taken by a ball bearing, while the second curve is

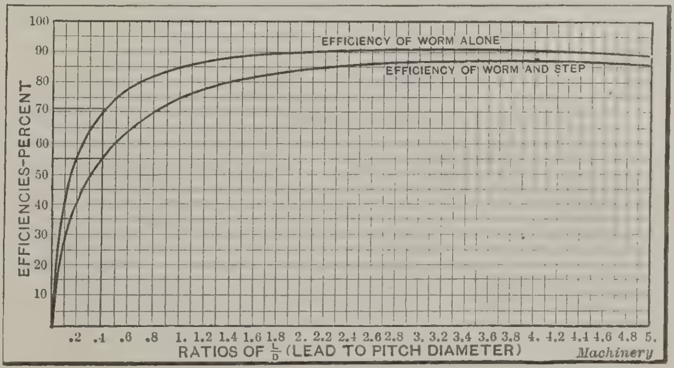

Diagram of Efficiencies of Worms and Screws

used when the end thrust is taken by an ordinary washer, causing friction at the end of the worm. The formulas upon which these curves are based are as follows:

$$\text{Efficiency of worm alone} = \frac{\tan \alpha\,(1 - f \tan \alpha)}{\tan \alpha + f}$$

$$\text{Efficiency of worm and step} = \frac{\tan \alpha\,(1 - f \tan \alpha)}{\tan \alpha + 2f}$$

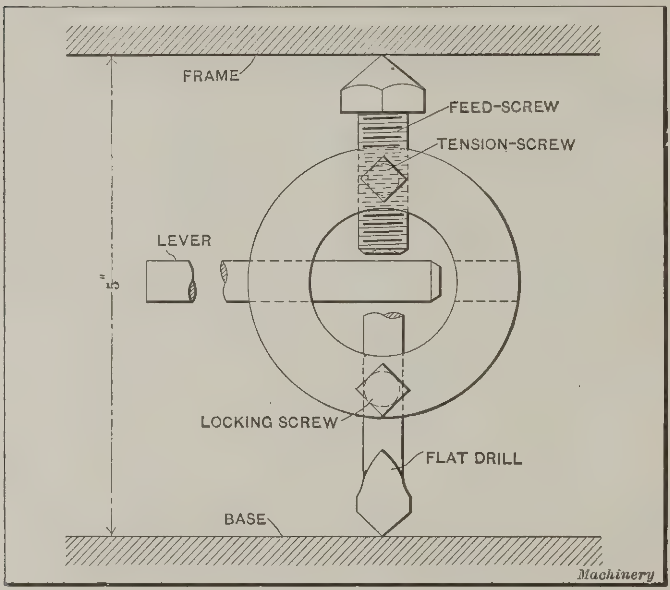
In these formulas α = angle of thread.
f = coefficient of friction, assumed as equal to 0.05.

As an example of the use of the diagram, find the efficiency of a worm with ½-inch lead, single thread, and 1¼-pitch diameter; the ratio of lead to pitch diameter is $0.5 \div 1.25 = 0.4$. From the curves we find that the efficiency is 71 per cent for the worm alone, and 55 per cent for the worm and step.

Scottdale, Pa. F. D. BUFFUM

AN IMPROVISED DRILL AND FEED

It was at one time necessary to drill two 1/2-inch holes in the base of a machine where there was only 5 inches of space available, as shown in the accompanying illustration. Our shortest ratchet drill was 7 inches over all, so that it could not be used. The job was in a hurry, so the man doing it picked up an old collar, drilled a few holes in it, arranged the



An Improvised Drill and Feed

two set-screws as shown, the lower one bearing against a flat spot on the drill, and the upper one screwed against a copper plug and the feed-screw. The latter set-screw provided a tension to prevent the screw from feeding too fast. A piece of 7/16-inch iron was then applied as a lever to turn the drilling device, and a wrench was used to work the feed-screw, which was a common set-screw with the head ground to a sharp point.

Newark, N. J. H. E. WOOD

[The tension-screw was unnecessary if the feed-screw was properly pointed on the outer end. The resistance to turning of the screw in its nut, under ordinary conditions, is always greater than that of a pivot of smaller mean diameter when both are carrying the same load.—EDITOR.]

STRAIGHTENING SHAFTING

There is one operation in machine shop practice to which even the best mechanics look forward with dread, *i. e.*, straightening a screw or shaft. This is due largely to the lack of understanding of the principles of straightening on the part of the majority of mechanics. While some shafts require more time to straighten than others, the operation becomes comparatively simple if approached with the proper understanding and appliances.

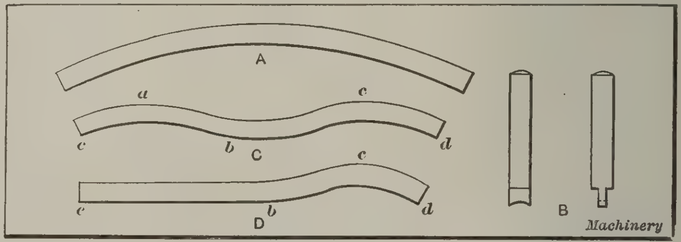
Every shop worthy of the name should have some good straightening devices. These, as a rule, can be made cheaply and are so simple that they need not be discussed. If nothing else is at hand an I-beam, a couple of V-blocks and a jack-screw serve the purpose, and these are especially good for straightening long shafting. A shaft becomes bent through various causes, *e. g.*, it may be strained beyond its elastic limit, as when overloaded; or it may be subjected to too much heat, causing unequal internal strains, as when taking a cut over a piece of rough iron or steel, or when keyseating a shaft especially when it is made from commercial cold-rolled steel.

By referring to the accompanying illustration it will be seen that the shaft which is shown at *A* has a single bend and is considerably longer on the top side than on the bottom. In order to produce this effect the fibers on one side were stretched and those on the other, compressed. Now to bring the shaft back to its normal state, this condition of the fibers must be reversed.

If through some accident a shaft is strained beyond its elastic limit it should never be used for the same purpose even though it be made to run practically true, unless the load is not excessive in proportion to its size. A shaft once distorted will never have the same resisting qualities that it had before the accident. Shafts running at a high rate of speed having keyways cut between the journals, even though splined on both sides, give trouble on account of the vibration caused by the shaft being out of balance. This can be avoided either by designing the shaft stronger than necessary, to give it additional stiffness, or by cutting a slot in each side one-half the proper width for that size of shaft. For instance, a ½-inch keyway being standard for a 2-inch shaft, cut a ¼-inch slot on each side of the shaft in diametrically opposite positions. This leaves the shaft strong and easy to straighten.

Shafts which have to withstand suddenly applied loads, such as the crankshaft of a gasoline engine, can be made to hold the flywheel so that it will not loosen by making the keyway wider than the standard width and having the key a good fit sideways. Crankshafts turned by the ordinary method in the lathe will invariably be found to spring slightly. This is caused by clamping too tightly the screw that is placed between the arms when turning the journals, so that when the screw is removed, the arms spring in, causing the shaft to bend. To remedy this, place a small jack-screw between the arms and by repeated trials, applying a little more pressure each time, spring the arms outward until the journals run true.

Shafting, arbors, lead-screws, etc., are straightened in three different ways. First by means of hammer blows, second, by steady pressure, and, third, by peening. To straighten a shaft by the first method support it upon its ends or between the ends, as the case may be, and strike it with a hand hammer or sledge, depending on the size of the shaft, upon the high or tension side. This forces the long side inward and the



Methods of Straightening Shafting

short side outward. The second method consists in supporting the shaft near its ends or between centers in the lathe (this is not good for the lathe) and applying pressure upon the high side by means of a lever or screw. The third method is a combination of the first and second and consists in stretching the low or compression side by tapping with a hammer at the same time that pressure is applied to the high side.

At *B* in the accompanying illustration is shown a tool for straightening shafting having a square thread cut on it. This tool can be made from an old chisel and will not mar the threads. It is placed between the threads, and while pressure is being applied underneath the shaft, the top of the tool is struck with a hammer. A shaft which is badly bent should be heated and straightened as true as possible. If worked when cold, the shaft will crystallize and break easily.

To straighten the shaft shown at *C*, center each end true, or, if it is too long to go between the centers of the lathe, rest each end upon V-blocks. Now rotate the shaft, and with a piece of chalk find the high spots which would be at *a* and *c*. If the shaft is rough and not very large, it can be quickly straightened by placing it upon an anvil or hollow block and

striking the high spots with a hammer. If the shaft is finished—having a smooth surface—commence at one end, the left-hand end, for example, and work towards the other end. To proceed, fasten end *e* and part *b* with the high side down, apply pressure at *a* and tap the opposite or low side with a hammer, care being taken to use some soft metal, such as sheet copper on both sides to prevent bruising the shaft. A point which should not be overlooked is this: While straightening a shaft by any of the methods given, the pressure or blows should be gradually increased. If it is found upon trial that the shaft is still sprung in the place where the pressure has been applied, the pressure has not been enough. If unfamiliar with the kind of steel, use very little pressure at the first trial.

If the part of the shaft between *e* and *b* shown at *C* is straight, as shown at *D*, fasten the shaft at *b* and *d* with the side *c* down, and apply pressure at *c*, proceeding in the same manner as before described until that part is straight. If the shaft is made from cold-rolled steel or common machine steel, it will be found that some of the bend has returned in the other end of the shaft previously straightened. In this case go over the shaft from the right-hand end in the same manner, and with a little patience and judgment it will be found that what was at first considered drudgery will become an interesting task. John W. Brandle

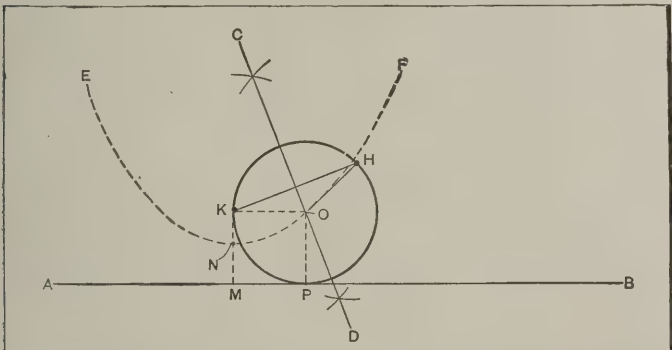
Nashville, Tenn.

A GEOMETRICAL PROBLEM

The following geometrical problem and its solution will probably be of considerable interest to the readers of MACHINERY. If this problem were given unaccompanied by its solution, it is probable that many good mathematicians would spend some time trying to obtain a solution. As far as the writer knows, this problem and its solution are original with him.

Given a straight line *AB* and any two points without it, but on the same side of it, as *K* and *H*. Required a circle passing through *K* and *H* and tangent to *AB*.

Draw *KH*, and bisect it by line *CD;* then the center of the required circle will be somewhere on line *CD*. From *K* draw a line *KM* perpendicular to *AB*; bisect line *KM* as at *N*. With *K* as the focus and *AB* as the directrix, construct a parabola



An Interesting Geometrical Problem

ENF. The point where the parabola intersects line *CD* is the center of the required circle.

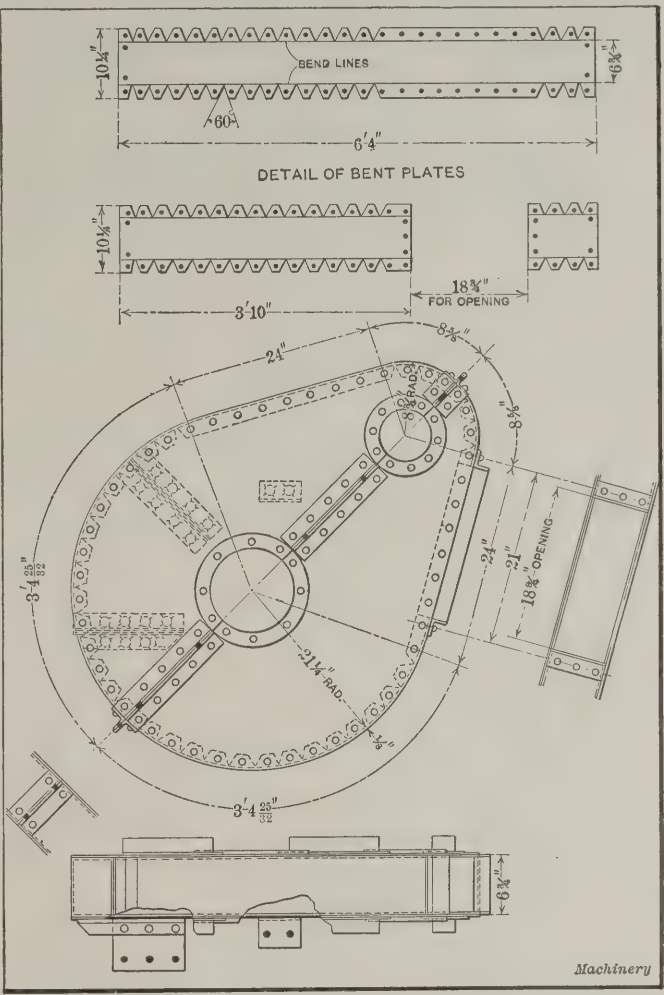
The proof is very simple. In any parabola, any point on its curve is always at an equal distance from its focus and its directrix, hence, $KO = OP$; but *KO* also equals *HO*; hence *O* is the center of a circle which satisfies the given conditions.

Chicago, Ill. C. W. Hinman

SHEET-STEEL GEAR CASES

All gears should be provided with cases that will permit them to run in a bath of oil or grease. We provide carefully for oiling all bearings, slides, etc. Why should we then expect gears to run with haphazard lubrication? A gear case prevents spattering and waste of the lubricant, and it deadens the noise. It also keeps dust out of the teeth, and most important of all, it prevents accidents more efficiently than any guard which does not entirely encase the gears. The day is rapidly approaching when the unguarded or unencased gear will be a thing of the past, and purchasers of machinery ought always to specify gear cases when ordering new machines. It will save money in the end, in addition to all the other benefits mentioned.

The gear case construction shown in the accompanying engraving may be of interest. The rigidity of such cases is surprising and their cost is very small; moreover, they weigh but a small fraction of what a cast-iron case would weigh in any given instance. If they are bent, they can be easily repaired, and they are hardly liable to any more serious injury. The accompanying engraving shows the construction of the



General Design of a Sheet-steel Gear Case

gear case somewhat in detail, but an ordinary sheet metal worker has made at least one hundred of these gear cases, nearly all of different sizes, with no information except the sizes of the gears and shafts. The case should fit over the hub of the gear, or over the box, instead of over the shaft, wherever this is possible. A large hand-hole is always a convenience, and there should be an inch or so of clearance between the teeth and the cases in the radial direction. Even in cramped quarters, inside clearance is sometimes of more importance than clearance on the outside, and it leaves room for various articles that might fall into the case and prevents them from being picked up by the teeth. There is no comparison in cost between the construction shown and one with bent corner angles. There is no trouble about making this case tight enough to hold grease or heavy oils.

Scottdale, Pa. F. D. Buffum

[The opening in the case should, of course, be in an upper side and not in a lower side, as erroneously shown in the engraving.—Editor.]

COMBINATION BENDING AND TWISTING DIE

Fig. 1 shows a latch for a go-cart which was formed and twisted in the die shown in Fig. 2. This latch is first cut off and formed to the shape shown at *A* in Fig. 1, after which it is placed in the die shown in Fig. 2, and bent and twisted to the final shape shown at *B*.

The lower bending die A, Fig. 2, is held in a cast-iron base B, and pins C, driven into the former, extend down through the base and come in contact with a pressure plate D operated by a rubber pad E. The top forming die F is held by screws and dowels, as shown, to the holder G, which has a shank to fit the hole in the ram of the press. This holder G is lined up with the base B by standards H, and holds two pins I which oper-

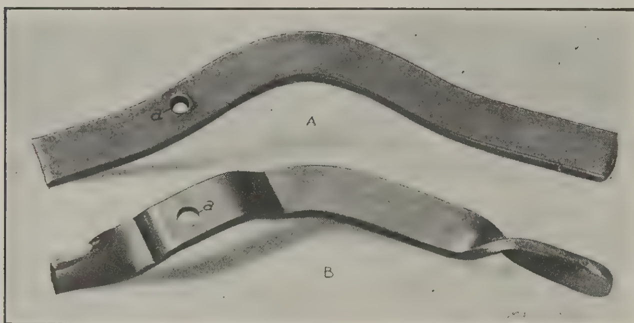


Fig. 1. The Go-cart Latch before and after Bending and Twisting

ate the lower twisting dies J and K. The twisting dies J and K correspond in shape to the dies L and M, which are provided with shanks and are held in the holder G by screws and dowels.

The lower twisting dies J and K are given a slight upward movement by means of the pins I, which come in contact on the downward stroke of the ram with fulcrumed levers N held on pins O. These fulcrumed levers are connected to the twisting dies by pins, as shown more clearly in Fig. 3, where the operation of the twisting dies K and M is illustrated.

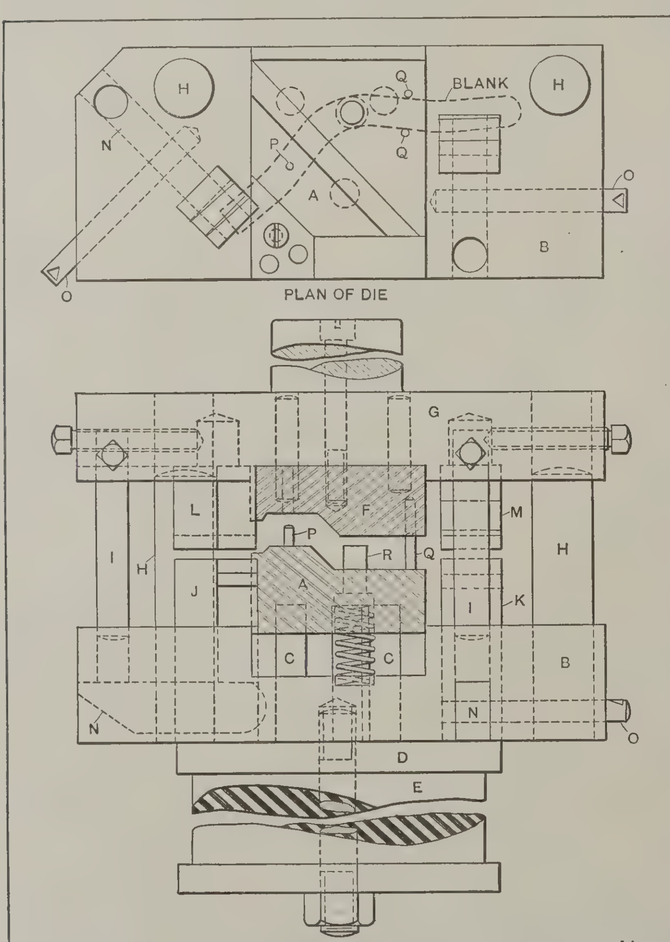

Fig. 2. Elevation and Plan Views of the Combination Bending and Twisting Die

In operation, the blank shown at A in Fig. 1 is placed on the lower die A, Fig. 2, the hole a fitting on the pin P and the blank being located between the pins Q. A spring plunger R, operated as shown in Fig. 2, prevents the blank from dropping down, holding it flush with the highest surface of the lower forming die. As the ram of the press descends, the upper former forces the blank down, bending it to the shape shown at B in Fig. 1, and as the ram still continues in its downward movement, the pins I operate the lower twisting dies through the levers N. The combined action of the upper and lower twisting dies forms both ends of the blank to the shape shown at B in Fig. 1. The lower die A, while the twisting

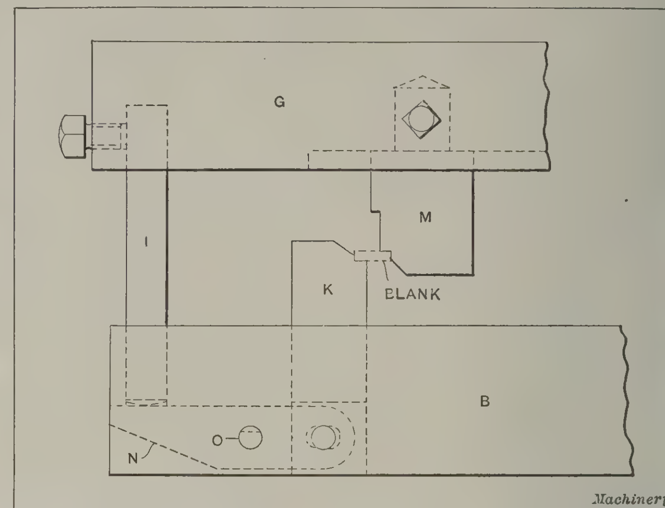

Fig. 3. Part View showing how the Twisting Dies K and M are operated

operation is taking place, has been forced down to the lowest point of its travel, compressing the rubber pad E, which returns it to its former position when the ram of the press ascends.

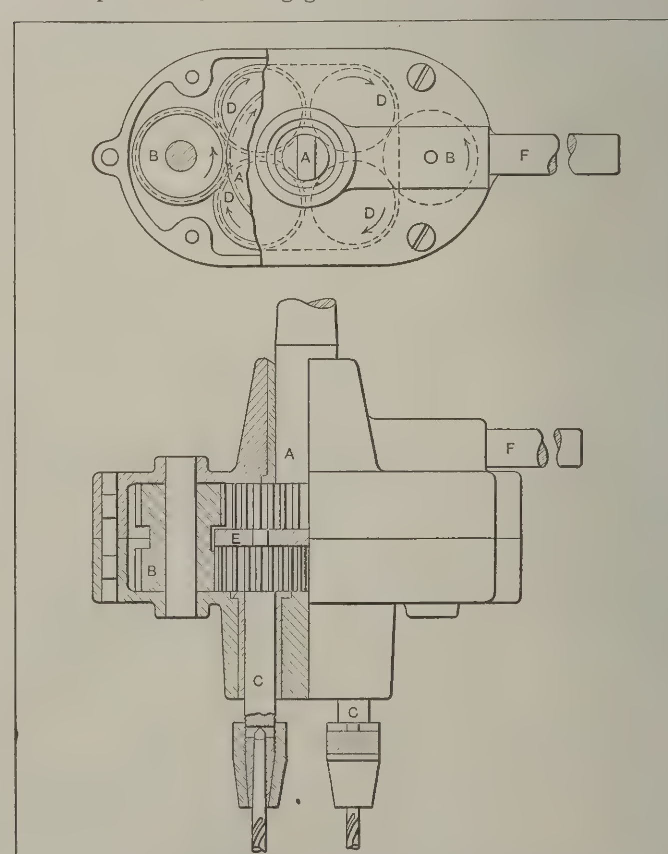
A FOUR-SPINDLE DRILLING HEAD

Having a large number of pieces to drill, each with four 3/16-inch holes, spaced 1 1/2 inch apart on a square, we designed this fixture to drill the four holes simultaneously. On account of the small space between the gears, and to avoid the necessity of making special left-hand drills, the arrangement of the gears shown in the accompanying illustration was adopted. The driving gear and shank A are made in one



A Four-spindle Drilling Head of Compact Design

piece, and the intermediate gears B drive the four spindles C through the gears D. The thrust of the four spindles is taken by a bronze plate E, and the intermediate gears B are cut out to clear this plate. The whole mechanism is enclosed

in two cast-iron covers, and is prevented from turning by the handle *F* which comes in contact with the column of the drill press. The intermediate gears *B* run on pins which are driven into one side of the case, and all of the spindles are provided with bronze bushings.

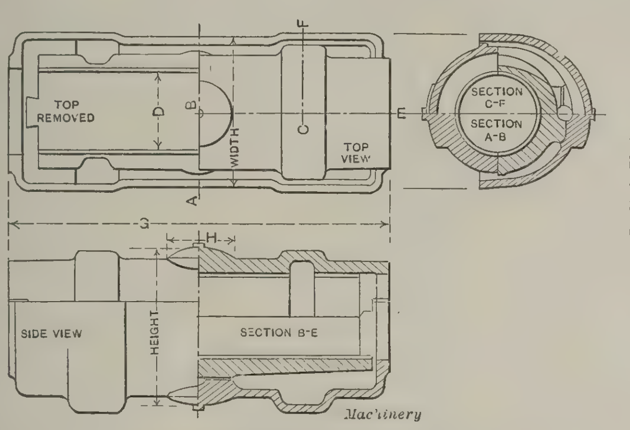
Stamford, Conn. KINGSTON FORBES

RING OR CHAIN OILING SELF-ALIGNING BEARINGS

The illustration shows side, plan and section views of a ring- or chain-oiling self-aligning box that I designed in eighteen standard sizes for 1 3/16-inch to 5 15/16-inch diameter shafts.

The table gives the length of bearing, length over-all, approximate weight complete, diameter of the spherical part *H*

RING OR CHAIN OILING BOXES



Size of shaft D	1 3/16	1 7/16	1 11/16	1 15/16	2 3/16	2 7/16	2 11/16	2 15/16	3 3/16

and other data necessary for the patternmaker and machinist.

The advantages of the ring-oiling self-aligning type of bearing should commend it to every designer of machinery, and I hope that these standard sizes may be of as much use to others as they have been to my friends and myself.

San Antonio, Texas. A. W. WINTERBORNE

NEAT'S-FOOT OIL AS A CUTTING LUBRICANT

Some time ago we had a lot of small iron nuts to tap. This job was done by boys in a lathe using taps about 5 inches long made from drill rod. Considerable trouble was experienced with the taps' breaking, and as an experiment we tried neat's-foot oil as a cutting lubricant. This ended the breakage of taps and they lasted until worn out. Since then we have used neat's-foot oil in the threading and difficult forming of steel, and it has always given good results.

We are now broaching soft steel pieces, and using this oil as a lubricant with success. The holes being broached are enclosed on three sides, the fourth side being open. This work has always given trouble because of the seizing of the broach which necessitated sawing the piece in two in order to remove the broach. Since using this oil we have not spoiled a piece, and the holes are smooth and correct to size. While a great many know that neat's-foot oil makes a good, if not the best, belt dressing, I have not met anyone who used it as a cutting oil.

New Haven, Conn. FRANK K. LOVELAND

PHYSICAL HEALTH AND DRAFTING

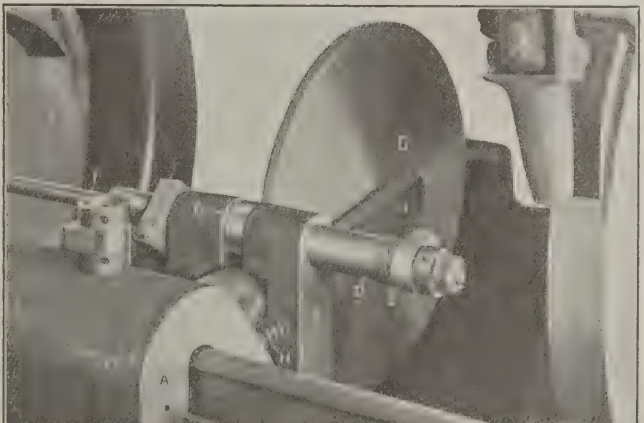
The question of physical health is of prime importance to draftsmen, and it has been freely discussed of late, but it still remains open. We do not all agree with L. R. W. A., in the November number of MACHINERY, in his denunciation of the "apron" type of draftsmen. It is practically, if not absolutely, impossible to avoid pressure on the abdomen in working. You must "get there" and produce, and the only way to reach the top of the board one moment and the bottom the next, is to use the body. There are, of course, extremes in this as in all other cases. I call to mind one "knight" of the board who used his abdomen as a pivot, (he was possessed of a fair-sized bay window) to enable him to roll to the top of the board. This "feat" in time will produce disastrous results—indigestion and its companion ailments. A moderate use of this part of the body, however, can have no very bad effects. If it were possible to avoid this altogether, why does not the instructor show the pupil the "only correct position" to assume when drawing? In teaching penmanship, stress is laid on the importance of proper posture, and why not in drafting? That is the time to correct the evil if it exists, as life-long habits are hard to break.

Exercise seems to me to be the one important factor in a draftsman's health. He needs something to take the kinks out of his system which are acquired in the "daily grind." A few simple bending and breathing exercises practiced morning and night will work wonders. Ventilation is also important. A stuffy steam-heated room is more of a health destroyer than anything else. Right here arises a difficulty: A opens a window and B growls, "Shut that window! Were you brought up in a barn?" That is human nature, but a draftsman should get all the fresh air he possibly can. It seems that a little more attention paid to details would eliminate all of this "slow death" idea and make drafting an attractive proposition, as it should be.

New Britain, Conn. J. M. HENRY

A CAM GRINDING FIXTURE

The accompanying illustration shows a cam grinding fixture applied to a Norton plain grinder. The base *A* of the fixture is clamped to the bed of the grinder, and carries a rocker arm *B*, which is hinged to it. The master cam *C* is keyed to the shaft *D* on which the cam *E* to be ground is held. This shaft is revolved by a flexible coupling *F* driven from the regular driving mechanism, and is held against the center



A Cam Grinding Fixture applied to a Norton Plain Grinding Machine

in the grinding head by a spring located in the shaft. The master cam *C*, when revolved, is kept in contact, by springs *H*, with the roller *G*, which is pivoted to the base *A*. These springs *H*, only one of which is shown, force the master cam against the roller, thus imparting an oscillating movement to the rocker arm, which controls the shape of the cam to be ground. A brake *I* is used to prevent the work from jumping away from the wheel on the relieved side of the master cam. With this attachment, which was designed and built in the apprentice department of the General Electric Co., we are able to make cams at the rate of one every ten minutes to within 0.002 inch of the master cam.

West Lynn, Mass. CHARLES K. TRIPP

REMARKS BY THE ONLOOKER

In reading the interesting article on ball making in the February number of MACHINERY, I recall one of my first jobs in an American shop—the finishing of a number of balls for a floating crane. I was quite proud of my achievement when after much labor the work was done. At noon some of the boys began to caliper the balls, the polish of which was of a considerably higher standard than their uniformity of size, and I suddenly began to lose my pride; in fact, what little remained after they were all calipered, quite disappeared when an old Scotchman said, "Well, my lad, the first one is alike anyway." The present perfection in ball making shows what can be done in the manufacture of great numbers, with proper application of energy and thought.

For years I have had an idea in my mind of some kind of a coating to protect certain parts of a piece when being hardened. Enamelite, as described on page 482, engineering edition, meets with the requirements. Time and time again I have wished for just such a preparation, and it seems to me that it ought to sell like the well-known "hot cakes."

The new design of milling cutter shown by the National Twist Drill & Tool Co., on page 97 of the advertising section, is something that interests me a great deal. It is not an easy thing to combine solidity and simplicity in an inserted tooth milling cutter, and to me it seems that this is almost, as they say down East, "the end of the asking"—just a turned up disk, a few drilled holes, some plain milling, a few pins, and there you are.

If Mr. F. B. Jacobs' article on "Sharpening Milling Cutters" could not only be read, but also acted upon, by those that have to do with the sharpening of these tools, the output of milling machines, I believe, could be increased by 25 per cent. I recall an old man once who, when taking charge of the milling department of a shop, remarked, "Yes, they have got a lot of millers up there that hiccough and grunt the stuff off," and that, I fear, is too often a true description of the way in which milling machines are allowed to do their work.

For years, drill press tables have been weak on account of their overhang, and many a careful mechanic has blocked up the table for heavy drilling or for heavy pieces by means of a screw-jack, or by some other means if no screw-jack was available. To-day this is not often required in modern machines, as drill makers are providing a support as indicated in the Barnes drilling machine, shown on page 480, and in the Taylor & Fenn radial, shown on advertising page 184, which, by the way, is a most convenient tool, although I think it would be an improvement if a slotted tie-rod were provided from the arm to the table. This would stiffen the tool and add but little to the cost. In the Gang radial drill, advertising page 162, a support for the table is also provided, and in some makes of shapers the idea is introduced to advantage. To a very large extent, this stiffening of machine tools is called for by the heavy cuts taken by high-speed steel tools, but the added accuracy of the work produced on solid machines has also acted as an incentive for tool builders to produce something which is not only strong enough, but also "non-vibrating" enough, to produce accurate work. The Lees-Bradner Co. says that "overhanging is a vital error in design," and mechanical designers are beginning to recognize this fact to a marked degree.

To change the subject, let us talk of twist drills. Just look at the row of "maimed soldiers" on advertising page 31. Of course the number of drill presses and collets now in use, scattered all over the world, could not be thrown away or changed without great expense, but the advertisement referred to shows a way to help matters. I do not believe that all the trouble with twisted tangs is due to their actual weakness, but very largely to neglect in seeing that the slots in the collets of drill presses are in proper order. I have often asked a foreman or superintendent if he ever inspected the slots in the drill-press spindles, and have seldom been answered in the affirmative. I feel sure that if the taper is a proper fit, and the tang also, the latter will rarely twist off with regular work.

Your editorial on the "efficiency engineer" is just to the point. That expression is a slur on the engineering profession, as it intimates that an "inefficient" engineer is also a calling. In my experience, the aim of all conscientious engineers has been the production of high quality at low cost—to get all that was possible out of the plant under the existing conditions. What is that if not efficiency?

I cannot quite join you in your time-saving idea mentioned in the editorial entitled "Saving Time in Machine Work." It is safe to say that we will find, if we analyze the operation of drilling a single piece, that not over 10 per cent of the total time is actually used in cutting metal. Drawing down the lever and throwing in the feed are not operations which require much time, and it is my belief that great time saving could be accomplished in securing the work rather than in handling the machine. Often the appliances for securing work on drill presses consist of a number of bolts and straps in a box which have to be dumped on a bench or on the floor in order to find the desired bolts. Usually a trip to the store-room for missing nuts is required, unless they can be conveniently appropriated from the very carefully guarded collection of the planer hand, who is generally the autocrat of the machine shop. To cut a long story short, I believe that time saving in drill press work is in the direction of appliances to quickly get the drill to do its actual work, and not in automatic adjuncts to the press. However, the reciprocating motion in the drill press shown on page 471, is certainly a very convenient addition. We have all worked the hand-feed lever at times to cut a keyway on a drill press, and wished for just such an attachment as this.

It is perhaps not difficult to understand why a drill press has so few appliances, and why those that are provided are so poor. Most likely it is because this machine is especially everybody's tool, unless the shop is a very large one. All hands do work on it, feeling no responsibility towards it, and only considering it their duty to get the job done, and the sooner they can get away from the machine the better. Unless a man is caught "red-handed," the drill marks on the table are done at night when it is positively known that the drills play "tag," and just get into the drill-press sockets all by themselves, which, of course, accounts for the disreputable appearance of the table. This curious night behavior of tools needs scientific investigation. I have known milling cutters or special tools to be taken in perfect condition to a tool-room at night, only to be found in bad shape the next morning, and even when a broken piece is found with the work done by it, it is merely a strange coincidence.

It seems strange to me that the multiple drill makers do not provide some kind of adjustable drill guides, as it would greatly enhance the value of these tools.

In answer to D. A. H.'s question as to rejected parts, my advice would be to destroy them at once, so that they cannot be used, or else you may be tempted to make use of them to the detriment of your reputation. Just be a Pharaoh and harden your heart, but do it at once, and make it part of your system.

"Amateur," judging from his letter on page 464, certainly is in trouble. The explanation of using a lathe for fine drilling "beats" anything that I have so far seen in print, and it is somewhat on a par with the advice given in a celebrated hand-book of engineering, where the following appears: "Boring.—For brass the speed is *one-half* that for cast iron." This shows the truth of the statement of the school-boy who said, "If it wasn't for books, we wouldn't know nothin'." W. D. F.

* * *

The development of electric rock drills of the percussion type has imposed the most severe requirements on steel used for the drills and hammers, but the economy of electric installations has made the development worth while. It is claimed that the electric drill using from one-half to two horsepower will equal the work of a compressed air drill using twelve to eighteen horsepower at the compressor. The changing of line wires is simple as compared with the shifting of pipes. Countervailing disadvantages are the dangers of short circuits and sparks and the lack of the fresh air that is a feature of the exhaust of compressed air drills of some importance.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

WIGGLESWORTH BORING, DRILLING AND TAPPING MACHINE

The Western Machine Tool Works, of Holland, Mich., has recently placed on the market a boring machine especially adapted for heavy boring, drilling and tapping operations. This machine is capable of driving 4-inch drills in steel and will operate an 8-inch pipe tap in cast iron. The general features of the machine may be seen by referring to Figs. 1 and 2,

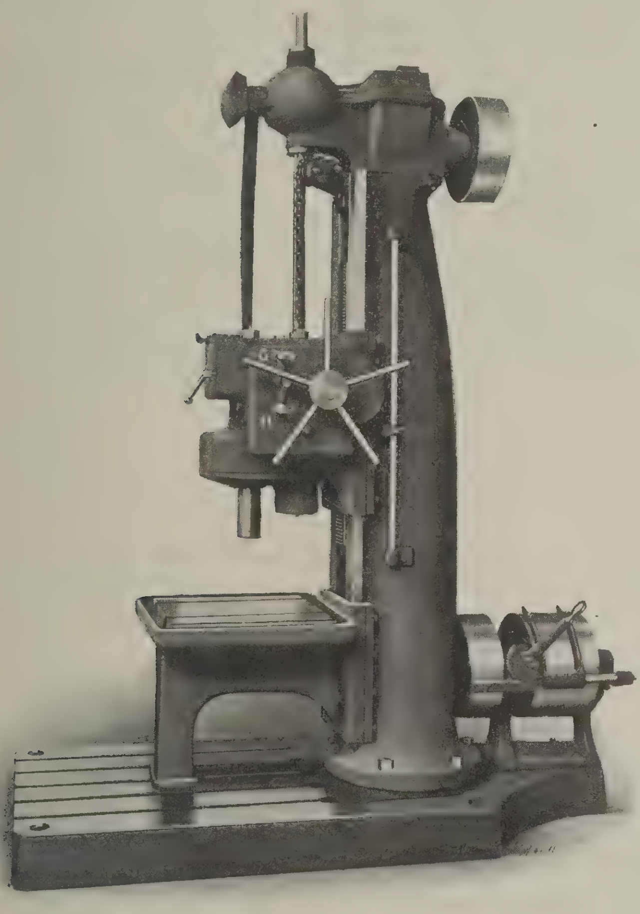


Fig. 1. Boring, Drilling and Tapping Machine, built by Western Machine Tool Works

of the accompanying illustrations, which show views of each side. When the machine is in operation, the spindle remains in a fixed longitudinal position with relation to the driving mechanism and spindle-head and the latter is automatically fed downward on the face of the column. The machine has nine changes of positive geared feed, ranging from 0.006 inch to 0.042 inch per revolution of the spindle, and, in addition, three positive geared "leads" for tapping eight, eleven and one-half and fourteen threads per inch. These tapping leads are independent of the feed changes and any desired lead may be obtained by means of extra change gears.

As will be noted, a belted connection is made between the countershaft on the base and the quick-change speed gear-box on the top of the column. By means of the speed change gears, eight different spindle speeds are obtained and this number is doubled by back-gears located in the head, thus giving a total of sixteen speeds, ranging from 25 to 400 revolutions per minute. From the gear-box the power is transmitted to the spindle head through horizontal and vertical shafts connected by bevel gears. There are three of these bevel gears and a friction clutch, which form the reverse mechanism for tapping. The lever *D*, Fig. 2, for operating this friction clutch, is located conveniently on the left-hand side of the head.

The spindle is driven by a large gear in the head. This gear is located in a fixed position near the lower end of the spindle and close to the work. This arrangement reduces the torsional strain on the spindle and tends to eliminate the chattering incident to heavy cuts. The automatic down-feed to the head is derived from a spiral gear located near the upper end of the spindle, the power being transmitted through feed change gears (as explained later) and a pinion which meshes with a rack in the face of the column. With this arrangement, the feed operates in conjunction with the spindle movements.

Figs. 3 and 4 show the construction of the quick-change gear-box which is located on top of the column and governs the spindle speeds. Shaft *A* is keyed to the belt pulley and, consequently, rotates at a constant speed. A cone of four gears, *B*, is splined to shaft *A* and can be shifted longitudinally by fork *C* which slides on a fixed stud in the gear casing. To the rear of this fork there is a straight rack engaging gear *D*, which is keyed to the vertical shaft *E* so that rotating the latter shifts the cone of gears *B*. The variable speed is transmitted to shaft *F* on which is mounted a rocker arm *G* having pivots *H* and *H'* supporting two sets of intermediate gears *J* and *J'*. Gears *J'* are directly geared to pinion shaft *F*, whereas

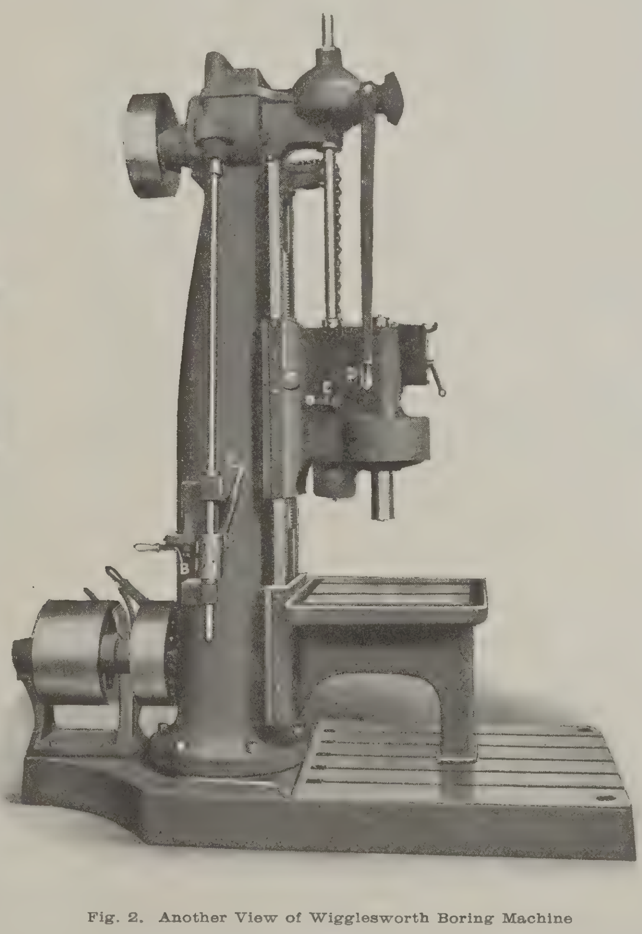

Fig. 2. Another View of Wigglesworth Boring Machine

J is connected by compound gearing as shown. On the upper end of rod *E* there is a circular rack which engages corresponding teeth in the sector face of rocker arm *G*. This rod may be raised or lowered and it can also be rotated to the right or left. Any vertical movement rocks arm *G* and permits either *J* or *J'* to mesh with one of the gears on shaft *A*, whereas rotating *E* to the right or left shifts cone *B* on shaft *A* to bring any one of the four gears into engagement with *J* or *J'*. By varying the gear combinations in this way, eight spindle speeds are obtained. The vertical and rotary movements of rod *E* are effected by the two levers *B* and *C*, Fig. 2,

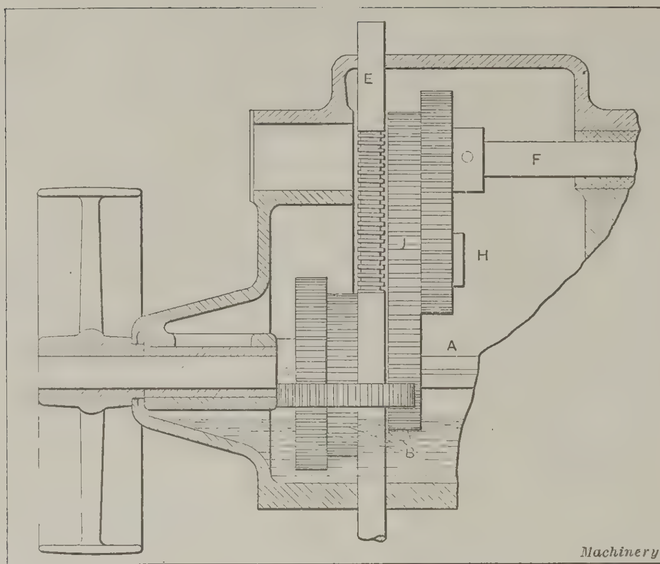

Fig. 3. Side View of Speed-changing Mechanism

which operate through the medium of a cylindrical part attached to the rod.

The method of driving the spindle either directly or through

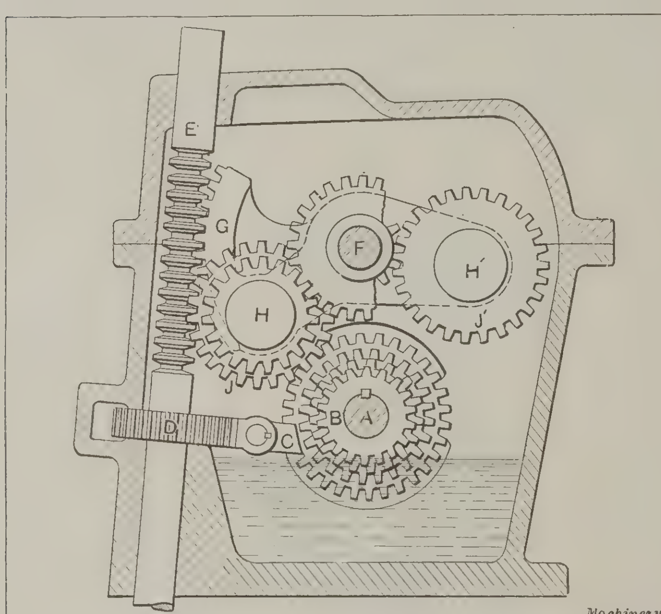

Fig. 4. End View of Speed-change Gears

back-gears, is clearly shown in Fig. 5. The vertical shaft *P*, which receives its motion at the top of the column, carries gears *B* and *X*, and the spindle carries the mating gears *Y* and *Z*. Gear *B* is splined to shaft *P* and when in the position shown, the spindle is driven through back-gears. To obtain a direct gear drive, gear *B* is dropped down inside gear *X* (which is bored out to receive it) by means of lever *E*, Fig. 2. Gear *X* has a large hub on its lower side and on the inside of this hub a two-jaw clutch is cut. This clutch is engaged by the corresponding clutch on gear *B* when the latter is lowered, and then the drive is direct from *X* to *Z*.

The details of the positive geared feed mechanism are shown in Figs. 6, 7 and 8. The power is derived from the spindle by a spiral gear *Q* which drives shaft *C*. The latter transmits movement to shaft *D* through three spur gears located in the small box seen on the front of the head in Figs. 1 and 2. (Incidentally, the different tapping leads are obtained by replacing gear *T*, Fig. 9, with another size). Shaft *D* carries five gears as shown in Fig. 7, all of which run loose on it excepting gear *X*, which is attached by a key. The two gears to the left on *D* are locked together and any one of the three middle gears may be keyed to the shaft by a diving key mechanism. This diving key is operated by lever *G*, Figs. 1 and 8, located on the right-hand side of the head. Above the three middle gears referred to, there is a cone of mating gears *E* (Figs. 6 and 7) which run loose on their shaft and are all joined together. Shaft *F* also carries three gears

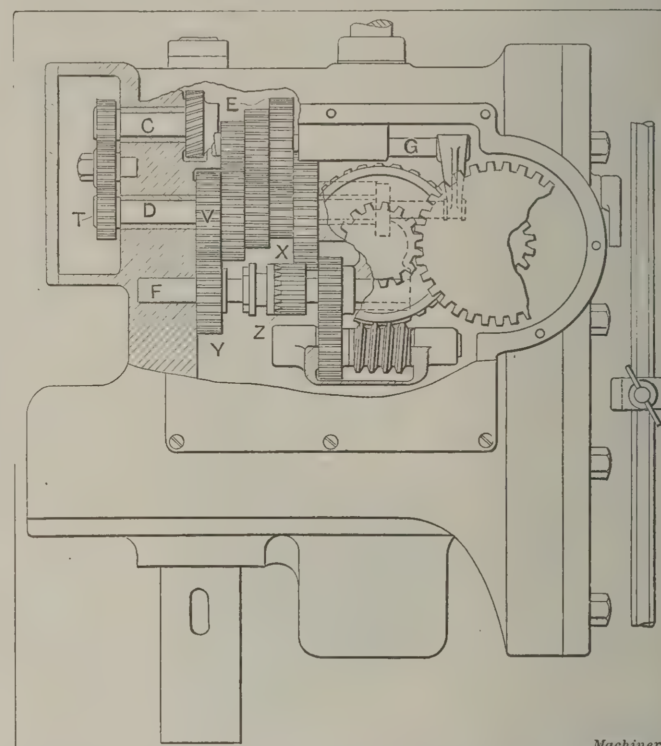

Fig. 7. The Positive Geared Feed Mechanism

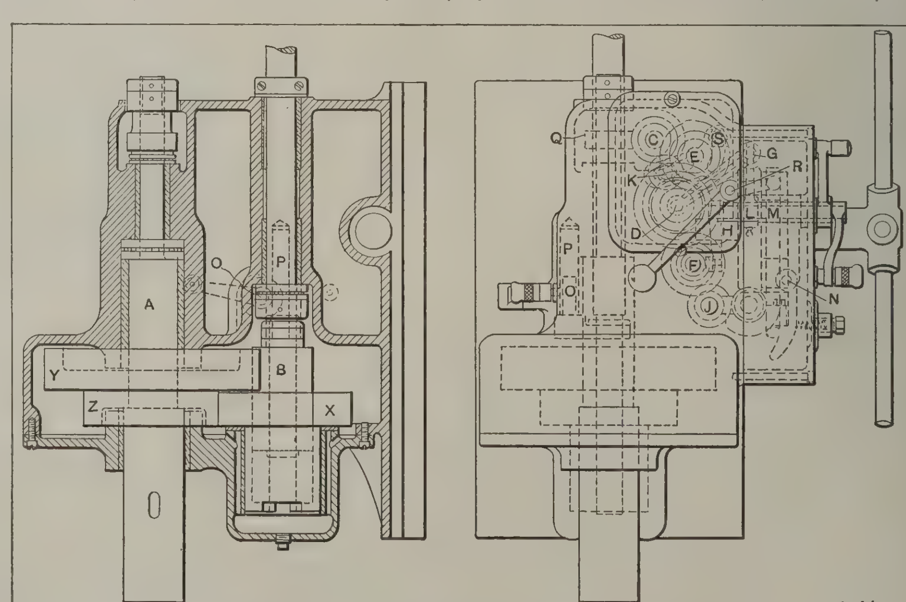
and the one to the extreme right is attached by a key. Gear *Y* runs loose on the shaft and gear *Z* has a positive clutch formed on the hub and is splined to the shaft. When tapping is being done, the drive is from shafts *D* to *F* through gears *X* and *Z* and when the regular spindle feeds are desired, gear *Z* is shifted to the left (by lever *H*, Fig. 8) until its clutch engages a corresponding clutch on gear *Y*, thus locking the latter to shaft *F*. The feed movement is then transmitted from *D* to *F* either directly through gears *V* and *Y* or indirectly through the cone of gears *E*, depending on the position of the dive key. Three feed changes are obtained by shifting the dive key and, by the use of two change-gears at *T*, six



Figs. 5 and 6. Spindle Driving and Feeding Mechanism

additional variations are secured. From shaft F power is transmitted to the feeding worm by a spur gear on shaft J, Fig. 6. The worm is hung in a bracket pivoted around shaft J and it can be raised into mesh with the worm-wheel by lever F (see Fig. 9) on the front of the head. When the worm is in mesh, it is secured by a finger f (Fig. 8). The feed is transmitted from the worm-wheel through the spur gearing shown in Fig. 7, to a rack secured to the face of the column which gives the vertical movement. The power feed can be automatically tripped at any point by means of an

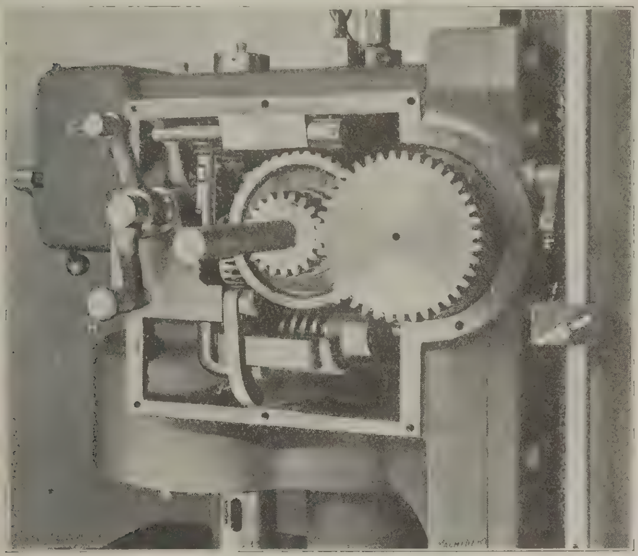


Fig. 8. Feed Box with Cover Removed

adjustable stop t, Fig. 8, which engages with lever r, thus releasing trigger f and allowing the worm-wheel to drop out of mesh. The spindle-head has an automatic down-feed on the column of 40 inches, and the distance from the column face to the center of the spindle is 14½ inches.

The design of this machine is compact and extremely rigid throughout. In case it should be desired to bore open-end cylinders or similar work, provision has been made for steadying the lower end of the bar, it simply being necessary to drill and bore a hole through the table into a hub on the under side and insert the necessary bushing. The lower end

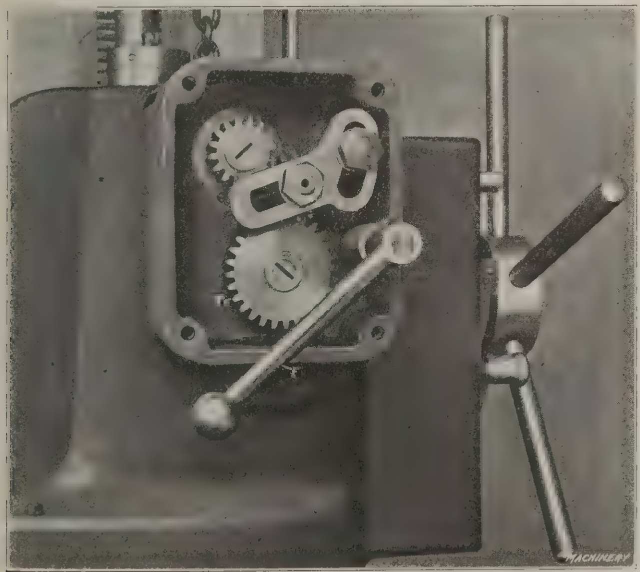

Fig. 9. Front Gear Box with Cover Removed

of the boring-bar can then be passed through this bushing which forms a rigid support.

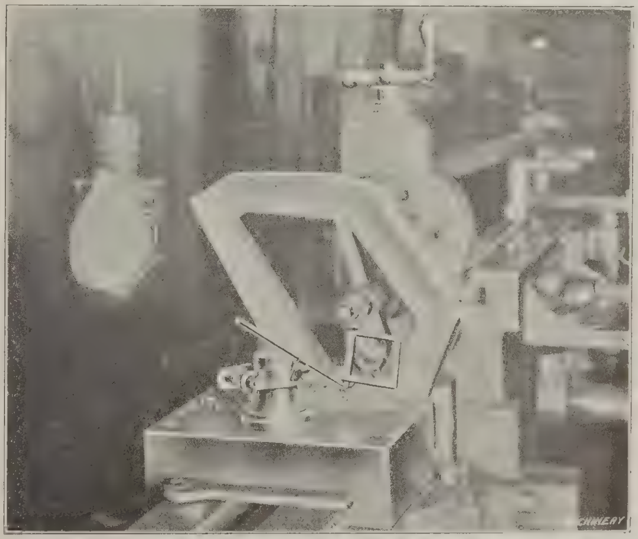
The lubrication of this machine has received careful attention. All gears in the head and quick-change box run in a bath of oil, and the head alone will hold seven gallons of lubricant. The bearings are made self-oiling by means of wicks fitted into slots milled in the bearings, the ends of the wicks dipping into oil reservoirs. The loose pulley on the countershaft also has a wick, the end of which dips into a reservoir cored out of the hub. These reservoirs hold enough oil to last for several months.

In case a motor drive is desired, the motor can be mounted on the back of the column in place of the countershaft. The weight of the machine is about 8500 pounds. It may be seen in operation at the demonstration shops of Hill, Clarke & Co., Inc., in Boston and Chicago, and in the branch offices at New York, Philadelphia, Cleveland, Milwaukee and Rochester.

UNIVERSAL CHIP GUARD

In the department of New Machinery and Tools for April, 1911, we illustrated a lathe chip guard manufactured by the Universal Stamping Co., 47 Poultney St., Buffalo, N. Y. This guard is now equipped with a stationary base block as shown in the accompanying illustration to adapt it for use on the shaper. The bottom of this block is covered with rubber, which prevents any slipping from the jar incident to the shaper's motion. Either a plain glass or a magnifying glass may be inserted in the holder. The magnifying glass not only protects the eyes of the operator but magnifies the layout lines on the work, which is often desirable, especially in connection with toolmaking.

The utility of a guard of this kind is shown by a report on the cause of shop accidents. From a total of 670 accidents in connection with lathe work, 127 were caused by flying chips, or by the flying out of articles being turned. Of course, most of these accidents were not very serious and



Method of using Chip Guard in Connection with Shaper Work

did not result in permanent injury, but the figures show that the protection afforded by a chip guard is very much needed for certain classes of work.

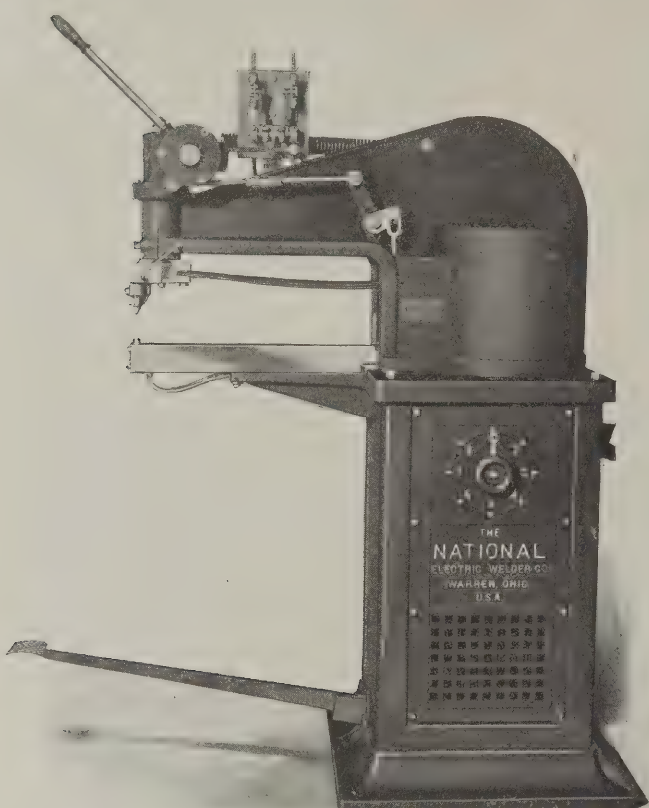
NATIONAL ELECTRIC SPOT WELDER

The use of the electric welding process, especially in connection with sheet metal work, is rapidly superseding the older method of riveting, in the manufacture of a great many parts. Many articles formerly made of wood are now constructed of sheet steel, which has resulted in still further increasing the use of the electric welding process. The spot welder not only gives an increased production, but a neater finish, which is an important feature in connection with many classes of work.

The electric spot welder shown herewith is a product of the National Electric Welder Co., Warren, O. This is a 24-inch size, which means that it will weld to the center of a 48-inch sheet. When this machine is equipped with points or dies not more than ⅜ inch in diameter where they bear on the work, it is said to make 1000 spot welds in 16 gage steel or iron for ten cents, with current costing four cents per kilowatt hour, or three cents per horsepower hour. An alternating current is used, and the 12- and 24-inch standard spot welders have an improved shell-type transformer of 15 kilowatt capacity, designed to reduce the line voltage to 4½

volts, which is the highest voltage required. The machine also has a regulating coil which gives eight different voltages at the welding points. These variations are indicated by a dial at the side of the machine, which is placed in the proper position by the handwheel shown. This feature is necessary, as the voltage required to spot weld varies with the thickness of the material.

This machine is equipped with an automatic switch so designed that it is absolutely impossible to turn on the operating current until the welding points are brought firmly into contact with the metal to be welded. The act of releasing the pressure on the points also immediately opens the switch, which prevents burning the work or destroying the



Electric Spot Welder, built by National Electric Welder Co.

copper points. The welding points are cooled by a continuous stream of water flowing through them, which increases their durability.

The machine can be operated either by hand or independently and without making any changes or adjustments. The use of the foot-lever permits the operator to hold and adjust the work between the welding points with both hands. The use of the foot-treadle, however, gives exactly the same results as when the hand lever is employed. When the machine is operated by the hand lever, the foot lever does not move and it can be removed readily if desirable. The extended hand lever can also be easily taken out as it is fitted into a socket in the clutch plate.

The switch is a new design of the double-pole, double-break type, having four points of contact. This switch opens both sides of the primary circuit in two places, which avoids excessive flashing with currents of high amperage and voltage. This switch is placed on top of the machine and it has the advantage of being stationary, which avoids any trouble from the crystallizing and breaking of the flexible leads. The contacts of the switch are so designed that they can be removed readily. A complete set of contacts costs only a few cents and will ordinarily last from six months to one year.

Two pieces of ⅜-inch boiler plate can readily be welded together with this machine. Sheet steel 1/16-inch thick can be welded at the rate of thirty spots or welds per minute, and ⅛-inch steel stock can be welded at the rate of twenty spots per minute. This machine is designed to be "foolproof," which not only minimizes the cost of maintenance, but increases the output.

BARNES DRILLING MACHINE

The Barnes Drill Co., 814 Chestnut St., Rockford, Ill., is now manufacturing a 26-inch all-geared drill of the sliding-head type. This machine, with the exception of the sliding head, is designed along the same general lines as the all-geared type formerly built by this company. Fig. 1 illustrates a standard machine, and Fig. 2 is a view showing the opposite side of a machine equipped with a motor drive.

This design is said to have the power of an ordinary 36-inch, cone belt driven type. There are eight geared speeds and a similar number of geared feeds, all of which may be controlled from the front of the machine. The feed for any position of the controlling lever is shown by plain figures, and the feeds range from 0.005 inch to 0.086 inch per revolution of the spindle. The spindle is 1 15/16 inch in diameter in the sleeve and it is double splined. The crown and pinion gears are of extra large diameter and have teeth of four pitch, thus giving a strong drive. The head and spindle are counterbalanced by a weight inside the column which is suspended on a roller-bearing sheave wheel. The head is securely locked to the column face at any point within its travel, by two quick-

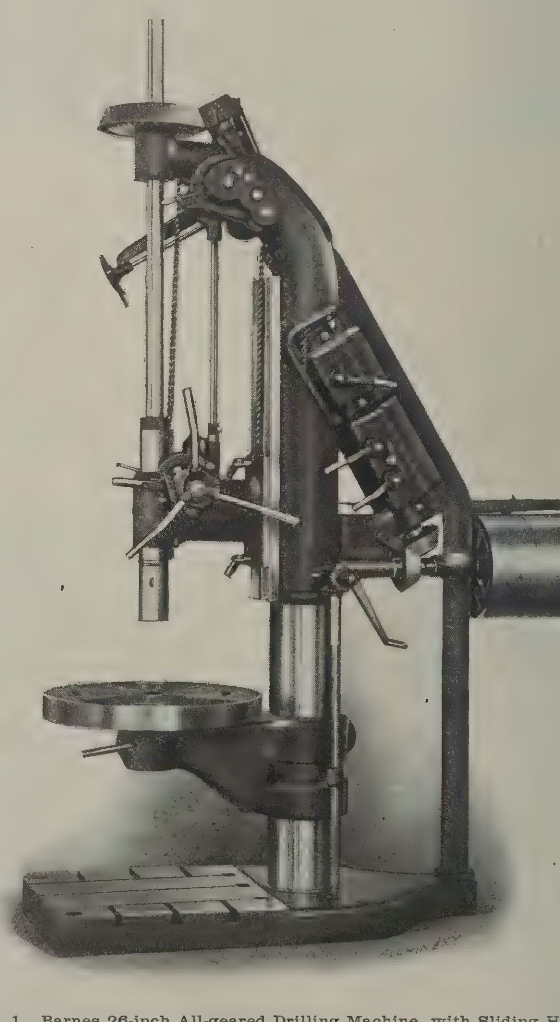


Fig. 1. Barnes 26-inch All-geared Drilling Machine, with Sliding Head

acting clamp screws, and it is raised and lowered by a crank pinion and rack which may be seen in Fig. 2.

This machine is guaranteed to drive a 2-inch high-speed twist drill with a feed of 0.041 inch per revolution of the spindle and at the rate of 6½ inches per minute, in cast iron without using the back-gears. A drill of this size has been driven at the rate of 8¼ inches per minute during tests. A 1-inch high-speed twist drill can be driven through cast iron at the rate of 13½ inches per minute, provided the drill itself will stand this pace.

Suitable feeds are available for boring-bar work, and the machine will bore holes 8 inches in diameter or even larger.

The machine illustrated in Fig. 2 is equipped with a special boring-bar which is used for boring and reaming the exhauster bodies of vacuum cleaners. The holes are 6 inches in diameter and 6½ inches deep, and the work is said to be done very accurately. The sliding head is necessary in connection with this work, in order to remove the tools. The adjustment of the head can be easily effected by the rack and pinion movement, previously referred to. It will be seen that the boring heads, two of which are shown on the base of the machine, are equipped with pilot bars. This same machine is also used for boring the bearings, one of which is shown at the foot of the column.

Some of the general dimensions of this machine are as follows: Distance from column to center of table, 13¼ inches; diameter of column, 7½ inches; diameter of table, 23 inches; vertical travel of table, 20 inches; vertical travel of spindle for one position of the head, 14 inches; adjustment of the sliding head, 23 inches; maximum distance from spindle to base, 54 inches; minimum distance, 18½ inches; maximum distance from spindle to table, 40 inches; ratio of back-gearing, 4 to 1; diameter of the crown gear, 10 7/16 inches; diameter of bevel pinion, 5 inches; net weight of machine, 1750 pounds.

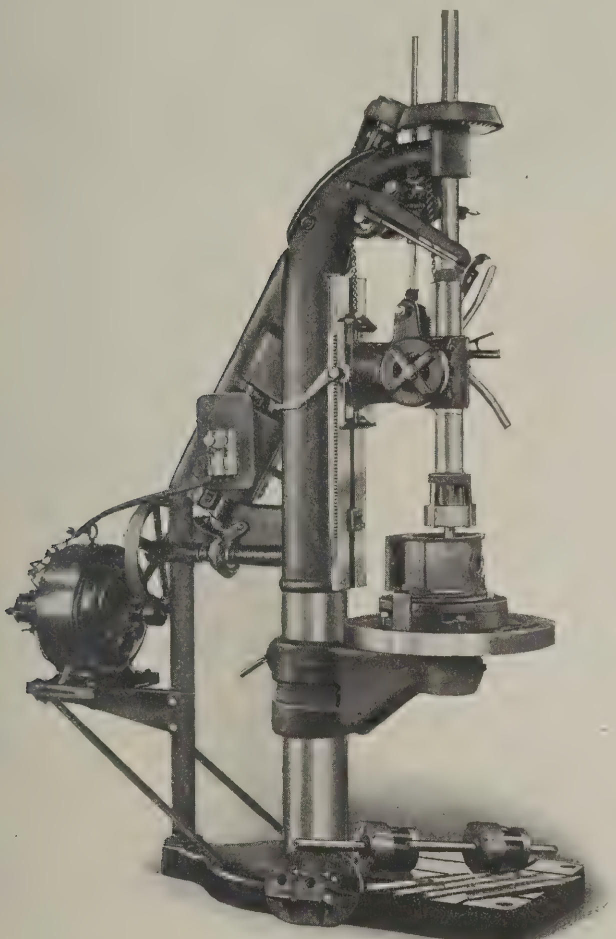

Fig. 2. Barnes Drill equipped with Motor Drive

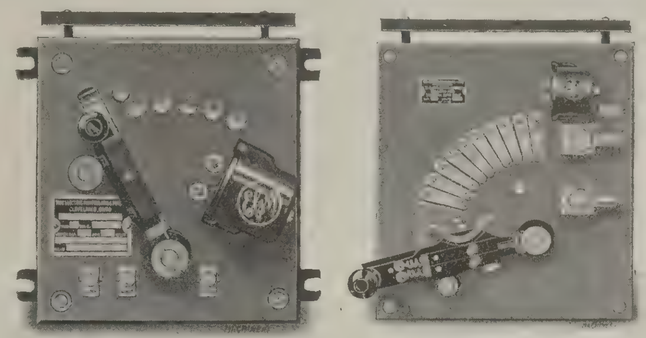
MOTOR-STARTING RHEOSTATS

The Electric Controller & Mfg. Co., Cleveland, O., has brought out a new line of starting rheostats for series, shunt or compound wound, direct-current motors. The contacts on all sizes of these rheostats, can be removed from the front without disassembling or interfering in any way with the wiring or resistance. The retaining magnet is iron-clad, thus being protected from mechanical injury. The resistance wire, the capacity of which is liberally proportioned, is wound on asbestos-covered, metallic tubes through which a draft of air flows. This draft of air conveys the heat away from the resistance, but does not at any time touch the hot resistance wire; the result is an unusual freedom from oxidization of the resistance wire.

These rheostats are regularly furnished in sizes varying from ¼ horsepower to 35 horsepower for 110 volts, and from ¼ horsepower to 50 horsepower for 220 and 550 volts. Starters similar to the style shown in Fig. 1, are supplied for motors up to and including 7½ horsepower with 110 volts, 15 horsepower with 220 volts and 20 horsepower with 550 volts. For larger sizes, the type shown in Fig. 2 is used.



Figs. 1 and 2. Rheostats made by Electric Controller & Mfg. Co.

BROWN PYROMETER WITH ILLUMINATED DIAL

The Brown Instrument Co., of Philadelphia, Pa., has added to its line of electrical pyrometers, a new illuminated-dial indicator having an exceptionally long scale. Frequently an instrument is desired which can be read easily by the operator of a furnace or kiln, at some distance, and this pyrometer with an illuminated dial is particularly desirable for just such conditions. This instrument has a scale 12 inches long and it can be furnished without the illuminated dial if desired. Where the illumination is sufficient, the instrument does not require an illuminated dial, as the long scale affords very open graduations and accurate readings. In many plants, however.

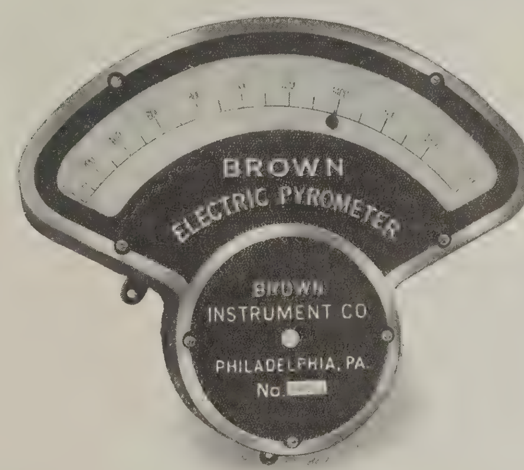


Fig. 1. Brown Pyrometer

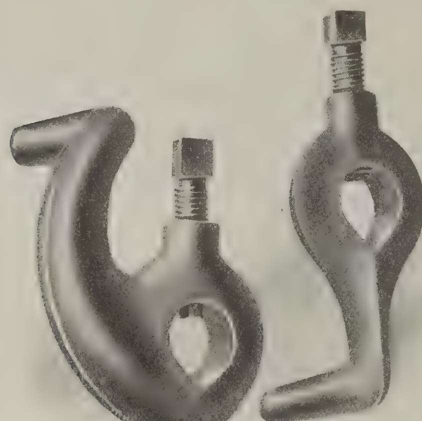
Fig. 2. Rear View of Pyrometer showing Method of Illuminating Dial

where there are dark rooms for hardening and heat treating steel, and where work is carried on day and night, the illuminated instrument is preferable. The scale is drawn on opaque glass, and a sixteen candle-power lamp is placed behind the scale, which makes the graduations and the pointer stand out clearly at a distance. Better results are often secured with this instrument because more accurate readings of the temperature can be obtained.

SAFETY LATHE DOG

Every machinist who has operated a lathe realizes the danger connected with the use of the ordinary lathe dog with its unguarded set-screw which tends to catch in the clothing, especially when filing. A safety lathe dog has been brought out by Elmer J. Michaud, S. Windham, Conn., which is so



Safety Dog and Ordinary Type

shaped that the set-screw is guarded. This new dog and also the ordinary type is illustrated herewith. The "tail" of the safety dog is curved around in front of the set-screw on the leading side—as determined by the direction of rotation—thus affording protection. This feature does not affect the convenience of loosening or tightening the set-screw.

UNIVERSAL EMERY WHEEL GUARD

The emery wheel guard illustrated in Fig. 1 is designed to be applied to practically any make of shop tool-grinder. It will cover emery wheels up to 8 inches in diameter and 1½ inch thick. This guard covers the outside of the wheel and also the end of the spindle and retaining nut. The inner side of the wheel is left open to permit using the full width

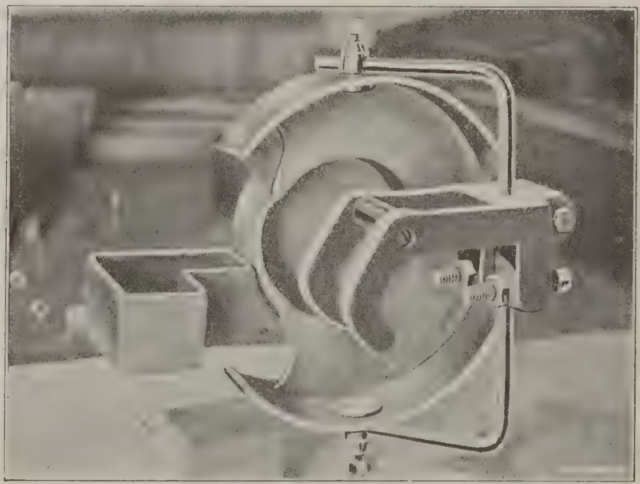


Fig. 1. Emery Wheel Guard made by Universal Stamping Co.

in case this is necessary. The application of this guard to a tool-grinder of the bench type is illustrated in Fig. 2. The guard proper is supported by a steel rod which, in turn, is held by a clamp attached to the spindle bearing box. This clamp, the form of which is clearly shown in Fig. 1, is made in two pieces which are held together by two cap-screws. It is clamped over the bearing boxes by two set-screws, which are locked with jam-nuts. By loosening the rear cap-screw on the clamp and the two binding posts seen above and below the guard, the supporting rod can be raised or lowered or swung to the right or left, thereby allowing the guard to be adjusted as the wheel wears. The water pan is located just below the grinding rest and is attached to the guard proper

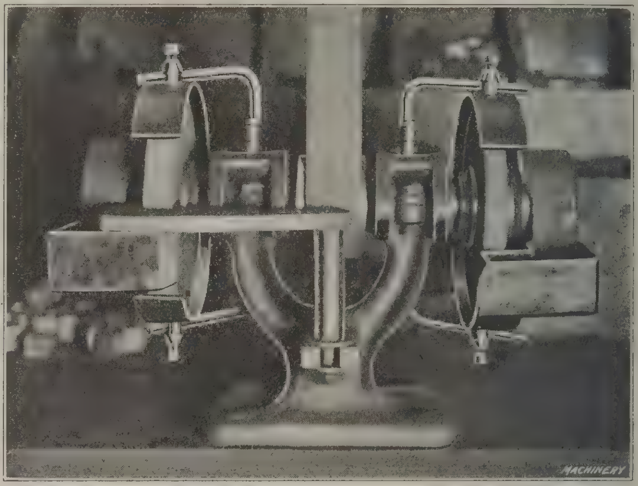

Fig. 2. Tool-grinder equipped with Universal Wheel Guards

by a screw. This pan is not only useful for cooling purposes, but aids greatly in settling the dust. It can be attached or removed quickly for cleaning or filling. When this guard is properly adjusted there is no chance of emery or grindings flying into the eyes of the workman. It is manufactured by the Universal Stamping Co., 47 Poultney St., Buffalo, N. Y.

SENECA FALLS 12-INCH QUICK-CHANGE LATHE

The Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y., has just placed on the market a 12-inch quick-change lathe of the same design as the 14-inch size described and illustrated in the department of New Machinery and Tools for December, 1910. The quick-change feed mechanism of this lathe provides forty-eight changes for the lead-screw, which is also used as a feed-rod. All standard threads from 1½ to 92 per inch, including 11½, can be cut, and feeds varying from 0.0023 to 0.142 inch per revolution of the spindle are available.

The index plate shows clearly how to obtain any thread or feed. There is a micrometer stop for the cross-slide by means of which minute adjustments can easily be made. The stop is adjusted by a worm-gear operated by a screw having a knurled knob. The graduations on the micrometer barrel are about ⅛ inch apart and represent 0.00025 inch. The stop mechanism is thrown in or out of engagement by a knob inside the handwheel. The reverse mechanism for the cross and longitudinal feeds and lead-screw consists of a set of spur gears and clutch in the headstock. The reverse mechanism is operated through levers connected by a rod with a hand lever arm on the apron. An automatic stop for the carriage operates in either direction by means of adjustable stops on the reverse rod. The headstock is a deep web pattern and has a forged crucible steel spindle revolving in large bearings provided with oil rings. A draw-in chuck with collets up to ¾ inch can be furnished. A new binding device secures the plain and compound rest to the cross-slide. An automatic safety device prevents engaging opposing feeds, and the feed gearing is disengaged when cutting threads so that the longitudinal handwheel does not revolve.

POLISHING STAND OR JACK

The general appearance and interior arrangement of a new polishing stand or "jack" built by F. E. Wells & Son Co., Greenfield, Mass., is shown in the half-tone engraving, Fig. 1, and the line illustration, Fig. 2. This machine was first built for the company's own use and proved so satisfactory that it has been placed on the market. By referring to Fig. 1, it will be seen that the machine is intended to be driven from beneath the floor. With this form of drive any chance of accidents from the driving belt is eliminated and

all of the mechanism is self-contained. The enclosed construction also furnishes an ideal protection for the bearings from dust.

The interior mechanism is shown by the sectional and side views Fig. 2. The driving belt which connects with a driving pulley beneath the floor, runs over pulley *C* on the main shaft *D* of the machine. This shaft runs in bronze boxes the bearings of which are lubricated by means of ring oilers *L*. The driving belt normally runs slack and then the spindle or polishing shaft *D* is at rest. The machine is started by simply depressing the hand lever *H* at the side of the column. This lever controls the movement of an idler pulley *F* which is

Fig. 1. Polishing Jack built by F. E. Wells & Son Co.

mounted on shaft *E*, contained in a yoke that fulcrums about shaft *G*, so that when lever *H* is depressed, the idler pulley is forced against the driving belt thus tightening it. Lever *H* has an adjustable weight *I*, and when the idler pulley is thrown into contact with the belt it is retained in that posi-

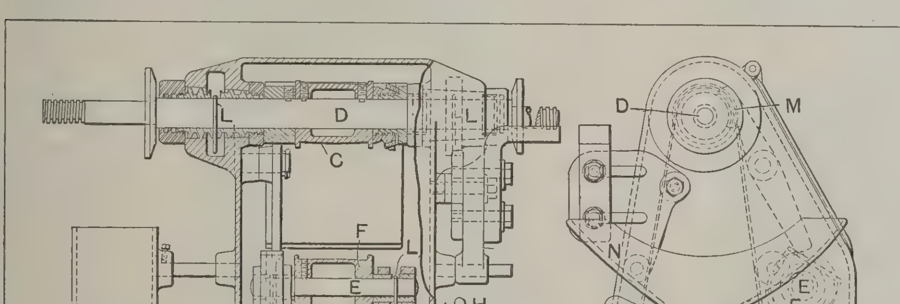

Fig. 2. Views showing Idler Belt-tensioning Device of Wells Polishing Jack

tion by the engagement of pin *J* with a projection *K* on the frame of the machine. As soon as the idler is swung away from the belt, the spindle *D* is quickly stopped by a brake *M*, which is automatically applied by the backward movement of the idler yoke. This machine can be equipped with a special shaft for carrying two wheels in case this is desirable. A swinging arm with a table for disk grinding can also be furnished.

FARWELL UNIVERSAL GEAR HOBBING MACHINE

The Adams Co., 874 Market St., Dubuque, Iowa, has added to its line of gear hobbing machines, a No. 4 size adapted to the cutting of spur or spiral gears, worm-wheels and worms,

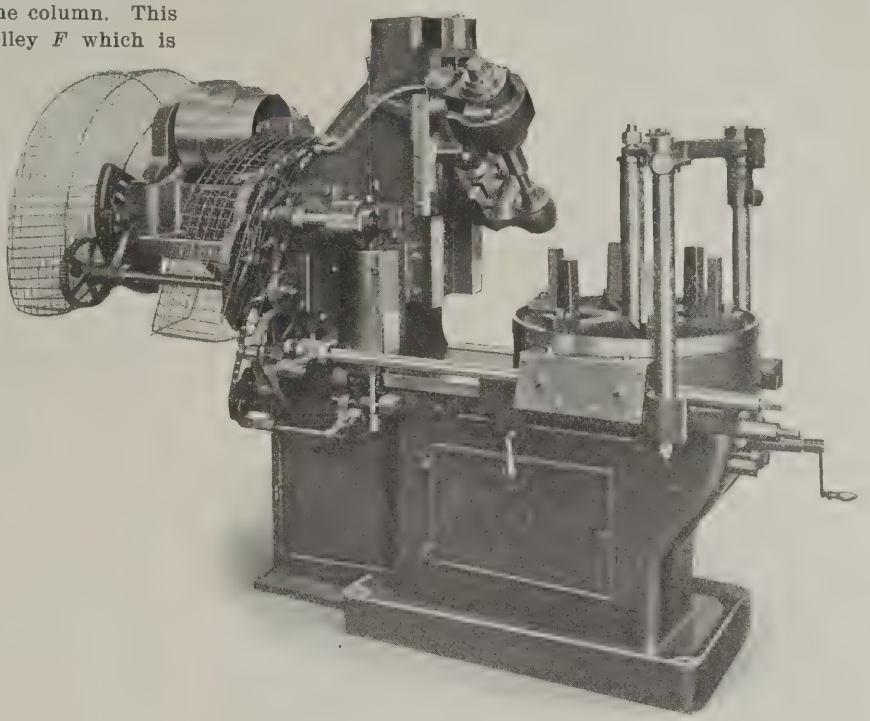

Fig. 1. Farwell Universal Gear-hobbing Machine

up to 24 inches in diameter and with 3 diametral pitch in cast iron and 3½ pitch in steel. This machine, a general view of which is shown in Fig. 1, has such a wide range of feeds and table speeds as to make it universal.

Change gears can be furnished for cutting a single-thread worm or a screw of fine pitch and, in addition, worm, spiral or spur gears, having a wide range as to the pitch and number of teeth, can be hobbed. The vertical feeds of the cutter head range from 0.002 to 0.500 inch per revolution of the table. The table may be geared to make one revolution to two revolutions of the cutter, or it may be geared to make one revolution to a thousand or more revolutions of the cutter. This wide range of feeds and table speeds is, of course, unnecessary for ordinary spur, spiral and worm-gear cutting, but no additional complication was incorporated in the design to obtain this range. The drive for the table and feeds is such that the compounding of a comparatively small number of moderate size gears enables this range to be obtained.

This machine is especially designed for gear- and worm-hobbing, but the slow table travel relative to the cutter speed, which is available, enables the machine to be used also as a continuous or circular milling machine. A special spindle and bracket, such as is shown in Fig. 3, may be secured for this purpose. The cutter-head has been made as rigid as possible by using a wide saddle and swivel of heavy construction. The cutter spindle is large and has a hole through which the arbor proper passes. The arbor is driven by a long key, and adjusting nuts on the arbor at each

end of the spindle provide a longitudinal adjustment of the hob. The spindle is driven by a steel spur gear and pinion, and both the spindle and pinion shaft run in adjustable bronze bearings located on each side of the gears, thus equalizing the strain.

There is but one pair of bevel gears in the spindle drive. A reducing gear of large diameter is interposed between the cone-pulley shaft and a universal-joint shaft which transmits power to the spindle. This is the same drive which has been satisfactorily used on the No. 3 machine. The universal joints are of special design and are provided with large wearing surfaces of steel bearing on bronze. Wear can be compensated for readily, and there are felt oil retaining pads to facilitate lubrication. The cutter-head has an automatic stop and a rapid power return movement.

The table saddle has a power inward feed ranging from one-quarter thousandth to three-eighths inch for each revolution of

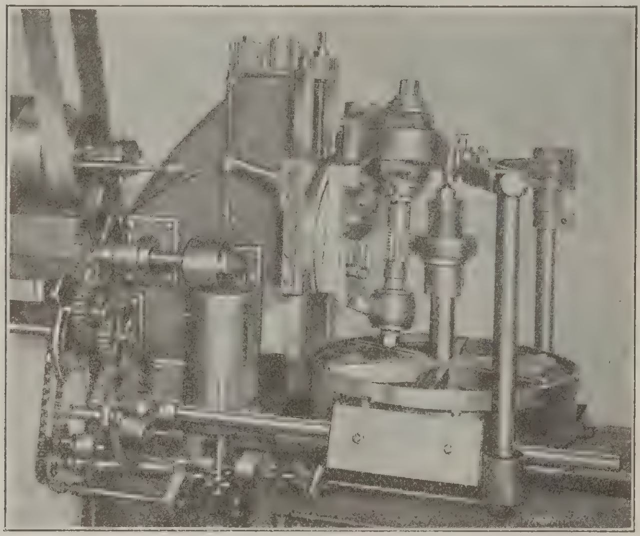

Fig. 2. Farwell Machine cutting Spiral Gear having Tooth Angle of over 80 Degrees

the table. An automatic depth stop is provided for worm-wheel hobbing. The table may be geared to cut anything from a single-threaded worm to a gear having a thousand or more teeth, including all prime numbers. A regular set of change gears (120 in number) will give all the feeds mentioned and will enable gears having any number of teeth up to 200, to be

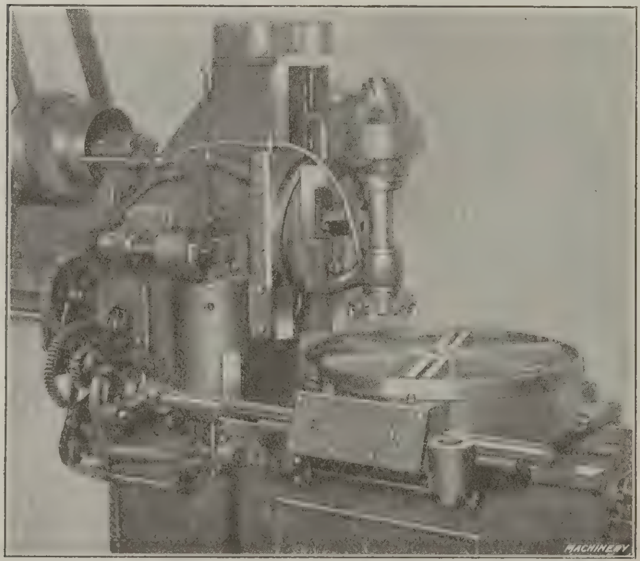

Fig. 3. Gear-hobbing Machine arranged for Continuous or Circular Milling

cut, and many composite numbers above the figure mentioned. Special gears can be furnished to cut all other numbers including prime numbers.

The countershaft furnished is provided with three clutch pulleys, giving a hobbing speed in both directions and a slow speed for driving milling cutters. The lubricating pump is arranged to run in the right direction when the direction of the spindle is reversed. The table is driven by a steel worm engaging a bronze ring worm-wheel. This worm-wheel is 20 inches in diameter which is within four inches of the machine's maximum capacity. Provision is made for easily taking up any wear, either in the mesh or end motion of the worm. The table is of heavy rib or spoke-and-rim construction, and the top between the ribs, instead of being level, is

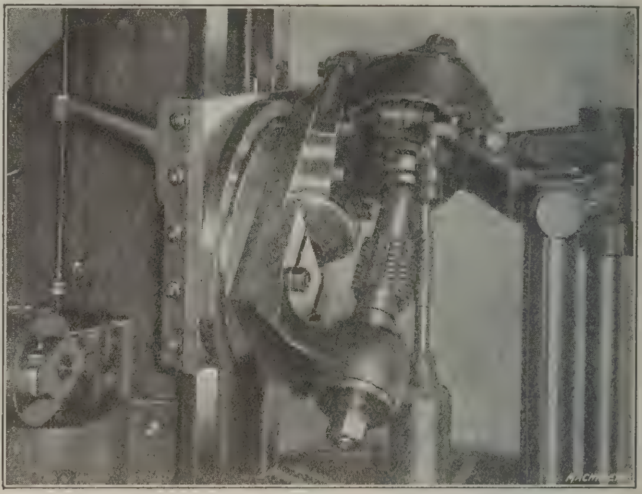

Fig. 4. Hobbing Small Five-threaded Worm on Gear-hobbing Machine

depressed to a cone shape. This conducts all chips and lubricant into a pan in the base of the machine. The lubricant drains out of the pan into a tank below. The pan may be removed easily through the door shown, when necessary. The weight of the machine, complete, is about 3900 pounds.

NIAGARA POWER DOUBLE SEAMER

The machine shown in Fig. 1 of the accompanying illustrations, is made by the Niagara Machine & Tool Works, Buffalo, N. Y., and is especially designed for double-seaming the heads of drums and other sheet-metal packages. The

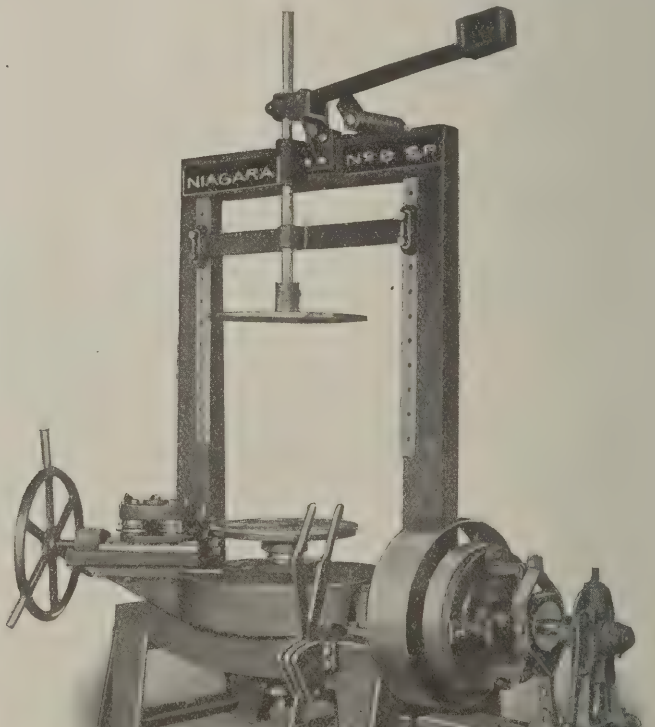

Fig. 1. Niagara Power-driven Double Seaming Machine

heads must be previously stamped to the proper shape by means of a press and dies. The work to be double-seamed is clamped between the top disk and the lower double-seaming chuck, which is shaped to suit the work. The chuck is driven by means of bevel gears, and the spindle carrying the chuck

has an adjustable end thrust bearing. The carriage with the double seaming rolls mounted in a turret head, is actuated by means of a screw and the handwheel shown. Either two or three rolls are used according to the type of the seam and thickness of the material. The motion is controlled by a friction clutch actuated by one of the hand levers seen at the right side of the lower chuck. The other lever is used to bring down the upper clamping plate, which is counterbalanced.

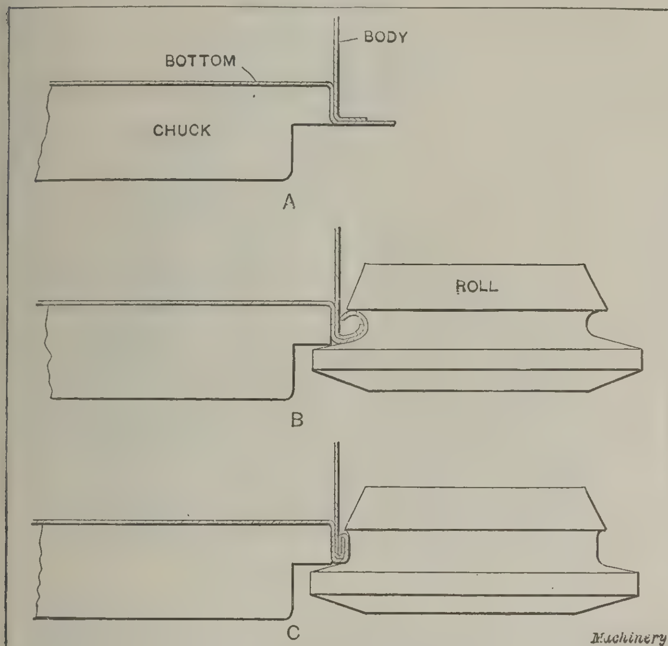

Fig. 2. Forming a Double Seam

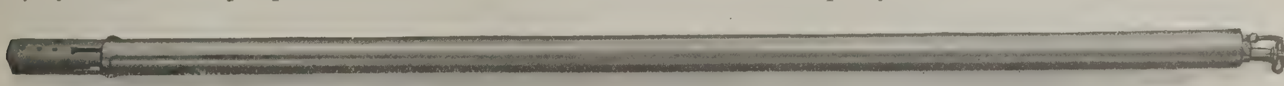
The successive steps connected with forming a double seam are illustrated in Fig. 2. The first view at *A* shows the body and bottom of the work assembled and ready for seaming. The first seaming roll is then brought up against the flanges on the work which are turned over as indicated at *B*. The turret is then indexed, thus bringing the finishing roll in position. This roll is then moved in against the work, thus flattening and locking the seam together as indicated at *C*. This seamer has a capacity for work varying from 10 to 32 inches in diameter and not exceeding 45 inches in height.

TURNER HOT BLAST TUBULAR TORCH

The Turner Brass Works, Sycamore, Ill., has designed a hot-blast gasoline torch, which is about five feet long, two inches in diameter and is made of heavy gage brass tubing. This new torch produces a very hot blast flame which is easily controlled by the gasoline valve. There is a powerful burner at one end, and the gasoline valve and pressure pump is located at the other end, as shown in the accompanying illustration. The long tube forming the body contains the gasoline that is delivered to the burner. This tube holds about three quarts. A controlling valve inside the tube regulates the flow of fuel in such a manner that the torch can be used in any position, the flame being pointed up or down, as required. Air pressure for the blast is pumped into the gasoline chamber, the same as in any other torch, by means of a pump at the end of the tube. The flame is about two inches in diameter at the burner and approximately twelve inches long.



Turner Hot-blast, Tubular Gasoline Torch

This torch is intended for foundry use in connection with drying and baking sand molds, and it can also be used for preheating purposes, burning paint (especially on a large scale) thawing out frozen pipes, melting ice, and for heating the ground in advance of general construction work. Other uses for a torch of this form will readily suggest themselves. The weight of the torch is about seven pounds.

UNIVERSAL VISE AND SURFACE TABLE

The vise illustrated in Fig. 1 has a universal adjustment which makes it possible to hold odd-shaped parts, as well as ordinary shapes in the best position for the workman. The swiveling base gives an angular adjustment and the vise can be raised or lowered to the most convenient height. The vise can also be turned about the axis of its supporting column. These various adjustments enable the workman to secure the best light on lines or prick-punch marks indicating finished surfaces, and they also prevent stooping or working in an awkward attitude as is often necessary with the ordinary fixed vise. The vise is rigidly held in any position by a single clamping lever, and when a vertical adjustment is made, the vise is held automatically until the lever is tightened by a locking collar on the stem. These vises are made in four styles and four sizes.

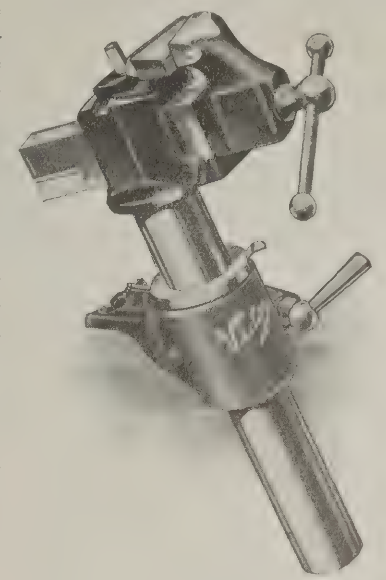


Fig. 1. Vise having Universal Adjustment

An accessory to this vise is illustrated in Fig. 2. This is a surface-table or plate which can be mounted in the base as shown. This plate can also be detached from the stem and used on the bench, the same as an ordinary surface-plate. The sizes of these plates are made to suit individual requirements. These vises and surface tables are the product of the Victor Vise Co., 15-19 W. Washington St., Springfield, O.

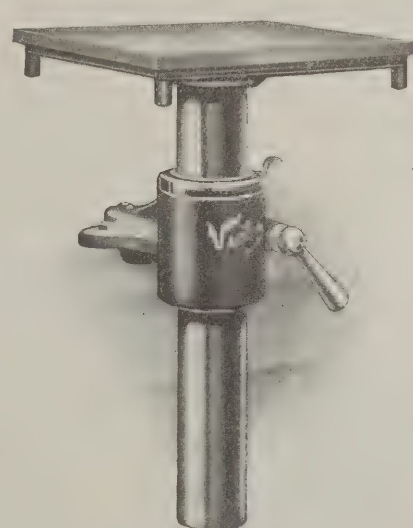

Fig. 2. Surface-table mounted on Vise Base

ROCKFORD HAND MILLING MACHINE

The No. 3 hand milling machine built by the Rockford Milling Machine Co., Rockford, Ill., is now equipped with a power longitudinal feed whenever such a feed is desirable. The arrangement of the feed mechanism is very simple. The power is derived from the rear end of the main spindle, which carries a three-step cone-pulley. This pulley connects by belt with a lower pulley mounted on the end of a universally-jointed shaft which transmits motion, through gearing, to the work-table. By reversing the cone pulleys, six changes of feed can be obtained. This machine has the regular combination screw and lever feed. These two feeds do not interfere, and the change from one to the other can be quickly made. The advantage of this double feed arrangement is obvious. This machine can be used for either horizontal or vertical milling, and, by means of special attachments, it is adapted to a wide range of work. There is a longitudinal power feed of

11 inches, a transverse feed of 4 inches and a vertical movement of $6\frac{1}{4}$ inches. The working surface of the table measures 18 by $4\frac{1}{4}$ inches.

BRADFORD GEARED-HEAD MOTOR-DRIVEN LATHE

The Bradford Tool Co., Cincinnati, O., has brought out a geared-head, motor-driven lathe, which is a departure from conventional designs, as will be seen by referring to Fig. 1. This lathe is designed to eliminate top-heaviness and vibration, and, at the same time, secure a more compact machine by locating the motor as indicated in Fig. 2. The lathe has a mechanical reverse movement and mechanical speed changes which are easily and quickly made. If a constant speed motor is used, eight spindle speeds varying from 12 to 398 revolutions per minute, are available, and an indefinite number of speeds can be obtained by using a $1\frac{1}{2}$ to 1 variable speed motor, having a simple starting and regulating rheostat.

An effort has been made to arrange the speed controlling levers so conveniently that the operator will always use an efficient speed. A selective type, automobile design of speed-box is incorporated in the drive and provides four of the speed changes. The revolutions per minute of the lathe spindle are plainly marked on a plate which shows the four positions of the speed-box lever and the right and left positions of the lever seen on the head. All of the changes are obtained by these two levers, and the speed-box lever is locked automatically when the lathe is running, thereby preventing breakage. The lower gear-box shaft is continued to the left of the gear-box and is in driving connection by means of a pair of gears as well as by a pair of Morse silent chain gears, with a short countershaft driven direct by a pinion on the end of the motor shaft. Either the gear or chain drive is engaged by friction clutch members controlled by the long shifter handle seen above the lathe. This feature enables the lathe to be run forward or backward and also provides an effective brake for stopping quickly when working up to shoulders. A shot-bolt in positive operating connection with the main clutch operating lever, prevents shifting the gears under load. The peripheral speed of the gears is very low. All parts are of easy access, and particular attention has been given to the matter of lubrication.

The head has for its first driver a short shaft carrying a Morse chain-wheel and a gear-wheel, both of which are in driving connection, respectively, with a chain-wheel on the right-hand upper gear-box shaft and a friction-clutch-operated gear on the main spindle. The latter gear is in driving connection with a gear on the back-gear shaft. This shaft also carries another gear which is, in turn, in driving connection back again to the lathe spindle by means of a second positive clutch-operated gear on the spindle. The lever seen on the head is in operative connection with the friction and positive clutches which respectively engage the high- and low-speed gears with the spindle. All supplementary speeds are obtained by the simple regulating rheostat, which is located just below the quick-change gear screw-cutting mechanism.

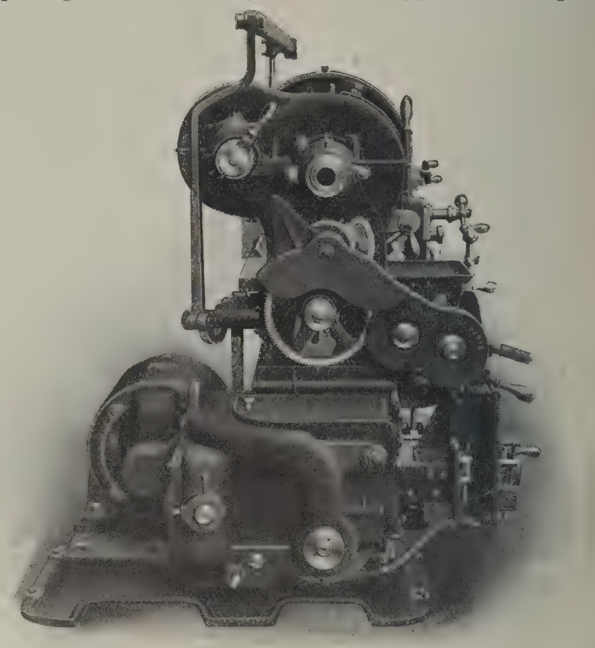

Fig. 2. End View of Bradford Lathe showing Location of Motor

The quick-change gear device is of the well-known Bradford type and enables the cutting of all standard and pipe threads, including $11\frac{1}{2}$ per inch. The gears are of forged steel, and ordinary change gears can be used direct between the spindle and lead-screw for cutting any odd thread. An automatic stop for the longitudinal feeds is provided regularly. The apron is equipped with a thread indicator and chasing dial, the worm-wheel of which can be disengaged from the lead-screw by a cam and knurled knob, thus avoiding unnecessary wear. All exposed gears are carefully guarded as the illustrations show, thus protecting both the operator and machine.

The spindle is made from high carbon crucible steel and it is mounted in adjustable, taper, bronze bearings. The bed

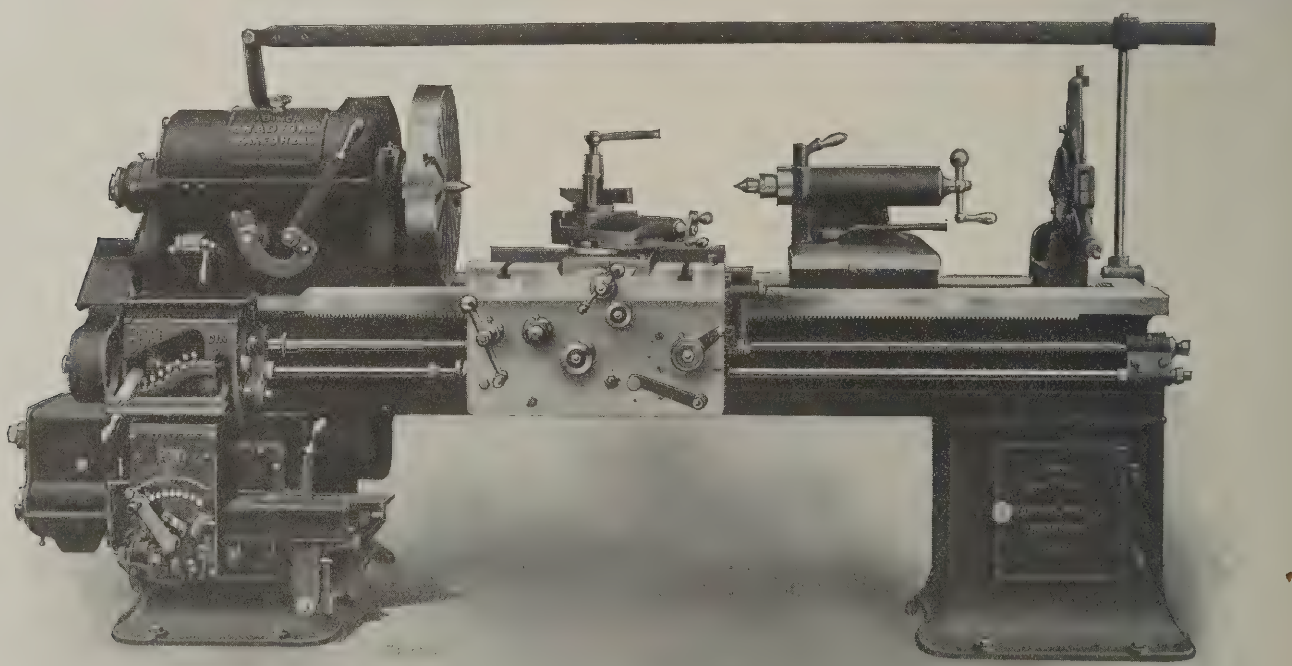

Fig. 1. Bradford Geared-head Motor-driven Lathe

is of extra weight and depth and is webbed in two-foot sections. The carriage has a full bearing on the vees its entire length and is gibbed front and back. The apron is of the double-plate pattern and has a non-interfering device to prevent the feed-rod and lead-screw from being engaged simultaneously. The pinions and studs are of high-grade steel, hardened and ground. The feeds cover a wide range and they are all positive geared. This lathe can also be arranged for a single-pulley drive instead of a motor drive. If a two-speed countershaft is used in conjunction with the selective speed-box and geared head, sixteen forward speeds may be obtained. The drive can be direct from the lineshaft if the latter is suitably located. The motor-driven and single-pulley lathes are made in 18-inch heavy pattern, 22- and 26-inch sizes.

HENDEY RELIEVING ATTACHMENT

The Hendey Machine Co., Torrington, Conn., has brought out an improved form of relieving attachment which can be used to relieve hobs or taps having spiral flutes. This new attachment can also be employed for relieving any of the work for which the design formerly built is adapted. The advantage of the spiral flute is that it gives a cutting edge that is square with the body of the tooth, which is conducive to better and faster cutting. This attachment is shown applied to a lathe in Fig. 1.

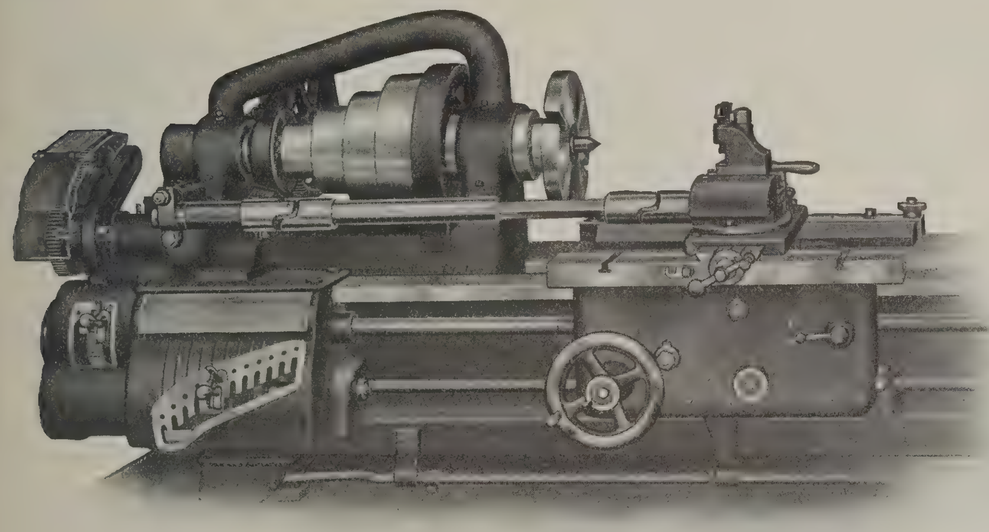

Fig. 1. Hendey Relieving Attachment applied to Lathe

The actuating mechanism is mounted on the main gear-box, the tool pan or cover of which is removed. The tool-slide interchanges with the compound or other rest on top of the cross-slide, and it can be swiveled to different angular positions for side and end relief work, as will be explained later. The mounting of the complete attachment requires but a few minutes. The amount of relief can be varied in a simple and easy manner, by means of a toothed coupling at the ends of the oscillating shaft and cam-lever, which permits the relative position of the eccentric on the tool-slide and the cam-lever to be changed, thereby lengthening or shortening the reciprocating travel of the tool. This adjustment gives the tool-slide a movement varying from zero to 5/32 inch on the 14-, 16- and 18-inch lathes, and the movement is increased to 3/16 inch on the 20-inch lathe, and to 1/4 inch on the 24-inch size.

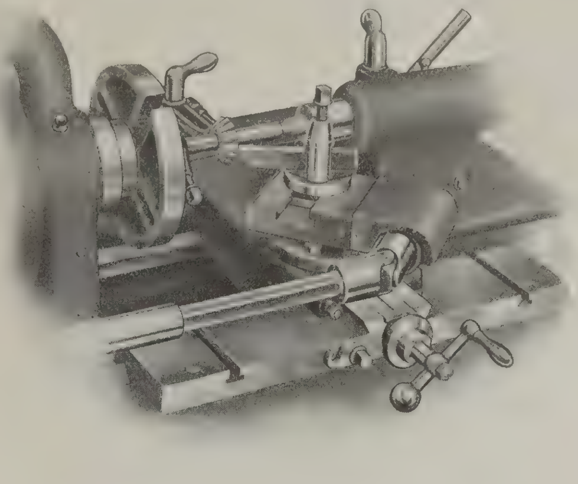

Fig. 3. Relieving Sides of Angular Cutter

If a hob or tap having spiral flutes is to be relieved with this attachment, the pitch of the spiral and the gears necessary to drive the attachment, are first determined. After the attachment is geared to suit the spiral and number of flutes, the lead-screw is engaged and the backing-off operation is performed the same as for straight flutes. The lead-screw should not be disengaged but the carriage is reversed by power, the lever at the right of the apron being used for that purpose. When determining the pitch of the spiral, it should be remembered that quite a variation in length can be made without any serious drawback. Fig. 2 shows the attachment relieving a spirally fluted hob.

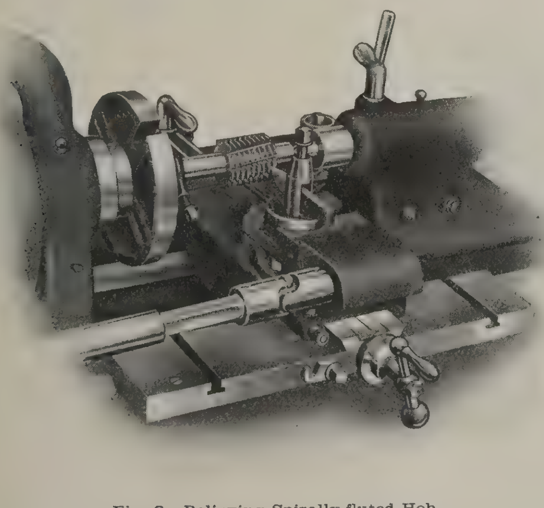

Fig. 2 Relieving Spirally-fluted Hob

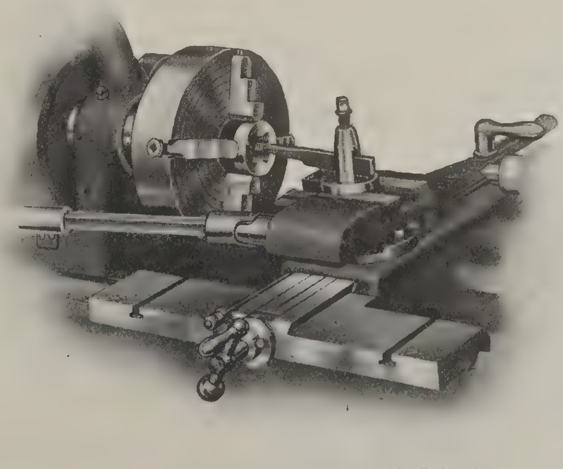

Fig. 4. Attachment arranged for Inside Relieving

Fig. 3 shows the method of relieving the side of an angular cutter. This application is made possible by means of the swiveling tool-slide which enables the tool to be placed in the

proper position. By the use of an additional universal joint and bearing to permit the tool-slide to be swung to a 90-degree angle, counterbores can be relieved as indicated in Fig. 5.

When the attachment is used for relieving inside work such as hollow mills and threading dies, the eccentric which controls the travel of the tool-slide is set so that the relieving movement is away from the axis of the cutter instead of toward it. This change is made by the toothed coupling connecting the cam lever and oscillating shaft, the latter being turned beyond the zero mark in a clockwise direction as far

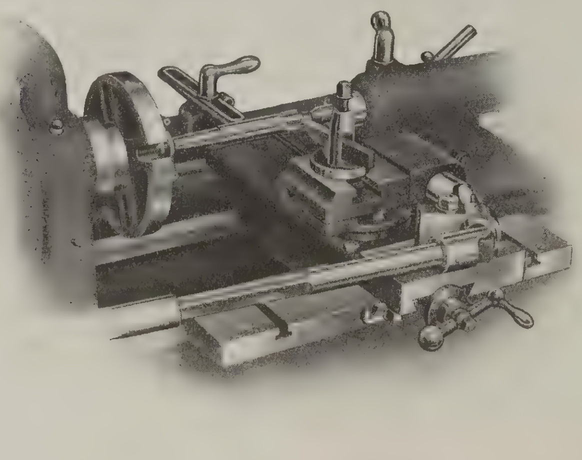

Fig. 5. Relieving a Counterbore

as is necessary to get the desired amount of travel. It is also necessary, for internal work, to change the position of the opposing spring in the tool-slide, so that it will press against the end of the slide and prevent the tool from "jumping" into the work. Fig. 4 shows an example of internal work.

When relieving a right-hand tap, the ordinary practice is to first set the tool as for cutting a thread. The tool is then accurately set with reference to the thread space by rolling

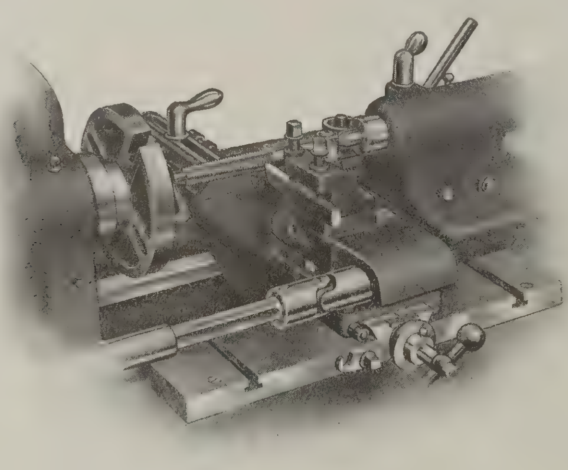

Fig. 6. Relieving Left-hand Tap having Spiral Flutes

the work in the dog or by disengaging the gears in the gear-box. The motion of the tool-slide is then adjusted so that the forward movement of the tool will meet the front of the tooth and the return movement begin promptly after leaving the end.

Left-hand taps can be relieved by two different methods. By the first, the cut is started at the cutting edge and ends at the "heel," and by the second, the start is made at the heel and discontinues at the cutting edge, the tool being drawn out from the work during the cut. When the first method is employed, the tap is placed with the point towards the headstock spindle and the shank end is supported by the tail-center as indicated in Fig. 5. An extension or blank end long enough to take the driving dog, is provided at the point of the tap. With the second method, the tap is held between the centers the same as a right-hand tap, but the travel of the tool-slide is set as for inside relief. As will be recalled, the necessary adjustment is made by the toothed coupling, and the opposing spring, in this case, is left in the same position as for right-hand work.

When work is being relieved, it should be revolved much more slowly than when turning, to give the tool-slide time to operate properly. A maximum of 180 teeth per minute is recommended, and if wide forming tools are used, the speed may be reduced to as low as 8 teeth per minute. It is also essential to use tools having a keen edge, and the tool-slide should work freely but without undue looseness. After a cutter has been formed, it is a good plan to color it either by heating or dipping it in a strong solution of copper sulphate. The operator can then plainly see the work done by the relieving tool and stop at the proper time. Re-milling after the backing-off operation, insures a sharp edge and reduces the amount of grinding necessary after the cutter is hardened.

D. & W. FUSE CO.'S MAGNETIC CHUCKS

As a labor saver, there is probably no form of electrical device which has proved of greater benefit in the machine shop and tool-room than the magnetic chuck. When a large number of pieces are to be machined, the time and labor saved by the use of a magnetic chuck, as compared with the old methods of clamping, or holding one piece at a time in a vise, will often pay for a chuck within a short time. Magnetic chucks of the flat and rotary types now being manufactured by the D. & W. Fuse Co., Providence, R. I., are illustrated in Figs. 1 and 2.

The flat chucks (see Fig. 1) have a horizontal face and are

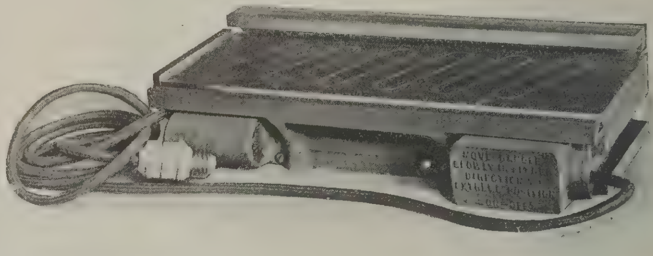

Fig. 1. Magnetic Chuck of Flat Type, built by D. & W. Fuse Co.

equipped with adjustable end and side stops, providing convenient means for locating and steadying the work. This form is particularly useful for holding such work as file blanks, scale blanks, thickness gages, punches, dies, accurate shims, gibs, or practically any part on which it is necessary to grind flat surfaces. Milling operations can also be performed with great facility, if the shape of the work is such that the end stop of the chuck can be raised to take part of the thrust. When used in this way, the smallest flat chuck built by this company will hold a 1- by 2- by 6-inch bar of tool steel, tightly enough to permit milling 0.050 inch from a surface 2 inches wide, and with a feed of 1 inch per minute. This chuck is also useful for holding stock requiring light planing and shaping operations.

The rotary chucks have been used effectively in plants manufacturing ball and roller bearings, for holding ball races dur-

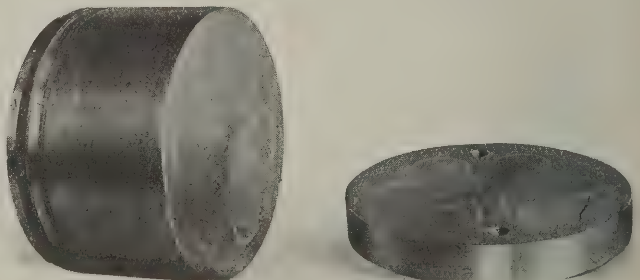

Fig. 2. Rotary Magnetic Chuck and Auxiliary Plate

ing the grinding operations. Rotary chucks are also used for holding pistons and piston rings which must be accurately ground. The rotary chuck illustrated in Fig. 2 is equipped with an auxiliary plate.

This company also manufactures vertical chucks which have a perpendicular holding face when clamped to a horizontal machine platen. They are especially adapted for grinders having a cup-wheel mounted on a horizontal spindle. The chuck proper

is similar to the flat type. The magnet coils of these chucks are wound with "Deltabeston" wire, having a special heat-proof insulation of pure asbestos. This insulation can safely withstand temperatures as high as 400 degrees F. In addition, the coils are wound by a special process which still further protects them from heat and moisture. This construction prevents burning out of the magnet coils when subjected to variations of voltage, moisture or prolonged service. The coils are rigid units which are interchangeable, and the arrangement of the chuck is such that they can be replaced readily. Auxiliary plates, which are made to fit these chucks, are used as jigs or fixtures for holding special pieces of irregular shape. By means of these plates, one chuck can be made to cover a wide range of operations, as any number of plates can be used.

Both the flat and vertical chucks have their ends machined true so that several of them can be lined up end-to-end for holding long work, or for machining many small parts at one operation. This feature permits the units to be used separately on different machines, or to be assembled into one long chuck controlled by a single switch. With the exception of the smaller sizes, the chucks are designed for use on direct-current circuits of 105 to 125 volts. If it is desirable or necessary to energize them on circuits of higher voltages, such as 210 to 250 volts, or even 550 volts, a convenient form of auxiliary resistance is supplied, which can be inserted at any suitable point in the circuit. The small chucks are equipped with standard external resistance units for use on 105- to 125-volt direct-current circuits.

The chucks are both oilproof and waterproof and are equipped with demagnetizing switches for readily releasing the work. When possible, a special switch is used, which is attached directly to the chuck. This switch, by a simple movement of the hand, automatically and positively demagnetizes the chuck. Where it is not practicable to mount this device on the side of the chuck, an independent control base is provided on which is mounted a knife switch with the demagnetizing unit. When the switches are mounted directly on the chucks, they are entirely enclosed in water-tight iron boxes. This affords thorough mechanical protection and serves to keep emery dust from cutting out the moving parts. Magnetic chucks can only be operated on direct-current circuits, and under no conditions can alternating currents be used. Where direct current is not available, direct-current generators are supplied.

REMINGTON GRINDING ATTACHMENTS

The external grinding attachment illustrated in Fig. 1 is for bench lathes and is of rigid design with a capacity for grinding wheels 4 inches in diameter and ½ inch face width. The grinding head may be removed and a head for internal grinding substituted if desired. The spindle of the internal grinding attachment is capable of speeds up to 30,000 revolutions per minute. The circular swivel base is graduated in degrees for grinding taper work. The lever movement is novel in that it is adjustable for quick short strokes, as well as for longer strokes. The method of making this adjustment is clearly shown by the illustration. There is a cross-movement of 7 inches from the center. The small lever just above the micrometer feed-screw, serves to release the feed so that the grinding head may be quickly moved to or from the work by means of a rack and pinion actuated by a lever. This feature facilitates the fitting of gages and replacing of the work. The grinding wheel is covered and is provided with an adjustable tube to direct the flow of water for wet grinding.

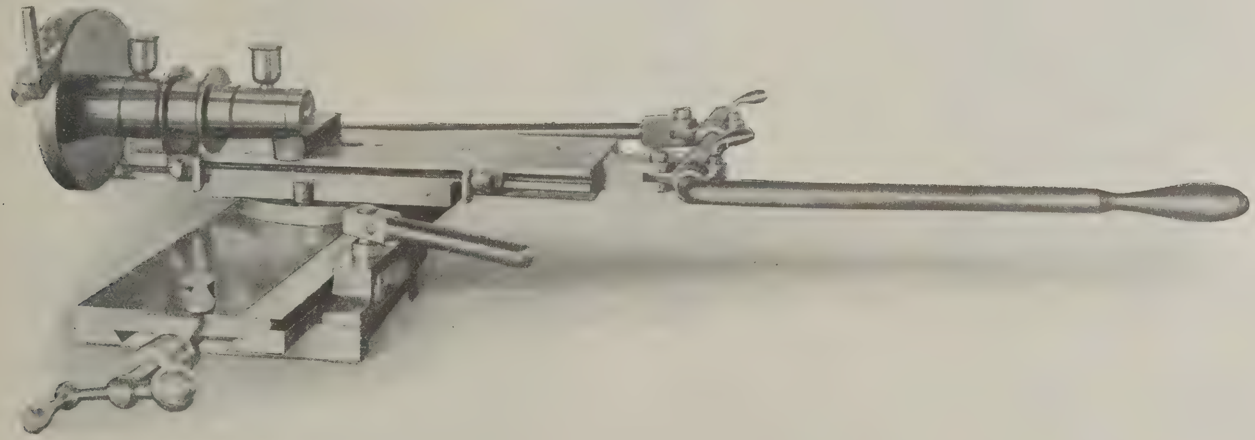

Fig. 1. Remington External Grinding Attachment for Bench Lathes

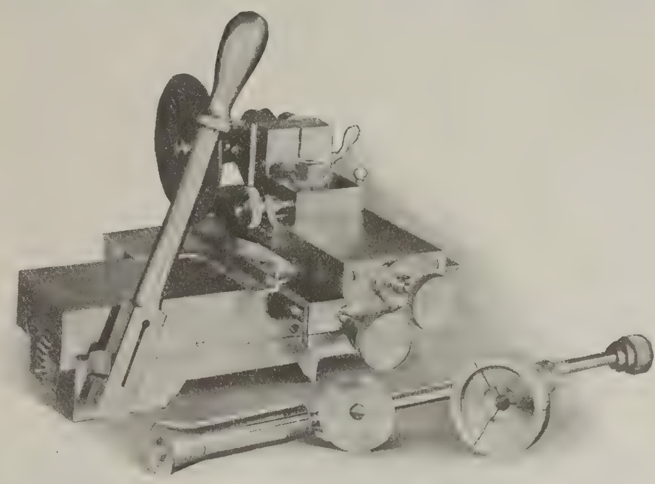

Fig. 2. Another Remington Grinding Attachment

Fig. 2 shows another external grinding attachment for bench lathes, which can be used in connection with the grinding of irregular forms without the necessity of re-setting the work for different angles. This attachment is particularly adapted to grinding hardened steel paper cutters. The illustration shows a paper cutter which has been ground on the plane, concave and bevel sides at one setting. Fine adjustments are provided throughout, both for setting the wheel and to compensate for wear. The circular swivel base is graduated in degrees for obtaining different angular adjustments.

Both of these attachments are recent developments of the Remington Tool & Machine Co., Woburn, Mass., and are designed to be used with the bench lathes manufactured by this company.

CHAMBERSBURG BOARD DROP HAMMERS

A new line of board drop hammers made in capacities from 400 pounds to 3000 pounds falling weights has recently been brought out by the Chambersburg Engineering Co., Chambersburg, Pa. A hammer of the new design is shown in the accompanying three engravings, illustrating the front, side and back views, respectively. The principal features of the new design are the manner of adjustment for lining up the dies, the manner in which the front rod is lifted up into place, and the knock-off construction. All the features incorporated have been subjected to most rigid and exacting tests in regular service.

The head or lifter is securely held in place on the top of the frames, by four through bolts, which pass through drilled

holes and which have spiral springs to absorb shock. The rolls are furnished either plain or geared, as desired. Together with their driving spindles they are located in hooded eccentrics—the front eccentric being used for operating, while the rear eccentric is for adjustment only. These eccentrics are made from steel castings, in one piece, this method insuring exact alignment. Provisions are made for preventing oil getting onto the rolls where they bear against the boards. The spindle bearings are made of ample size; they are bronze bushed and provided with oil reservoirs.

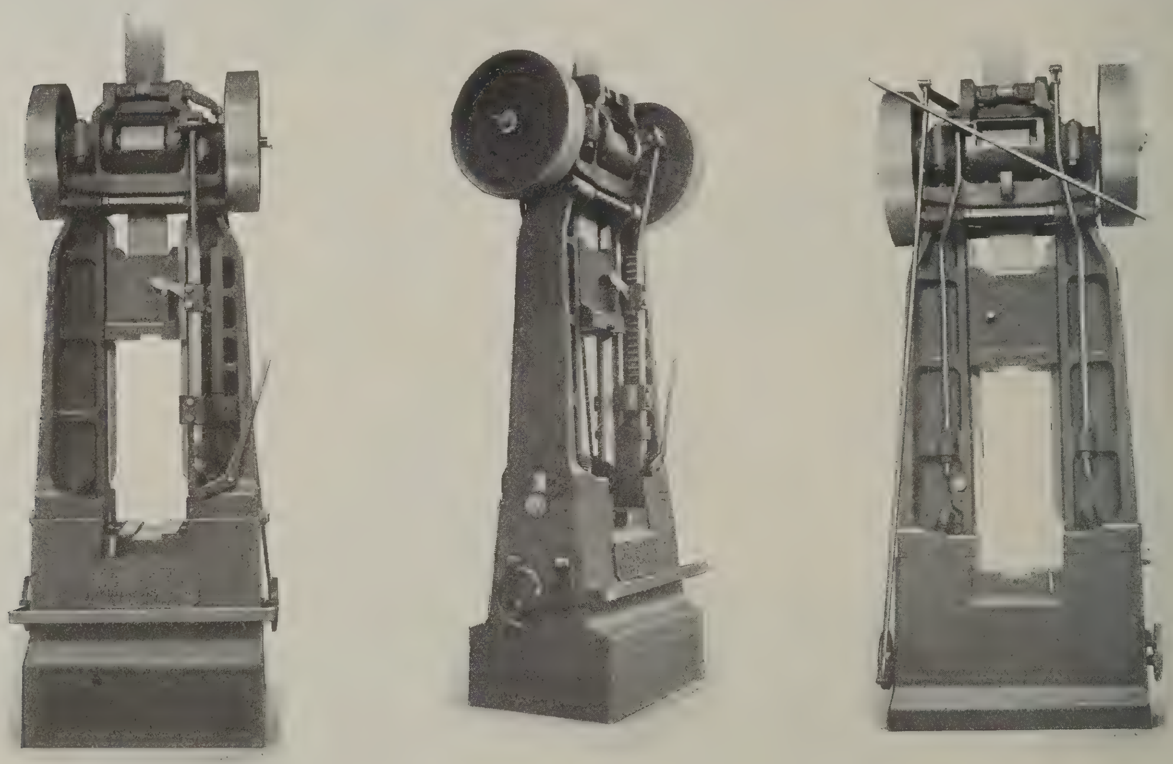
The board clamps are located at the extreme top on double eccentrics. A permanent alignment of both rolls and board clamps is insured, even if the operator is careless. When the ram is suspended the board is so gripped that it hangs free of both rolls. The board clamps are so designed that they will grip instantly the heaviest rams in any position without sliding, even if the board is badly worn. When the treadle is fully depressed, the board falls freely, no matter how worn it is at the point of pick-up. The trouble of drag through the clamps just before the blow is struck, which is a common difficulty, is thus overcome.

The adjustments necessary to the back roll and board clamp to take up the wear of the board, are quickly made from the floor by means of adjusting bars led down the back of the machine to within easy reach of the operator, as shown in the rear view of the hammer, Fig. 3. Adjustments can be made for wear of the board up to 7/16 inch. The pulleys may be either Rockwood compressed paper pulleys, or pressed steel pulleys, as desired.

The frames are of reinforced I-beam section to withstand the heavy strains imposed on them in "break-down" work. They are about 2 feet shorter than is the general standard, although the extreme fall of the ram is greater than the average. This feature of design insures greater rigidity. The frames are free from cores, and are of uniform section throughout. They are deeply pocketed in the anvil, having a bearing on their outside edges for the entire length of the tongue, and also bearing on the entire bottom surface, thus insuring satisfactory and permanent alignment of the frames and ram. The tops of the frames are tongued and fitted to the lifter head. The frames are spaced, and held in line with the lifting rolls, by steel tie-bolts with distance pieces. The bearing surface of the V-guides has been made especially large, so as to provide amply for wear.

The frame adjustment to align the top and bottom dies is made by large tension bolts, the construction being such that in case of fracture the bolts can be passed out into the die space and quickly replaced without dismantling the machine. In the usual construction it is necessary to dismantle the entire superstructure to make such repairs. The bolts are supported for their whole length in bored holes. Lock washers are provided to positively hold the adjusting nuts in any position. The frames are designed for the minimum adjustment of 0.0026 inch. The ram or hammer is of 40-point carbon open hearth steel, properly balanced, and made deep enough from front to back to insure the alignment of the dies. The lifting boards are of well seasoned maple, let into the ram and secured by an under-cut plate with teeth on one side so as to enable the use of a straight board, and at the same time prevent the board from pulling out.

The anvil is made of cast iron in one piece, and the anvil cap is made from 40-point carbon open hearth steel. Anvils weighing from fifteen to twenty times the rated falling weight of the ram can be furnished, and can be made of steel, if desired. The anvil is secured to the frames by four bolts, spiral springs being provided to reduce the shock. These bolts are set at a slight angle in order to locate the pocket for the bolt head on the compression side of the anvil, so as to prevent the possibility of breakage due to bolt-head pockets on the tension side.



Figs. 1 to 3. Front, Side and Rear Views of Board Drop Hammer built by Chambersburg Engineering Co.

The front rod lever has a safety stop, which will positively prevent accidents while adjusting dies, etc., as it automatically drops and locks the front rod release when the hammer is not in use, or when the operator is adjusting the dies. This provision prevents many accidents that occur from this source. As indicated in the engravings, the foot treadle does not extend across the back of the anvil, but leaves this space free for forgings.

The stroke is adjusted by means of a rack and segment lever, and the adjustment can be quickly and easily made. The front rod, due to the eccentric construction, is practically straight, and is lifted up into place without the usual shock and jar, as the releasing lever is rolled along in the rack, and gives the front rod a direct and gradual "pick-up." The adjustment for various heights of dies is made by means of a knock-off, clamped to the lower part of the front rod, this adjustment allowing the use of any thickness of dies. The incline for the knock-off is so laid out that no impact is imparted to the front rod. The breakage of the front rod, due to crystallization, which has been a constant source of trouble in this

class of machines, is thus obviated. This design permits the hammer to run at a higher speed than is ordinarily used, thus increasing the output.

RELIANCE SPEED DIAL FOR MACHINE TOOLS

As the output of a machine tool depends to a great extent on the use of the most efficient cutting speed, it is very important to have some accurate method by which the operator can easily adjust the driving mechanism, so as to obtain the prescribed speeds for the cutting tool under different conditions. When the speed changes are effected by means of cone-pulleys or gears, the spindle has a definite number of revolutions per minute and the speed for different gear combinations is usually shown on a plate attached to the machine. It is a comparatively easy matter to embody in a blueprint specified instructions showing the step of the cone-pulley, or the gear combination, which will give the most efficient speed for each operation to be performed. With an individual adjustable-speed motor drive, the number of speed changes is, of course, greatly increased and it is more difficult to indicate the proper combination for a given cutting speed. Consequently, the speed adjustment is usually a matter of guesswork, with the result that the efficiency of a given machine depends largely on the judgment of the operator.

The Reliance Electric & Engineering Co., 1056 Ivanhoe Road, Cleveland, O., has developed a speed dial which enables the operator to obtain the required cutting speed under different conditions. This dial is calibrated for use with the Reliance adjustable-speed motors, and can be applied to shapers, drills, lathes, milling machines, boring mills or any machine tool having speed variations. The Reliance adjustable-speed motor is of the armature shifting type and has an infinite number of gradual speed changes, so that it is always possible to obtain a given cutting speed, provided the operator has some means of accurately adjusting the speed of the motor in accordance with the cutting speed required. The function of this speed dial, one form of which is illustrated in Fig. 1, is to

Fig. 1. Reliance Speed Dial for obtaining Proper Cutting Speed—This Particular Dial is intended for a Back-geared Crank-shaper

enable the proper adjustment of the motor to be made. The dial can be mounted on the machine at any convenient place and it is simply necessary to provide a positive connection with the means employed for shifting the armature of the motor. Fig. 2 shows one of these dials applied to a drilling machine. As the illustration shows, positive connection is made with the motor by a chain and sprockets. The upper sprocket is mounted on a shaft carrying a handwheel which is used in making the adjustments. As the armature of the motor is shifted and a gradual change in speed is obtained, a pointer moves on the speed dial and shows what adjustment must be made to obtain the desired cutting speed. The scales on the dial are, of course, graduated differently for different types of machines, and take into account the different gear ratios between the driving motor and the cutting tool. Therefore it will be seen that this speed dial is not a means of indicating the speed at which the motor is running, but is an automatic calculator which enables the operator to quickly adjust the motor speed so as to obtain any desired speed at the cutting tool and, as previously stated, the dial is arranged to take care of all the variable factors which would affect the problem. All the operator has to do is to set the dial for the

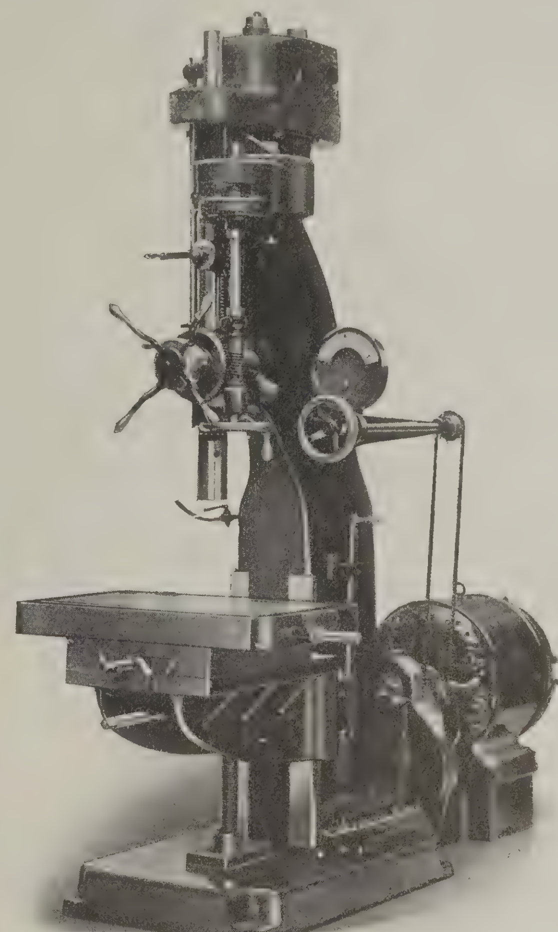


Fig. 2. Foote-Burt Drilling Machine equipped with Speed Dial which is positively connected to Reliance Adjustable Speed Motor

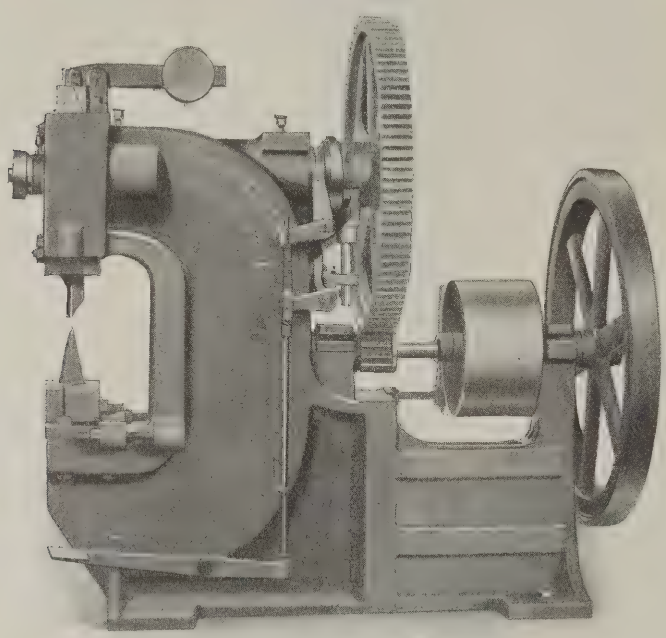
cutting speed required and then shift the armature of the motor, in the usual manner, until a pointer indicates the diameter of the cut to be taken (in the case of lathe work) on the proper scale for the gear combination used.

The particular dial illustrated in Fig. 1 is intended for use on a crank-shaper. This dial has an upper scale which shows the cutting speed in feet per minute, and two lower scales indicating inches of stroke. The upper scale for the stroke is used when the back-gears of the shaper are engaged, and the bottom scale is used when the back-gears are out and the drive is direct. The scale showing the cutting speed in feet per minute, is stationary and the small pointer seen opposite figure 40, is mounted on revolving disks with the two lower scales. When mounted on revolving disks with the two lower scales. When the shaper is to be set for a given cutting speed, the lower scales and the pointer referred to, are turned, by means of the small knurl seen just below the center of the dial, until the pointer is oposite the desired cutting speed. The armature of the motor is then shifted by turning the handwheel seen in Fig. 1, until the pointer over the lower scales (which is geared to the handwheel rod) is opposite the stroke to be used. Of course when making this adjustment, the operator uses the lowest scale if the back-gears are out, and the one above it if the back-gears are in mesh. The illustration shows the dial set for a cutting speed of 40 feet, with a stroke of 20 inches, and the back-gears engaged. It should be remembered that the cutting speed of a crank-shaper depends on the length of

the stroke for a given motor speed, and that is why the scales are graduated for the different lengths of stroke. The convenience and advantage of this dial and its effect on the efficiency of a tool, are obvious. It not only serves as a guide in setting the speed accurately, but is always in plain sight so that the foreman can see what speeds are being used.

WHITING GEARED SPRUE CUTTER

A geared sprue cutter recently designed and built by the George Whiting Co., 1701 Elston Ave., Chicago, Ill., for use in steel foundries, is illustrated herewith. The knives on the particular machine illustrated are intended for cutting off risers, gates and sprues up to the capacity of the machine, but if desired, an extra pair of cutters can be furnished for



Geared Sprue Cutter for Steel Foundries

trimming light fins from steel castings. These cutters are made so that the cutting edges come as close to the casting as practicable. The knives can be set either at right angles to the throat or with the cutting edges parallel to the throat.

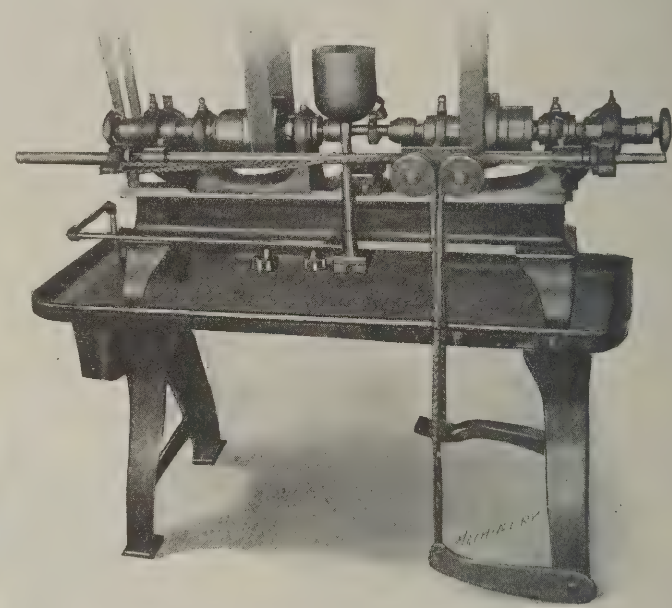
This machine is fitted with an automatic stop and is equipped with tight and loose pulleys. The large flywheel at the rear is crowned for a belt in case a motor drive is desired, and provision is made for attaching a motor directly to the machine. There are means of compensating for the wear of the lower blade, and the knives have been designed so that they can be re-ground economically and, at the same time, have serviceable edges for general work.

The machine is made in different capacities and either with or without the geared drive. The geared type runs about thirty strokes per minute and the quick-acting machine makes about ninety strokes per minute. The lower block which holds the cutter, is provided with an adjustment for aligning the blades to secure accurate cuts. The upper head can also be adjusted vertically for setting the top cutter in the proper position. This machine is designed to enable the operator to work as close to the casting as possible.

DUPLEX DRILLING AND COUNTERBORING MACHINE

A special drilling and counterboring machine built by the F. E. Wells & Son Co., Greenfield, Mass., is shown in the accompanying illustration. This machine operates on both sides of the work simultaneously, by means of opposed horizontal spindles. The particular machine illustrated is used for drilling and counterboring wrench parts. One spindle carries a combination drill and counterbore and the opposite spindle a counterbore only, so that a hole is drilled through the work and counterbored on each side.

The construction of the machine is very simple as the illustration indicates. The two spindles are moved toward each other by means of a foot-treadle. This treadle is connected

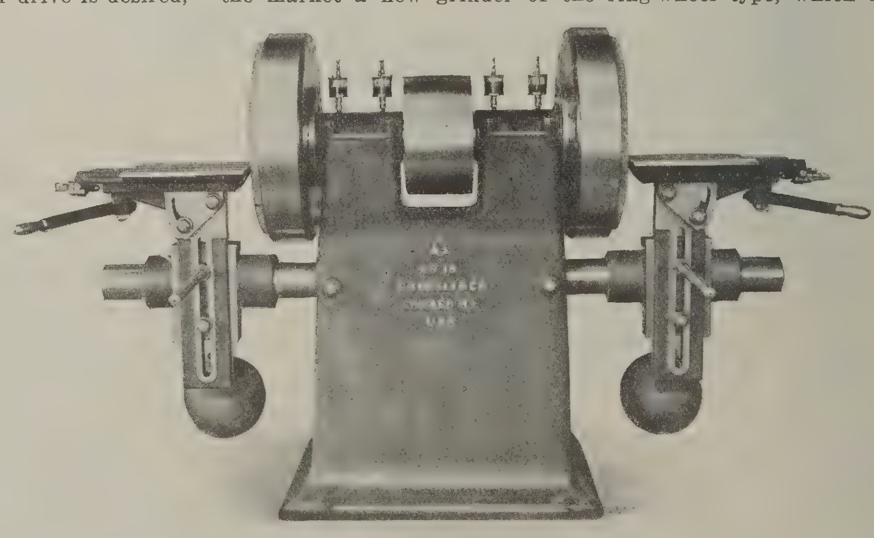


Drilling and Counterboring Machine

with the spindles by chains which pass over sheaves and are attached to arms connecting with the spindles. A guide rod at the rear of the machine takes up the torsional strain on the spindles when the drilling and counterboring tools are at work. Stops are provided for limiting the depth of the drilling and counterboring. When operating the machine, it is simply necessary to hold the work in position and apply foot pressure to the treadle for feeding the spindles. A drip tank is provided for supplying a cooling compound to the tools when machining steel or other metals requiring a coolant.

BESLY RING-WHEEL GRINDER

Charles H. Besly & Co., Chicago, Ill., have recently placed on the market a new grinder of the ring-wheel type, which is



Large Ring-wheel Grinder built by Charles H. Besly & Co.

heavier and more powerful than any grinder heretofore built by this company. This machine, which is illustrated herewith, is equipped with two, geared lever-feed work-tables and two pressed steel ring-wheel chucks holding ring or cylinder grinding wheels 24 inches in diameter. This grinder is intended for larger and rougher work than is ordinarily done on disk grinders. The vitrified grinding rings naturally will stand

more severe service than the emery-cloth-covered steel disk wheels. The design is massive and rigid, and the machine, as illustrated, weighs over 3500 pounds.

The geared lever-feed table weighs about 600 pounds and has a leverage of 18 to 1. The spindle pulley is 15 inches in diameter. It will take an 8-inch belt and transmits over 30 horsepower. The spindle is 3¼ inches in diameter and each bearing is 12 inches long. The rockershaft is 4½ inches in diameter and 7 feet long. The end thrust is taken on hardened and ground collars of over 20 square inches area. Each pressed steel ring-wheel chuck weighs 275 pounds and with a new grinding ring in place, weighs 415 pounds. A new grinding ring is 24 inches in diameter, 5 inches deep and has an 11-inch hole.

This machine will rough 1/16 inch stock from the bottom of a sad iron casting in about ten seconds, and the feeding pressure on the surface being ground is approximately 100 pounds per square inch of area. On a machine of this type, with hand-lever feed, the ratio of the leverage (18 to 1) is an important feature as it enables the workman, without undue exertion, to put sufficient pressure on the work to secure the maximum efficiency of the grinder. This large ratio of leverage is obtained through a gear and rack with a lever only 20 inches long. This geared motion gives the necessary table travel with a maximum ratio of leverage for the length of lever used. A longer lever would not be convenient for the workman. The lever is clamped to the pinion stud, and its position, relative to the stud, may be changed to suit the convenience of the operator.

RECENT DEVELOPMENTS IN LARGE PRESSES

A few years ago presses having more than two cranks and measuring over four or five feet between the housings, were rarely built, but at present the multiple-crank type having three or four cranks and varying in width from three to ten feet between the housings, is quite common. The accompanying engravings show several different types of large presses that have recently been built by the E. W. Bliss Co., 17 Adams St., Brooklyn, N. Y.

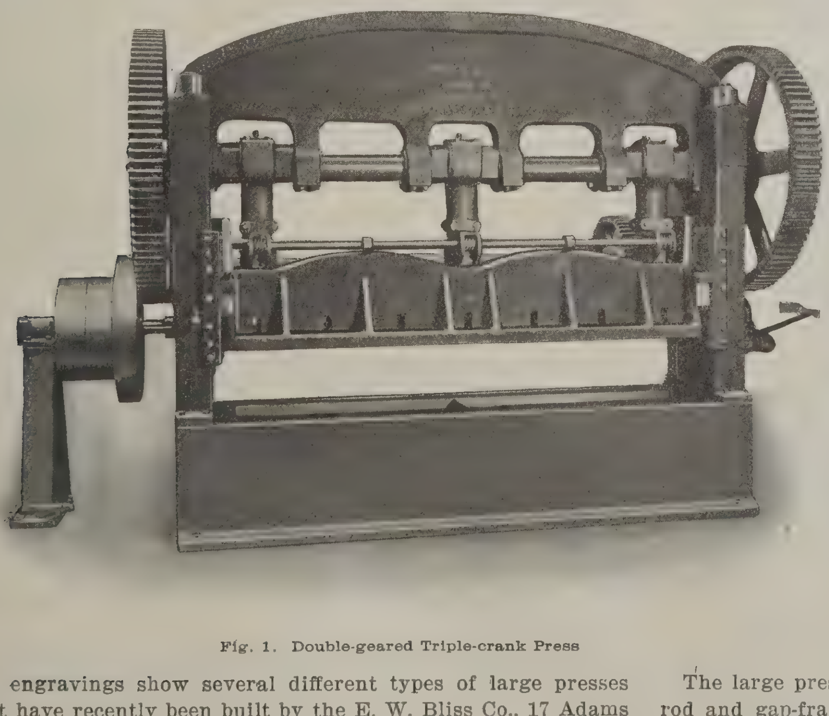


Fig. 1. Double-geared Triple-crank Press

Fig. 1 shows a multiple press having a triple crank. This machine has a width of 11 feet between the housings and a slide movement of 4 inches. Owing to the great width, it is equipped with a twin drive, a driving gear being mounted on each end of the crankshaft. This method of driving reduces the torsional strain on the crankshaft and also equalizes the pressure on the journals and gears. The action of this press is controlled by a hand-operated friction clutch. The flywheel is 40 inches in diameter and has a 6-inch face. The total weight of the machine is 59,000 pounds.

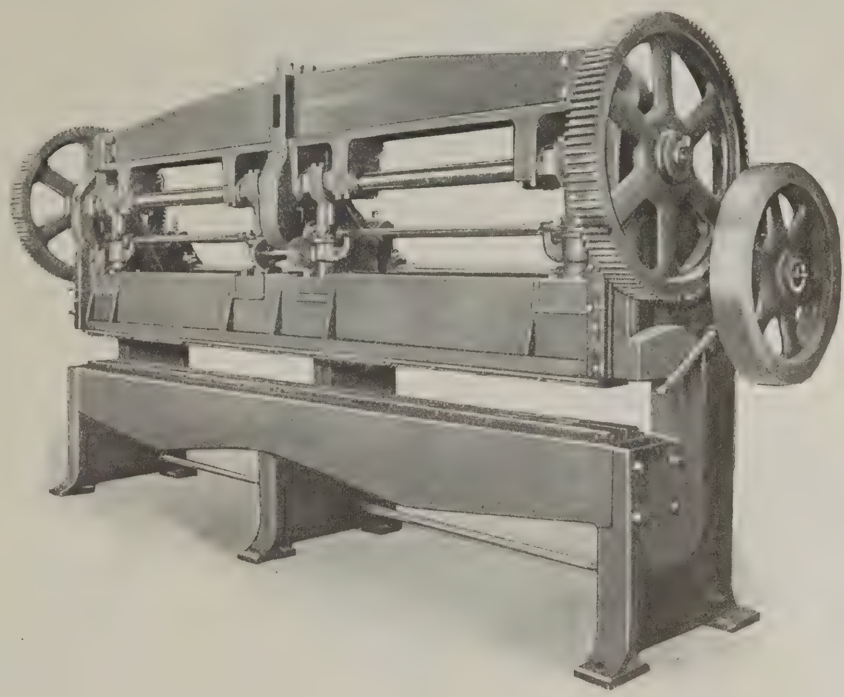

Fig. 2. Four-crank Press having Width of 14 Feet between Housings

A four-crank press is illustrated in Fig. 2. The capacity of this machine is comparatively small. but it is extremely wide, the width between the outer housings being 14 feet. The construction is of the built-up frame type with gap or overhanging housings. This press also has the twin drive, and the ratio of the gearing is 15 to 1. The crankshaft is 4 inches in diameter and has a 2-inch stroke. The flywheel weighs 600 pounds, and the weight of the complete machine is 25,000 pounds.

Fig. 3 shows a rear view of a large double-crank press. It usually takes from two to four men to operate large presses of this type, and, ordinarily, it is necessary to have at least one man back of the machine to handle the work. This is a dangerous position when the gearing is exposed and low enough to come within the workman's reach. For this reason all the large presses built by the E. W. Bliss Co. have the gearing mounted on the housings above the crankshaft, as shown in Fig. 3. With this arrangement of the driving shaft, the gearing is above the operator's head, where it is entirely out of the way. This machine and also the one illustrated in Fig. 1 are commonly known as the straight-sided, tie-rod type. The bed and crown are each a separate casting, and all the strain is taken by steel tie-rods which pass through the side housings so that the latter simply act as a guide for the slide. Machines of this type are used for blanking, forming and drawing operations on large sheets such as are used for steel range bodies, automobile parts and similar work.

The large press shown in Fig. 4 is a combination of the tie-rod and gap-frame type. The bed and crown are each a separate casting and the side housings are of box section and have a gap or opening at the front, as shown. The bed and crown are held in place by two large steel rods which pass through

the housings just back of the crankshaft and take all the strain. There are also two smaller steel rods in front of the crankshaft. These do not go below the gap and are to prevent the crown from rolling. There are also two additional rods

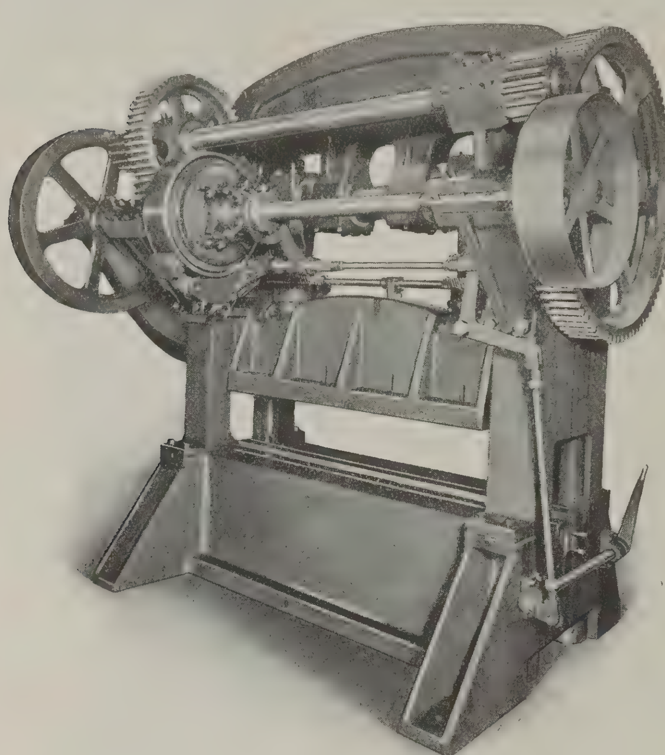

Fig. 3. Rear View of Double-crank Press

that pass through the bed and prevent the housings from springing away at the rear as they would tend to do when the main tie-rods, which pass close to the front, were shrunk in place. This construction is said to make a machine of the gap type as strong as a straight-sided press, as all the strain

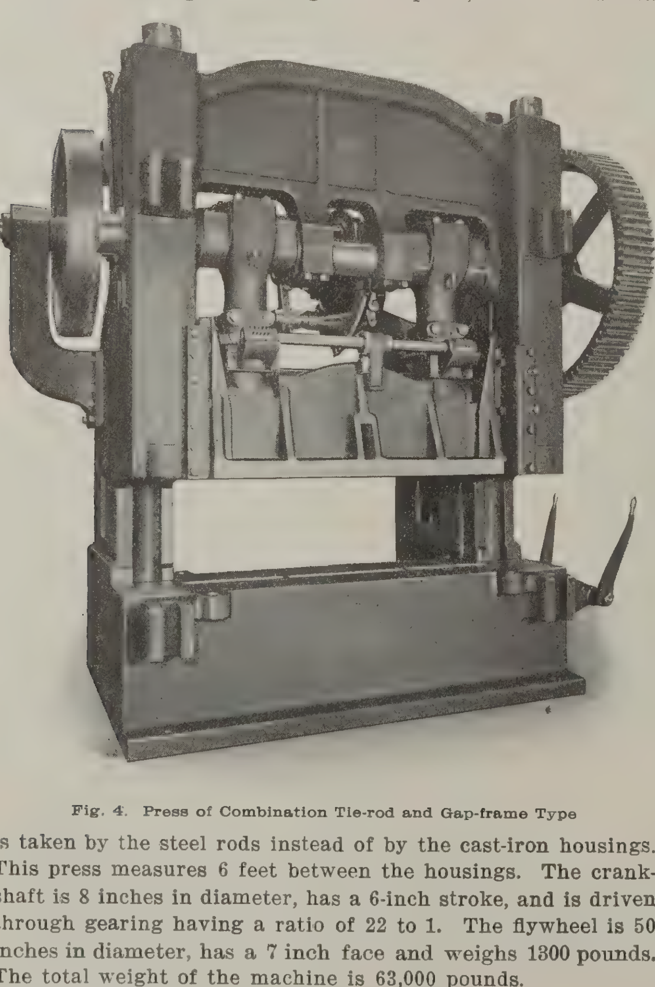

Fig. 4. Press of Combination Tie-rod and Gap-frame Type

is taken by the steel rods instead of by the cast-iron housings. This press measures 6 feet between the housings. The crankshaft is 8 inches in diameter, has a 6-inch stroke, and is driven through gearing having a ratio of 22 to 1. The flywheel is 50 inches in diameter, has a 7 inch face and weighs 1300 pounds. The total weight of the machine is 63,000 pounds.

NEW MACHINERY AND TOOLS NOTES

Light Holder: Ryede Specialty Works, Rochester, N. Y. Adjustable light holder which can readily be attached to the ceiling, wall or floor, and has universal adjustment which permits placing the light in the best position. The entire bracket is made of steel and is either nickel plated or oxidized.

Stock and Tool Trays: F. O. Weydell, 224 S. Jefferson St., Chicago, Ill. Cast-iron tool and stock trays made in different styles and sizes and intended for holding taps, drills, chisels and other tools. These trays consist of independent units which can be hung under a bench like a drawer or arranged in stacks, as required.

Shim for Bearings: Lindhe Shim Co., New York City. Shim or liner for bearings composed of a series of brass layers 0.002 inch thick which are firmly held together by a very thin film of solder. The thickness of the shim is varied by peeling off one or more layers. This shim is applicable to all classes of machinery having split bearings.

Pipe Threading Machine: Oster Mfg. Co., Cleveland, O. Machine for threading straight or bent pipe. The work is held in a swivel vise which can be adjusted to any angle for threading pipe bent to any radius from 6 to 24 inches. The vise is locked in position and the angle is shown by graduations. There is an automatic trip for cutting threads of a standard length.

Tool Grinder: W. W. Oliver Mfg. Co., 1500 Niagara St., Buffalo, N. Y. Tool grinder (No. 8) equipped with Hyatt roller bearings, which are oiled through dustproof cups. The spindle is made of machine steel accurately ground and machined, and the wheels are guarded. The height from the floor to the spindle is 38 inches, and the length of the spindle is 13⅞ inches. The net weight of the grinder is 96 pounds.

Die-plate: Scott-Rose Co., Marquette Building, Chicago, Ill. Die-plate covering a range of sizes from 3/16 to 3/4 inch. The hardened steel removable die blocks are fitted in parallel jaws. The distance between these jaws can be varied by a calibrated ratchet wheel which, through the medium of a cam, adjusts the jaws by small variations. This die-plate is 15 inches long overall, and it is furnished with U. S. standard threads unless otherwise specified.

Gas Forge: Simplex Tool & Supply Co., 125 Purchase St., Boston, Mass. Gas forge for forging or hardening lathe, planer or other tools made of carbon or high-speed steels. The width of the furnace is 10 inches and the height 8 inches. There are four burners, and 100 cubic feet of gas is consumed per hour. An air pressure of one and one-half pound is required. The advantages claimed for this forge are the facilities for watching the tool, a clean output and elimination of fusing of the tool-point.

Vertical Surface Grinder: Pratt & Whitney Co., Hartford, Conn. Vertical surface grinder which resembles the machine formerly built by this company, but is an improved design of heavier construction. It is adapted to either plain or circular grinding. A cup-shaped wheel 14 inches in diameter and 4 inches high is used. The table has a working surface 11⅜ by 36 inches, and the maximum distance from the table to the grinding surface of a new wheel is 14 inches. The machine can be equipped with a belt or motor drive.

Centering Tool: Robert H. Fay, Chicopee Falls, Mass. Centering tool for use on the lathe or hand screw machine. The body of the tool is composed of two sections which are screwed together and can be adjusted with relation to each other. The forward section carries a combination centering drill and it is beveled on the rear side to an angle of 60 degrees. The other section is in the form of a ring and is also beveled on the inside. By means of this adjustment the conical bearing can be varied to suit the angle of the lathe center, in case the latter should not be ground to the standard angle. The two sections are locked at any point by a small knurled screw.

Rolling Mill: Standard Machinery Co., Providence, R. I. Steel rolling mill designed for the cold rolling of sheet steel. The machine is driven by a sixty-horsepower motor, and there are three rolls to which power is transmitted through spur gears and cast steel herringbone pinions. The top and bottom rolls are 11 inches in diameter and have a 12-inch face. The center roll, which is known as the "baby" roll, is 5 inches in diameter and has a 12-inch face. The mill is so arranged that the 11-inch rolls can be replaced with 14-inch sizes when necessary for special work. The baby or friction roll is hardened, ground and mirror lapped. Both the 11- and 14-inch sizes are of the shell type forced over arbors, the shell part being hardened and ground tool steel. The weight of this mill is 26,470 pounds.

Crank Press: Niagara Machine & Tool Works, 639 Northland Ave., Buffalo, N. Y. Double crank-press, especially adapted to the requirements of sheet metal works manufacturing specialties of heavy and light gages. The frame is built in sections and the bed, the two housings and the arch are held together by four steel tie-rods which are shrunk in place and take the strain. Particular attention has been paid to the design of the slide cross-head and guides to adapt the

press for very accurate work. The Niagara automatic jaw clutch is used. This clutch has a safety lock which guards against accidental engagement in case the brake is not properly adjusted. The distance between the housings is 61 inches and the distance from the bed to the slide with stroke and adjustment up, is 25 inches.

Cylinder Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. Special five-spindle cylinder boring machine having two uprights and a cross-rail. The right-hand upright can be shifted in or out whereas the left-hand upright is bolted to the bed. The cross-rail, which is mounted on top of the uprights, has a fore-and-aft adjustment. There are two vertical spindles on the cross-rail each having vertical and horizontal hand adjustments and a vertical feed. The left-hand horizontal spindle is mounted on a saddle attached to a knee having vertical elevation on the upright. This spindle also has a fore-and-aft hand adjustment as well as a cross-feed. The right-hand vertical saddle carries two spindles which operate in unison. This machine was especially designed for air brake cylinder work.

Safety Device: Benjamin Electric Mfg. Co., 120 S. Sangamon St., Chicago, Ill. Safety device for stamping presses which protects the hands of the operator by necessitating the removal of both hands from the point of danger in order to trip the press. The release of either hand permits the trip to return to its normal position, thus making it impossible for the press to repeat unless both hands are kept on the levers until the downward stroke begins. The operator then will not have time to get his hands back into the danger zone before the operation is completed. The device consists of an operating lever normally made inoperative, though free to move downward. This lever is made operative by an electro retaining magnet through a circuit closer. The press cannot be tripped by the operating lever unless the circuit through the magnet is first closed. This safety device can easily be applied to all standard presses.

Profiler: Pratt & Whitney Co., Hartford, Conn. Semi-automatic profiling machine capable of milling contours of practically any shape. The machine has a heavy base casting to which are bolted uprights and a cross-rail cast in one piece. The head on which the roughing and finishing spindles are mounted is clamped to the cross-rail and remains stationary when the machine is in operation. The rotary work-table is mounted on the front end of a swinging arm, journaled in the bed between the uprights. The table is actuated by worm-gearing and is provided with a change-gear mechanism by means of which any desired feed may be obtained. The table is oscillated by a cam or former under it, which is kept in contact with a roller mounted on a pin fixed to the bed. To generate this cam or former, the roller is removed and a milling cutter of the same diameter is inserted in its place. A model of the work is then mounted on the machine and a former pin of the same size as the cutter to be used, is inserted in the cutter spindle. The cam is then milled by the cutter previously referred to, which is driven independently from the main shaft.

PERSONALS

Otto R. Winter recently opened an office at 785 Bruck St., Columbus, Ohio, as tool and machine designer.

Robert Wilde has resigned as factory manager of the R. C. H. Corporation, Detroit, Mich., manufacturer of automobile and metal products.

F. H. Brown, formerly with Chas. A. Strelinger Co., Detroit, Mich., has been made sales manager of the W. P. Davis Machine Co., Rochester, N. Y.

W. Nicholson, of W. H. Nicholson & Co., Wilkes-Barre, Pa., sailed in February for a six-week's trip in Europe in the interests of the mandrel department of his company.

Paul J. Smith, assistant foreman of the tool and die room of the Ford Motor Co.'s pressed steel plant, Buffalo, N. Y., has been promoted to the position of chief inspector.

At a meeting of the board of directors of Manning, Maxwell & Moore, Inc., New York, January 26, Mr. James B. Brady was elected vice-president in place of Mr. W. O. Jacquette.

Emory T. Smith, for a long time draftsman for the Waltham Watch Tool Co., Springfield, Mass., has resigned to take a similar position with the Chapman Valve Mfg. Co. of Springfield.

C. R. McCullough, formerly connected with the Packard Motor Car Co., Detroit, Mich., has joined the sales organization of Manning, Maxwell & Moore, Inc., and will make his headquarters in Detroit.

E. J. O'Hayer, Jr., vice-president of the Miehle Printing Press & Mfg. Co., Chicago, Ill., has taken charge of the company's office at 38 Park Row, New York, succeeding Mr. F. L. Montague, resigned.

Frank P. Smith, formerly connected with the sales office of Manning, Maxwell & Moore, Inc., New York, has again become associated with this corporation. His work will be confined chiefly to the railway department.

L. H. Mesker, who has heretofore been connected with the Cleveland branch of Manning, Maxwell & Moore, Inc., has been appointed manager of the St. Louis, Mo., branch of this corporation, succeeding Mr. C. L. Lyle. The St. Louis office is in the 'Frisco Bldg.

Howard W. Evans has taken a position with the Best Mfg. Co., Pittsburg, Pa., as general manager of sales. Mr. Evans will supervise the company's sales, order and engineering departments. He was formerly connected with the Crane Co., of Chicago, in a similar capacity.

James McCrea, president of the Pennsylvania R. R., has been appointed a member of the American Honorary Committee of the International Congress for the prevention of accidents and industrial hygiene to be held in Milan in May, 1912. The Pennsylvania R. R. only recently received a medal from the American Museum of Safety for being the American employer to do the most in the past year for the protection of the lives and limbs of its workmen.

F. W. Boye, Jr. and W. T. Emmes have purchased the interest of Mr. W. A. Schumacher in the firms Schumacher & Boye and Schumacher, Boye & Emmes, and have incorporated a new company under the name of the Boye & Emmes Machine Tool Co., to take over these two concerns. Mr. Emmes is well known in the machine tool world, having been the general superintendent of the company for a number of years. He is the inventor of improvements in quick change gear devices and other features of engine lathes.

OBITUARIES

William W. Young, purchasing agent of the Union Switch & Signal Co., Swissvale, Pa., died January 21.

S. S. Smith, of Dallas, Texas, manager of the General Fire Extinguisher Co., of Texas, died suddenly at New Orleans, January 20.

Frank D. Smith, for the past ten or twelve years traveling salesman for the Waltham Watch Tool Co., Springfield, Mass., died January 24 at his home in Springfield after a few weeks' illness, aged fifty-nine years.

C. P. Miller, general superintendent of the Weir Frog Co., Cincinnati, Ohio, died suddenly at his office of heart failure, February 9. Mr. Miller had been connected with the company as general superintendent since 1906. He was buried at Hilburn, N. Y., his former home. He leaves a widow and three children.

Walter A. Post, president of the Newport News Shipbuilding & Dry Dock Co., Newport News, Va., died February 12, aged fifty-five years. Mr. Post was a civil engineer, and his connection with the Newport News Shipbuilding & Dry Dock Co. dates back to 1890, when he was put in charge of the erection and equipment of the plant. This work was carried out so satisfactorily that in 1898 he was made general manager. He was elected president in 1911.

S. D. Conover, a prominent citizen of Dayton, Ohio, and founder of the Miami Valley Machine Tool Co., died February 8, aged sixty-nine years. Mr. Conover was president of the company up to about a year ago when he retired from active business on account of ill-health. He was a director of the Gem City Building and Loan Association, and was interested in a number of enterprises. He leaves a widow, daughter and son, the latter being Mr. P. P H. Conover, the present head of the company.

FRANCIS H. STILLMAN

Francis H. Stillman, president of the Watson-Stillman Co., and a prominent figure in machine tool and engineering industries, died suddenly, February 18, of intestinal hemorrhage at his late residence, 105 Rodney St., Brooklyn, in his sixty-second year. The day before his death he was at his office as usual, and apparently in the best of health. Mr. Stillman was born in New York on February 20, 1850, and was graduated from Yale in the class of 1874 with the degree of B. S. He was a member of Hyatt Lodge, F. and A. M., a member of the thirty-second degree in Aurora Grata Consistory, a Knight Templar, a Noble of Kismet Temple, Mystic Shrine, and a member of the Royal Arcanum. He was a member of the Hanover Club of Brooklyn, the Engineers Club, the American Society of Mechanical Engineers, and continuously since its organization a director of the National Association of Manufacturers. He organized the Machinery Club of New York, and was its first president, and was also first president of the National Metal Trades Association. In addition to being president of the Watson-Stillman Co. at the time of his death, he was also president of the Bridgeport Motor Co., and of the Pequannock Commercial Co., and a director in other manufacturing firms. Aside from his continuous activities in various engineering organizations and projects, Mr. Stillman was one of the recognized pioneers and, perhaps, the most prominent American engineer on hydraulic machine and tool construction. On leaving college, Mr. Stillman first associated himself with the Cottrell Printing Press Co., then with his stepfather, Mr. Lyons. In 1883 he organized and became president of the

Francis H. Stillman

firm of Watson & Stillman, which succeeded Lyons & Co. The firm was incorporated in 1904 as The Watson-Stillman Co., Mr. Stillman remaining its president up to the time of his death. Under Mr. Stillman's direction, his firm early became prominent in the hydraulic engineering field, and it has built upwards of 4000 different types and sizes of hydraulic machines, and now has a large and active plant in Aldene, N. J. Mr. Stillman's kindly disposition, high standard of business integrity and kind personal interest in all those with whom he came in contact, won for him a large circle of friends that will keenly regret their loss in his death. He is survived by his widow, formerly Miss Irene A. Bancroft of Boston, and by two sons, Austin Frank and Edwin Arthur Stillman.

* * *

COMING EVENTS

May 13-15.—Triple convention of the American Supply and Machinery Manufacturers' Association, National Supply and Machinery Dealers' Association, and Southern Supply and Machinery Dealers' Association, at Norfolk, Va., Monticello Hotel, headquarters. F. D. Mitchell, secretary-treasurer, 309 Broadway, New York.

May 14-17—Sixth annual convention of the Master Boiler Makers' Association at the Fort Pitt Hotel, Pittsburg, Pa. J. R. Flannery, of the Flannery Bolt Co., Frick Bldg., Pittsburg, Pa., secretary and treasurer of the general committee of arrangements.

June 4-7.—Spring meeting of the American Society of Mechanical Engineers in Cleveland, Ohio. Calvin W. Rice, secretary, 29 W. 39th St., New York.

June 12-14.—Annual convention of the American Railway Master Mechanics' Association at Atlantic City, N. J.

June 17-19.—Annual convention of the Master Car Builders' Association at Atlantic City, N. J.

July 9—Annual convention of the American Railway Tool Foremen's Association in Chicago. H. L. Miller, secretary of the supply association, 835 Monadnock Bldg., Chicago, Ill.

August 20.—Annual convention of the International Railroad Master Blacksmith's Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7.—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. Mr. H. F. J. Porter, secretary, 1 Madison Ave., New York.

SOCIETIES AND COLLEGES

American Society of Engineer Draftsmen, 116 Nassau St., New York, held its regular monthly meeting in the Engineering Societies Bldg., 29 West 39th St., New York, on February 15, at 8:15 P. M. The subject of the meeting was "The Training of Draftsmen." by Prof. F. G. Higbee, head of the department of descriptive geometry and drawing, Iowa State University. Mr. Wm. F. Turnbull of the engineering department of the American Locomotive Co., delivered a lecture on "Some Common Faults of Draftsmen."

National Association of Master Steam and Hot Water Fitters, Wool Exchange Bldg., 260 West Broadway, New York. The 1912 U. S. standard schedule of standard weight and extra heavy flanged fittings and flanges which was lately adopted by the joint committee on standardization of the National Association of Master Steam and Hot Water Fitters and the American Society of Mechanical Engineers. The American Society of Heating and Ventilating Engineers' special committee on standards has reported in favor of recommending its use by members of that society. Copies of the schedule will be sent to architects, mechanical engineers, heating and ventilating engineers, manufacturers, dealers, and others interested, without cost, upon receipt of request.

Inventors Guild, Ralph D. Mershon, 60 Wall St., N. Y., president, has addressed a resolution to President Taft regarding inadequate patent protection given to American inventors. The substance of the resolution is that a patent is in effect a contract between the government and the inventor, by which the government in consideration of the right to publish the invention agrees to secure to the inventor for a limited time the exclusive right to use his invention, and that under present conditions these rights are not properly safeguarded. Under existing methods of trying patent causes, an inventor-patentee of average means cannot at his own expense carry to a conclusion a patent litigation against a wealthy opponent, and, therefore, a few wealthy concerns have acquired many important patents in their field, to the great damage of the nation, because of the restraint of competition and because of the resulting tendency of such inventors to seek protection for their inventions by keeping them trade secrets, or by ceasing to develop inventions.

NEW BOOKS AND PAMPHLETS

Year Book of the American Electrical Institute, 1912. F. L. Hutchinson, secretary, 23 West 39th St., New York.

The Vermont Bulletin. Catalogue 1911-1912. 190 pages, 5 by 7½ inches. Published by the University of Vermont and State Agricultural College, Burlington, Vt.

The Kingdom of Dust. By J. Gordon Ogden. 116 pages, 4¼ by 7 inches. Numerous halftone illustrations. Published by Popular Mechanics Co., Chicago, Ill. Price 50 cents.

Comparative Railway Statistics of the United States, United Kingdom, France and Germany. Published as Bulletin No. 24, by the Bureau of Railway Economics, Washington, D. C.

New Hampshire Highways. Report of an Inspecton of Highways in the State of New Hampshire, August, 1911. By Charles H. Hoyt. Published by U. S. Department of Agriculture, Washington, D. C.

Proceedings of the American Electric Railway Engineering Association, 1911, containing a complete report of the ninth annual convention held at Atlantic City, N. J., October 9-13, 1911. H. C. Donecker, secretary-treasurer, 29 West 39th St., New York.

The Modern Submarine Boat. Chart 14 by 28 inches. Published by Norman W. Henley & Son, New York. Price 25 cents.

This chart is printed on heavy paper, suitable for framing, and contains a cross-section showing clearly and distinctly the interior parts of a modern submarine boat. Two hundred parts are numbered and named in a reference list printed alongside of the illustration. The chart is drawn accurately to scale.

The Essentials of Lettering. By Thomas E. French and Robert Meiklejohn. 94 pages, 9 by 6 inches. 119 illustrations. Published by McGraw-Hill Book Co., New York. Price $1.00.

This is the third edition of a manual on lettering for students and designers. Like the previous editions, it contains an outline on the history of lettering, and then contains chapters on letter construction, composition and titles, selection of styles, letters in design, design and composition, monograms, ciphers and marks, and on drawing for reproduction.

Engineering Directory. 1496 pages, 4 by 6¾ inches. Published by D. Crawford Publishing Co., Chicago, Ill. Price $5.00.

This is the 1912 edition of this well-known directory, now in its nineteenth year of publication. In the classified section, manufacturers' products are found under 3850 classifications. The directory contains the names of more than 6000 manufacturers, producing over 4000 varieties of engineering goods and having more than 50,000 trade or brand names. The book is bound in leather and has thumb indexes to its fifteen sections.

Hand Forging and Wrought-iron Ornamental Work. By Thomas F. Googerty. 197 pages, 5¼ by 8 inches. 122 illustrations. Published by Popular Mechanics Co., Chicago, Ill. Price $1.00.

This book has been written in order to meet the demand for an inexpensive text-book on the subject of hand-wrought ornamental iron work. It contains numerous examples of ornamental forging, giving explicit directions for doing the work. It contains twelve chapters headed as follows: Introductory; Equipment; Working at the Forge; Various Forms of Welding; Welding (Concluded); Twisting, etc.; Scrollwork; Box Forging; Embossing; Drawer-pulls and Hinges; Doorplates; Iron Lamps.

An Investigation of the Strength of Rolled Zinc. By Herbert F. Moore. 24 pages, 6 by 9 inches. 14 illustrations. 13 tables. Published by the University of Illinois, Urbana, Ill. Price 15 cents.

This bulletin, No. 52 of the Engineering Experiment Station of the University of Illinois, records the results of tests made in the laboratory of applied mechanics of the University on the tensile, compressive and shearing strength of zinc. Comparison is made with results of tests made in Europe. The resisting power of the zinc to stress is shown to be from 30 to 40 per cent of that of soft steel. While normally sold at a price of 15 cents, copies of the bulletin may be obtained free of charge upon application to Prof. W. F. M. Goss, University of Illinois, Urbana, Ill.

Efficiency as a Basis for Operation and Wages. By Harrington Emerson, 256 pages, 5 by 7½ inches. Published by the *Engineering Magazine*, New York. Price $2.00.

This is the third edition of this work. It has been revised and enlarged, but, of course, the subject matter is in the main the same as in the previous editions. While, as the author says, when the first edition was brought out, it was almost as the voice of one crying in the wilderness. with a new doctrine and an unusual form of teaching it, the subject is now fairly familiar to the engineering world. The main changes in the third edition consist in the revision which has been due to the rapid change of public sentiment, and the enlargement of the text designed principally to emphasize certain points upon which experience has shown added emphasis to be necessary.

Prevention of Railroad Accidents or Safety in Railroading. By George Bradshaw. 173 pages, 4½ by 6½ inches. Numerous illustrations. Published by Norman W. Henley & Son, New York. Price 50 cents.

The author of this book, a practical railroad man, has for ten years been constantly engaged in the investigation and settlement of claims for personal injuries and death resulting from railroad accidents. This direct experience gives his work especial value. The book is addressed especially to railway employes and is, therefore, confined to that class of accidents that are within the power of the employes to prevent by their own personal efforts. The illustrations in the book show in a graphical manner how dangers may be avoided in railroading, and illustrate also the careless methods which are the cause of many accidents. The book is of considerable interest even to non-railroad men, and some of the general sections would be useful to anyone in the mechanical trades.

Twelve Principles of Efficiency. By Harrington Emerson. 423 pages, 5 by 7½ inches. Published by the *Engineering Magazine*, New York. Price $2.00.

The earlier book—"Efficiency as a Basis for Operation and Wages" —by the same author, was essentially the statement of a philosopher. It contains a new view of the industrial problem and defines the relations and proportions of the factors that enter into it. This latter volume is in a sense a continuation of the earlier work, but it is more specific in its statements and reduces the doctrine of efficiency to a practical basis. The twelve principles of efficiency the author enumerates are as follows: Clearly defined ideals; common sense; competent counsel; discipline; the fair deal; reliable, immediate and adequate records; despatching; standards and schedules; standardized conditions; standardized operations; written standard practice instructions; and efficiency reward. The book contains a great many examples from practice indicating possibilities for improved efficiency and makes altogether interesting reading even if one should not everywhere agree with the conclusions of the author. On many important questions the author, although at odds with the trend of the times, undoubtedly strikes the true keynote of efficiency, as for example when he scores the great terminal stations of railroads as monuments of inefficiency, and shows that they are lacking in the application of true engineering principles.

STREET LIGHTING. By J. M. Bryant and H. G. Hake. 61 pages, 6 by 9 inches. 28 illustrations. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill., as Bulletin No. 51.

Efficient and economical street lighting is a subject on which little information of a definite and tangible character has been published. Bulletin No. 51 is designed to supply such information concerning electric street lighting. The subject has been treated in a simple, direct manner, and while of especial interest and value to the technically trained illuminating engineer, will appeal particularly to city councils and central station managers. The general theory and construction of electric lamps, both incandescent and arc, are discussed together with the standard systems of electric distribution for lighting, and accepted methods for the measurement and study of illumination, with and without shades and reflectors. These principles are then applied to the study of street illumination, curves and calculations being given to show the candle-power distribution for the various lamps used, equipped with their proper glassware and reflectors, and others to show the illumination along the street for representative installations and conditions. Based upon these results, a discussion is given of the proper lighting of business streets, cross streets, boulevards, residence streets and outlying districts. The subject of economy for the several systems and lamps is discussed—the initial cost, up-keep, interest, and depreciation of various lamps and equipment are considered in tables and curves showing their relative economy at standard costs of power. Attention is also called to the economical selection of different lamps for certain classes of illumination.

NEW CATALOGUES AND CIRCULARS

WALTER O. AMSLER, Pittsburg, Pa. Descriptive pamphlet of the Amsler gas producers and accessories.

UNITED NUT LOCK CO., Springfield, Mass. Leaflet advertising the "Hugtite" nut lock manufactured by the company.

EMERSON ELECTRIC MFG. CO., St. Louis, Mo. Catalogue of Emerson fan motors for alternating and direct currents.

ROBBINS CONVEYING BELT CO., New York. Bulletin No. 48 on chains, sprockets and elevators; Bulletin No. 49 on conveyor belts.

HARVEY HUBBELL, INC., Bridgeport, Conn. Folder advertising the Hubbell lamp guard, a wire guard for protecting the bulbs of electric lamps.

CALCULAGRAPH CO., 9 Maiden Lane, New York. Circular on the advantages of the calculagraph for registering actual working time in shops, mills, factories, etc.

NATIONAL TUBE CO., Pittsburg, Pa. Bulletin No. 8 treating of the necessity for protecting pipe with a coating material, and giving suggestions relating to the laying of pipe covered with "National" coating.

SPRAGUE ELECTRIC WORKS OF THE GENERAL ELECTRIC CO., 527 W. 34th St., New York. Catalogue No. 325 of Sprague electric fans, illustrating and describing the various types of fans made by the company.

FAWCUS MACHINE CO., Pittsburg, Pa. Booklet on worm gearing, containing a general outline of the requirements of worm-gearing installations, and tables of standard worm-gearing manufactured by the company.

CHICAGO PNEUMATIC TOOL CO., Chicago, Ill. Bulletin No. E-19 on universal electric drills operating on direct or alternating current; bulletin No. E-20 on a new line of electric drills for heavy duty for direct current.

PAWLING & HARNISCHFEGER, Milwaukee, Wis. Folder illustrating "P. & H." apparatus for steel mills, rolling mills, foundries, etc., comprising grab buckets, charging machines, mono-rail systems, mill type cranes, etc.

NATIONAL TUBE CO., Pittsburg, Pa. N. T. C. bulletin No. 4 on "Corrosion of Boiler Tubes," by Rear Admiral John D. Ford, U. S. N., being an abstract of a paper published in the journal of the American Society of Naval Engineers, May, 1904.

ELECTRO-DYNAMIC CO., Bayonne, N. J. Circular No. 39, entitled "Ratings and Dimensions of Inter-Pole Constant and Adjustable Speed Type 'S' Motors." The circular, which covers 24 pages, is principally devoted to tables giving this information.

ELECTRIC CONTROLLER & MFG. CO., Cleveland, Ohio. Bulletins No. 1017, on automatic controllers; No. 1018, motor field rheostats; No. 1019, protective panels for direct-current motors; No. 1020, automatic float switch; No. 1021, motor starting rheostats.

UEHLING INSTRUMENT CO., Passaic, N. J. Bulletin No. 102 on recording instruments, describing a line of recorders for pressures up to 30 pounds per square inch. These instruments are calibrated either in ounces, pounds, inches of water or mercury.

SEAGER ENGINE WORKS, Lansing, Mich. 1912 catalogue of Olds gasoline and kerosene engines. Various types of engines from the smallest sizes up to 70 H. P., intended for miscellaneous uses—for small power plants as well as for agricultural work—are illustrated and described.

LINK-BELT CO., Philadelphia, Pa. Circular illustrating application of the "Maximum" silent chain to automobile engines. The illustrations show the "Maximum" chain applied to driving the magneto, pump and camshaft, thus eliminating all toothed gearing in mesh and reducing the gear noise.

WESTERN TOOL & MFG. CO., Springfield, Ohio. Catalogue of shop furniture comprising portable vise stands, tool stands, lathe stands, stands for blacksmith and machine shops, assembling stands, driving block stands, steel racks, power hacksaws, bench legs, drill holders, emery wheel dressers, etc.

THOMAS E. BUTTERFIELD, consulting engineer and gas power specialist, 68 William St., New York. Circular indicating the work which Mr. Butterfield is prepared to undertake, such as testing gas and oil engines and producers, designing of gas engines and producers, building, equipping and organizing new shops, etc.

LEXINGTON INSTRUMENT WORKS, Lexington, Ohio. Bulletin No. 1 on the Smith recording gas calorimeter, type A. This instrument is designed to supersede the ordinary type of calorimeter which requires the services of a skilled chemist in order to get satisfactory results. The Smith calorimeter will give reliable results in the hands of the ordinary plant operator.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletins No. 4887, on small turbo-generator sets from 5 K.W. to 300 K.W.; No. 4900, on series incandescent lighting apparatus; No. 4918, on direct-current switchboards; No. 4919, on small plant direct-current switchboards; No. 4920, on GE-203A railway motor; and No. 4924, on Thomson prepayment watthour meters.

SMITH-BOOTH-USHER CO., 228-238 Central Ave., Los Angeles, Cal. Catalogue A of machinery, supplies, pipe and fittings, comprising equipment for pumping and irrigation plants, power plants, distillate engines, steam boilers, steam engines, air compressors, transmission machinery, machine tools, woodworking machinery, mining machines, concrete and brick machinery, etc.

GEORGE J. HENRY, JR., hydraulic and mechanical designing and constructing engineer, Rialto Bldg., San Francisco, Cal. Booklet entitled "Water Power," giving hints as to its economical and efficient development and use for hydro-electric transmission for mining and industrial plants, and containing miscellaneous information relating to hydraulic power plant developments.

B. F. STURTEVANT CO., Hyde Park, Mass. Catalogue No. 190 on Sturtevant steam turbines illustrating and describing the new slow-speed type particularly adapted for direct connection with blowers, ventilating fans, gas exhausters, mechanical draft installations, electric generators, centrifugal pumps, and other apparatus for which efficient turbine speeds have generally been too high.

NATIONAL ELECTRIC WELDER CO., Warren, Ohio. Circular of the National spot welder, which in the 24-inch size will weld to the center of a 48-inch shape and unite two 3/8-inch pieces of boiler plate. The machine has a capacity of thirty spot welds per minute in 1/16-inch sheet steel and twenty per minute in 1/8-inch sheet steel. The company makes both spot and butt welding machines.

LANGELIER MFG. CO., Providence, R. I. Bulletin No. 28-32 on Langelier multiple drilling machines with three interchangeable heads. These heads embody the well-known Langelier design of multiple spindles with cranks driven by a common crank plate on the main spindle. The design of drilling head enables the maker to place spindles in any desired relation and at a minimum distance apart.

FITCHBURG STEAM ENGINE CO., Fitchburg, Mass. Pamphlet on the Fitchburg plan of industrial education by Mr. W. B. Hunter, director of the industrial department of the Fitchburg high school. All who are interested in industrial education should procure copies of this pamphlet which describes the successful Fitchburg plan of educating boys in the high school and the shops simultaneously.

CORK INSERT CO., 16 State St., Boston, Mass. Booklet entitled "Here's the Proof," containing a number of letters from customers of the company, giving the results obtained from cork-insert installations; also folder entitled "Relative Cost per H. P. transmitted by means of Plain and Cork-Insert Pulleys." This folder contains a diagram to illustrate the comparison, and tabulated cost estimates.

SIDNEY C. CARPENTER, Box 191, Plainville, Conn. Binder with sheets of engineering data useful to draftsmen, designers, mechanical engineers, and others concerned with the design, construction and use of machinery. These data sheets comprise weights and measures, steam engines, air brakes, pay-rolls, drafting-room conventions, machine shop work, machine design, etc. Prices given upon application.

HINCKLEY MACHINE WORKS, Hinckley, Ill. Circular of the Davis milling attachment and compound table for drilling machines, consisting of a circular base carrying a saddle on cross-slides which are operated by screws having balanced handles. The circular illustrates the use of the attachment showing how any upright drill press from 14 inches to 42 inches swing can be converted into a vertical milling machine.

WHEELER CONDENSER & ENGINEERING CO., Carteret, N. J. Booklet entitled "Steam Tables for Condenser Work." This is a hand-book of steam tables with pressures below atmosphere expressed in inches of mercury referred to a 30-inch barometer. It also includes a discussion of the use of the mercury column. None of the tables given have ever been published before, but have been calculated especially for this book.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4893, describing automatic time switches; No. 4901, on alternating-current switchboard panels; No. 4904, on small plant alternating-current switchboard; No. 4905, on small plant alternating-current switchboards; No. 4906, on the lighting of textile mills with Edison Mazda lamps; No. 4907, on the lighting of offices, banks and public buildings; No. 4917, on direct-current exciter panels.

FERRO MACHINE & FOUNDRY CO., Hubbard Ave. and E. 66th St., Cleveland, Ohio. Catalogue of "Ferro" gasoline engines, including a practical treatise on the subject. This handsome publication will be found of general interest by all concerned with the use and operation of gasoline engines, being fully illustrated and showing details of construction throughout. The catalogue illustrates the company's line of marine engines for launches and power boats.

JAMES CLARK, JR., ELECTRIC CO., Louisville, Ky. Catalogue of "Willey" electrically driven tools, dynamos and motors, comprising portable drills for alternating or direct current in a variety of styles; lathes, center grinders, suspended surface grinders, buffers and bench grinders, water tool grinders, wet and dry grinders, sensitive bench drills, upright floor drills, two and three spindle drills, radial drills, notching presses, winding machines, etc., all electrically driven.

MORTON MFG. CO., Muskegon Heights, Mich. Catalogue of draw-cut shapers and keyseating machinery, comprising bulletins Nos. 1, 2, 3, 4, 5, 6 and 7 on keyseating machines, portable planers and portable keyseaters, standard pillar draw-cut shapers, 26-inch stroke draw-cut shaper with rod brass and shell planing attachments, 30-inch stroke shaper with rod brass shell planing and parallel shoe and wedge attachments, special railroad draw-cut shaper and traveling head draw-cut cylinder planers with full equipment.

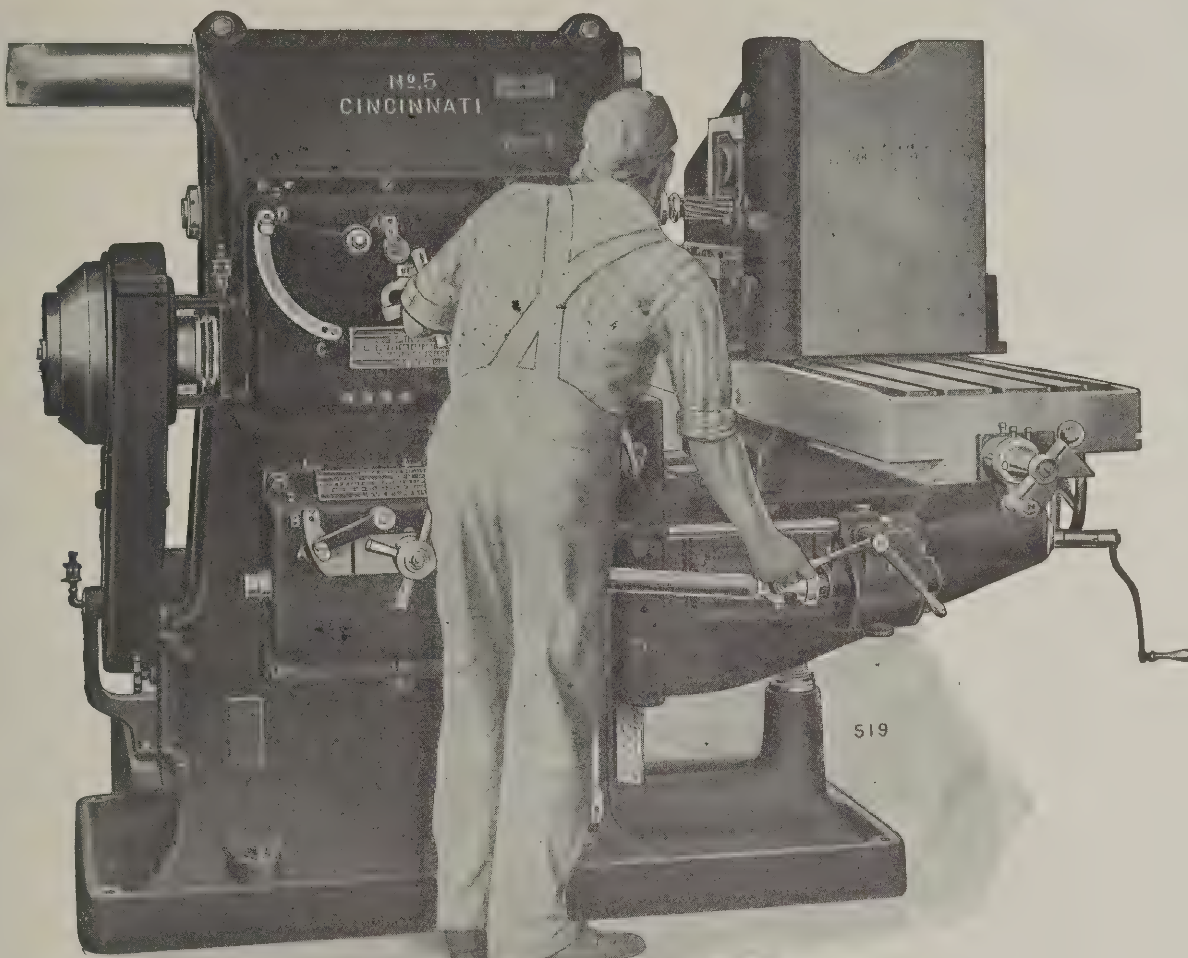
V & O PRESS CO., Glendale, Brooklyn, N. Y. Bulletin No. 6 illustrating and describing automatic attachments for power presses; bulletin No. 1A on inclinable presses; and bulletin No. 200 on sheet metal working machinery. The latter bulletin describes several types of sheet metal working machines which supplement the ordinary press and die equipment of manufacturers of sheet metal articles, such as small automatic screw machines, knurling machines, hand wire ring machines, beading and flanging machines, draw benches, and rolling machines.

WESTINGHOUSE ELECTRIC & MFG. CO., East Pittsburg, Pa. Folder No. 4222, on economy coils for tungsten display lighting; descriptive leaflet No. 2299-A, on Westinghouse type HF slip ring induction motors; leaflet No. 2386, on alternating current heavy duty type MW slip ring induction motors; leaflet No. 2387, on type MS alternating current elevator motors; leaflet No. 2390, on type E alternating current generators for engine drive; leaflet No. 2389, on type G alternating current generators for belt drive; and folder 4213, on oil circuit breakers.

ARMSTRONG MFG. CO., 297 Knowlton St., Bridgeport, Conn. Catalogue showing the company's full line of pipe threading machines and parts. The catalogue comprises 45 pages, 6 by 9 inches. An interesting feature of this catalogue is that every detail that enters into the manufacture of this company's machines is illustrated and either lettered or numbered, so that a customer can order duplicate parts directly from the catalogue, and can thus replace broken or worn parts without delay, which is an extremely important feature in the case of a breakdown.

NEW DEPARTURE MFG. CO., Bristol, Conn. Catalogue of ball bearings containing 76, 6 by 9 inch pages, giving information of a technical character relating to ball bearings, well illustrated with high-grade engravings. The book treats of the double row, the single row, and the "radax" type of ball bearings, and describes the accurate methods for testing used in the company's plant. The greater part of the catalogue is given over to concise descriptions of the application of ball bearings and suggestions for their proper use. A number of useful tables are included.

Cincinnati Handiness



WHEN you have a job of end or face milling to do on a Horizontal Miller, don't you find it hard to operate the feed lever and at the same time keep your eye on the cutter? That's because the machines you are using can be operated from only one place. Our new High Power Machines have an additional feed lever at the side of the knee.

The operator can stand close up to his work, with the cutter in full view, and control the machine from this position.

With this one lever he can operate and reverse table, cross or vertical feeds.

The main starting lever is immediately in front of him and the speed and feed changers are at his elbow, so that the entire machine is under complete control from here. *Ask for the catalog.*

The Cincinnati Milling Machine Company

Milling Specialists **CINCINNATI, OHIO, U. S. A.**

EUROPEAN AGENTS—Alfred H. Schutte, Cologne, Berlin, Brussels, Milan, Paris and Barcelona. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Sam Lagerlofs, Stockholm, Sweden. Axel Christiernsson, Abo, Finland. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow. CANADA AGENT—H. W. Petrie, Limited, Toronto, Montreal and Vancouver. AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne. JAPAN AGENTS—Andrews & George, Yokohama. CUBA AGENT—Krajewski-Pesant Co., Havana. ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Ayres.

MARVIN & CASLER Co., Canastota, N. Y. Catalogue of the Marvin & Casler offset boring tool for lathes, milling machines, drilling machines, boring machines, etc. The tool is graduated to 0.001 inch and provision is made for holding the adjustment so that the tool stays where it is set. The catalogue is illustrated with examples showing uses of the tool that will suggest other uses to interested persons. The tool is made in five sizes, the small size having offset capacity of 3/16 inch and drill chuck capacity of 1/2 inch, and the large size 5/8 inch and 1 1/2 inch respectively.

T. B. WOOD'S SONS Co., Chambersburg, Pa. Catalogue No. 55 entitled "Modern and Approved Appliances for the Transmission of Power." This catalogue comprises 242 pages, 6 by 9 inches, and is substantially bound. It lists a complete line of power transmission appliances with dimensions and price lists, and includes shafting, shaft collars, flange or plate couplings, double cone compression couplings, Collins compression couplings, clutch couplings, hangers and hanger bearings, pillow blocks, belt shifting appliances, countershafts, pulleys, belt tighteners, friction clutches, rope sheaves, etc.

VEEDER MFG. Co., 39 Sargeant St., Hartford, Conn. Catalogue of the Veeder products, including the Veeder hub odometer or mileage recorder for trucks, automobiles or taxicabs; the Veeder tachodometer, which is a combination of speed indicator and mileage recorder; cyclometers for bicycles and motor cycles; the Veeder counters for different purposes; revolution counters for finding the revolutions per minute made by a shaft or any other revolving part; and printing press counters and tachometers. The catalogue gives complete descriptions of the various instruments and their use and care. It also includes illustrations and descriptions of die castings, which this firm makes for the trade.

NORTON Co., Worcester, Mass. 1912 edition of catalogue of grinding wheels and machinery, listing the Norton products, including alundum grinding wheels, crystolon grinding wheels, alundum grain for polishing, crystolon grain for polishing, India oilstones, crystolon sharpening stones, glass cutting wheels, razor hones, scythe stones, Norton alundum refractories, Norton valve grinding compound, rubbing bricks and stones, grinding wheel dressers, and grinding machinery. The catalogue comprises 142 pages, 6 by 9 inches, and shows excellent illustrations of all the products of the company. It also contains considerable information of a general nature, useful in the grinding department of a machine shop.

MORSE TWIST DRILL & MACHINE Co., New Bedford, Mass. Catalogue of increase and constant angle twist drills, reamers, chucks, milling cutters, taps, dies, machinery and machinists' tools. This catalogue for 1912 is the largest and most comprehensive catalogue issued by the company. The alphabetical index of contents covers nearly seven and one-half pages, and the index by numbers nearly six and one-half pages. The two indexes make the finding of any desired article an easy matter. Tables and data which conclude the catalogue are of general value to users of machine tools, and the catalogue will be of general interest and value to superintendents, foremen, machinists, toolmakers, apprentices, etc.

CARLYLE JOHNSON MACHINE Co., Manchester, Conn. Booklet entitled "The Johnson Friction Clutch as Applied in Machine Building," showing illustrations of well-known machine tools in which the Johnson clutch is being successfully used. The illustrations comprise the Newton horizontal milling machine, Betts vertical boring mill, Gridley multiple spindle automatic screw machine, Beaman & Smith quick operating vertical spindle milling machine, J. E. Snyder & Son's upright drill, Merrell Mfg. Co's pipe threading machine, Fay Machine Tool Co's automatic turning lathe, National-Acme Mfg Co's automatic screw machine, etc. The booklet illustrates the construction of the clutch, showing its compactness and simplicity.

CRESCENT MACHINE Co., 56 Main St., Leetonia, Ohio. Catalogue No. 51 of the Crescent universal wood-worker which comprises a band saw, jointer, shaper, saw table and borer in one machine. It is not, however, a combination in the sense of a single machine that can be adapted for different uses, but is a combination of machines each independent of the other, arranged compactly and self-contained so that all can be driven by one main belt from the lineshaft. It is not necessary to run more than one machine when only one is in use, but four persons may use different machines at the same time without hindrance. The value of a machine of this compact arrangement for pattern shops and other places where space is limited, is obvious.

CHARLES H. BESLY & Co., 118 N. Clinton St., Chicago, Ill. Catalogue of Besly spiral disk grinders, band polishing machines, "Helmet" spiral circles, etc. The growth of the disk grinder business is strikingly shown by this catalogue of 112 pages. It has been necessary to index the different types of grinders, covering their general purposes, the divisions being single spindle, belt-driven machines; single spindle, motor-driven machines; double spindle, belt-driven machines; vertical spindle and special grinders, and patternmakers' disk grinders. It has been the aim to make the catalogue answer any reasonable question, and not only is full information given in connection with each machine, but also detailed dimensions, weights, etc., of disk wheels, ring wheel chucks, various types of floor presses, work tables, countershafts, fixtures, accessories, etc.

HEALD MACHINE Co., 20 New Bond St., Worcester, Mass. Booklet "Oversize Standards for Pistons and Rings," by Mr. James N. Heald, being a reprint of a paper presented at the summer meeting of the Society of Automobile Engineers, June, 1911. The author advocates establishing certain oversize standards for automobile pistons and rings, the object being to enable automobile engines to be refitted with new pistons at low cost. If worn automobile cylinders are bored or ground under present conditions it is necessary to make patterns for new pistons, and to fit the pistons up from the rough castings. The automobile manufacturers should provide oversize pistons as they have the jigs, fixtures and patterns that can be easily adapted to the oversize requirements. The oversizes suggested are 0.010, 0.020 or 0.050 inch more than the standard sizes. With these sizes in stock a repair man could regrind an auto cylinder and fit it with a new piston and rings in short time and at small expense.

TRADE NOTES

MUMFORD MOLDING MACHINE Co., Plainfield, N. J., reports the sale of a large 24-inch jolt rammer, having a capacity of 24,000 pounds, to the Canadian Rand Co., Sherbrooke, Quebec, Canada.

STARK ROLLING MILL Co., Canton, Ohio, has furnished a large amount of formed sheet metal of anti-corrosive "Toncan" metal for the United States coaling station at Pearl Harbor, Hawaii.

WESTINGHOUSE AIR BRAKE & TRACTION BRAKE Co., has removed the office of its southeastern manager, Mr. R. A. Craig, from the general office Wilmerding, Pa., to 308 Westinghouse Bldg., Pittsburg, Pa.

ADAMS-BAGNALL ELECTRIC Co., Cleveland, Ohio, manufacturer of electric light apparatus specializing on electric lighting systems for industrial plants, is now located in its new factory at 7125 Platt Ave., S. E., Cleveland.

RUGGLES-COLES ENGINEERING Co., 50 Church St., New York, reports that the Bayonne Casting Co. has just cast the second propeller for one of the Japanese battleships. These propellers, each of which weighs approximately 12,000 pounds, are to go to the Fore River Ship-Building Co. for finishing and will then be sent to Japan.

H. W. JOHNS-MANVILLE Co., has moved its Pittsburg office from Liberty Ave. above Ninth St. to the eight-story stone, reinforced concrete and steel building at the northeast corner of Wood St. and First Ave. The company has leased the entire building for a term of years and will occupy the whole of it. The building is 31 by 96 feet and contains a gross floor space of approximately 23,800 square feet.

H. W. JOHNS-MANVILLE Co., 100 William St., New York, has acquired the sole selling agency for the Frink reflectors and illuminating specialties. The company is already known in the illuminating field by reason of its J-M linolite system of illumination and will now be in position to design and sell lighting systems for every known form of artificial illumination. An extensive engineering department will be maintained.

STANDARD ELECTRIC TIME Co., a Connecticut corporation formerly located at Waterbury, Conn., and now temporarily located at Foxboro, Mass., will move to its new factory building on Logan St., Springfield, Mass., in April. The general office of the company, which has been in Boston, Mass., will also be transferred to Springfield. Mr. George L. Riggs is president and general manager, and Mr. G. F. Harter, works manager.

BEST MFG. Co., Pittsburg, Pa., has equipped its new plant to expeditiously fill all orders for piping of every description. It is prepared to lay out entire piping systems, furnish material cut and fitted ready for erection, or to take contracts and install complete, ready for operation. Mr. H. W. Evans, formerly with the Crane Co., Chicago, is general manager of sales in charge of the sales, order and engineering departments.

BOYE & EMMES MACHINE TOOL Co., Cincinnati, Ohio, is the successor of Schumacher & Boye and Schumacher, Boye & Emmes. Mr. F. W. Boye, Jr., and W. T. Emmes have purchased the interest of Mr. W. A. Schumacher in both firms. Mr. Emmes has been connected with the firm for a number of years and has a wide reputation in the mechanical line. The firm of Schumacher & Boye has been in existence for about fourteen years.

H. B. BROWN Co., East Hampton, Conn., recently had an important change in personnel of its officers. Prof. Charles S. Brown has acquired a controlling interest, and has been made president; Abner W. Barton is secretary and treasurer; and Henry B. Brown, the late president, after forty-six years of continuous and successful labor, retires from active duty. The company manufactures bolt and nut machinery, and its product is well known throughout the world.

VERMONT MACHINE TOOL Co., Windsor, Vt., has been incorporated to manufacture a multiple-spindle automatic turret drilling machine, designed by Mr. G. O. Gridley of the Windsor Machine Co. In addition to the advantages of the usual type of multiple-spindle drill, this machine is fully automatic in its action, so that its output is not dependent upon the personal element of the operator, and it has in addition certain features in common with the turret machines.

NEIL MACHINERY Co., successors to Geo. E. Neil, machine tool dealer, has opened large display rooms at 711-713 St. Clair Ave., N. E., Cleveland, Ohio, and will handle a line of machine tools. The company will represent, among other concerns, the Springfield Machine Tool Co., Springfield Ohio; Oliver Machinery Co., Grand Rapids, Mich., and the Waterbury, Farrel Foundry & Machine Co., Waterbury, Conn. Mr. Neil was for a long time connected with the W. M. Pattison Supply Co., but has been doing business for himself for the past three years. The company is open for arrangements for agencies in non-competing lines.

LEA EQUIPMENT Co., manufacturer of high-duty centrifugal pumping equipment and the "Lea-Simplex" cold saws, which has heretofore had general offices at 97 West St., New York, has found it necessary to enlarge its manufacturing facilities to accommodate its extensive and growing trade by removal to the works at the corner of Stenton and Wyoming Aves., Philadelphia. The general sales offices will be located at the works under the supervision of Mr. H. R. Williams, the general sales manager. The company will retain quarters in the West St. building, New York, from which point the export and Eastern trade will be served by the president, Mr. Albert G. Lea.

BAUSH MACHINE TOOL Co., 200 Wason Ave., Springfield, Mass., has increased its capital stock to $500,000, 6 per cent accumulative preferred stock and $1,000,000 common stock following the transfer of a controlling interest from Mr. Frank H. Page, president of the National Equipment Co., to Mr. C. K. Lassiter, mechanical superintendent of the American Locomotive Co. The company will take over the manufacture of multiple-spindle and hydro-pneumatic drills, bolt turning machines and stay-bolt threading machines, designed and patented by Mr. Lassiter. The officers of the new company are: C. K. Lassiter, president; Frank E. Bocorselski, vice-president; Walter H. Foster, treasurer; J. A. Eden, general manager; and Charles A. Smith, superintendent.

VAN DORN & DUTTON Co., Cleveland, Ohio, reports that it is receiving many orders from concerns that appreciate the high electrical and mechanical efficiency of its electrical portable tools. The McClintic-Marshall Construction Co., Pittsburg, Pa., several months ago purchased for its Panama Canal work twelve of the Van Dorn & Dutton hard service electric reamers, and later duplicated the order. The same company has recently given another order for twenty-four of the type DC-3 hard service electric reamers. The Hupp Motor Co., Detroit, Mich., recently ordered twenty-five Van Dorn & Dutton electric drills, having found them peculiarly adapted to motor car construction work. The C. R. Wilson Body Co., Detroit, Mich., has twenty-four electric drills in service, and the Haskell & Barker Car Co., Michigan City, Ind., has twenty in its new steel freight car shop.

EAGAN-ROGERS STEEL & IRON Co., has been incorporated under the laws of the state of Pennsylvania with a capitalization of $100,000. The company has acquired a five-acre tract on the Pennsylvania Railroad in the Chester district between Crum Lynne and Eddystone, Pa., and has started the erection of modern steel buildings, the contract for which was let to the McClintic-Marshall Construction Co. The men most actively interested in the company are Messrs. Daniel C. Eagan and John I. Rogers. Mr. Eagan is the son of the late Daniel Eagan and has had wide experience in this line of work, and Mr. Rogers is an engineer who was formerly with the Midvale Steel Co., and has been in consulting practice for the last few years in New York and Philadelphia. The company will specialize on forging plants; hammer, hydraulic press, and drop forging; tire and wheel rolling, etc. The plant is expected to be in active operation about March 1.

PERMANENT MANUFACTURERS EXHIBIT RAILWAY SUPPLIES AND EQUIPMENT, Karpen Bldg., 900 S. Michigan Blvd., Chicago, Ill., has been established on the twelfth floor, having an area of 26,000 square feet. Provisions have been made for additional floors should they be required. The purpose of the exhibition is to display all kinds of railway supplies. In connection with the exhibition there are large assembly and committee rooms for the use of railway associations, free of charge, and also a large club room, which, in furnishings and service, is of the highest class. The booths or display spaces are furnished by the management with all the necessary equipment for doing business, such as rugs, furniture, heat, light, janitor service,

MACHINING LOCOMOTIVE CYLINDERS*

PRACTICE AT THE JUNIATA SHOPS OF THE PENNSYLVANIA RAILROAD

By FRANKLIN D. JONES†

THE cylinders of locomotives vary considerably in their general arrangement, and the exact method of machining them depends altogether on the type, but as the variations in practice are of minor importance, we shall deal with the subject in a general way instead of describing in detail the operations for each particular design. The various operations referred to represent the practice at the Juniata shops of the Pennsylvania Railroad, where all the passenger locomotives and many of the freight class used in this extensive system are built. The style of cylinder now used almost exclusively on the new locomotives built by the Pennsylvania Railroad, is the single-expansion piston-valve type. Figs. 3 and 4 show two designs which differ in that the cylinders illustrated in Fig. 3 are cast integral with the saddle, whereas the cylinders shown in Fig. 4 are bolted to the saddle which forms a separate casting. The advantage of this three-piece construction is that a broken cylinder can be replaced more quickly because the saddle does not need to be detached from the boiler or frames. With the design shown in Fig. 3, considerable time is required to fit and bolt the flange on the saddle of a new cylinder to the boiler.

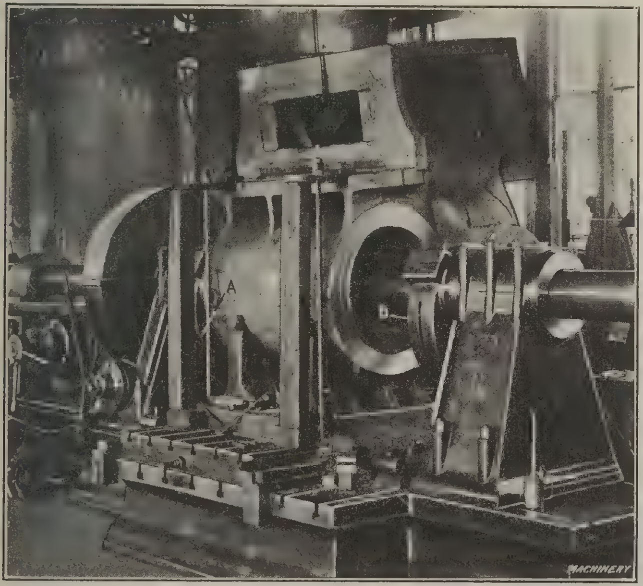

Fig. 1. Boring a Locomotive Cylinder

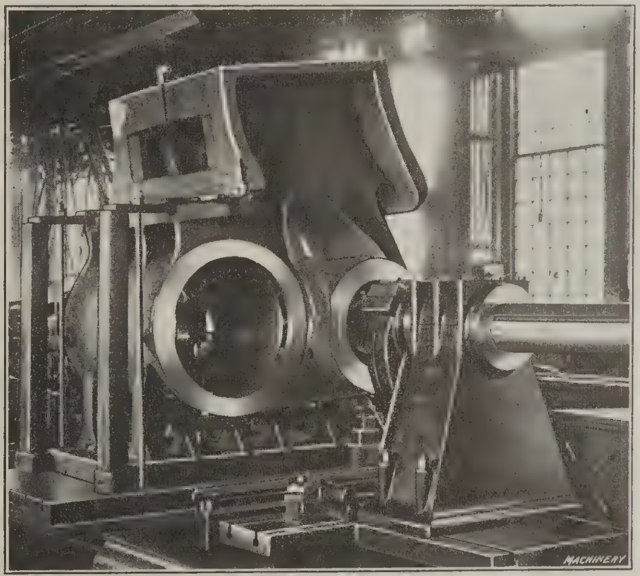

Fig. 2. Cylinder set for Boring Valve Chamber

Boring the Cylinders

The first machining operation on a cylinder casting is that of boring the cylinder proper. The boring is done by the large machine illustrated in Figs. 1 and 2. The cylinder casting is supported at the right height by a fixture, as shown. The flanges are first rough-faced by radial facing arms *A* and *B*, the tools of which are fed by the well-known star feed. The bore is then finished by one roughing and one finishing cut, four tools being used for roughing and two for finishing. Broad-nosed tools are used for the light finishing cut and are given a feed of 3/8 inch per revolution of the boring-bar. As the boring-bar is very rigid, these coarse feeds can be used without chattering. The cylinder is also counterbored as far in as the inner edge of the steam ports, to prevent the piston-rings from wearing shoulders at the ends of the piston stroke.

After the cylinder bore is finished, the table or platen of the boring machine is moved over the right distance for boring the valve chamber, the proper adjustment being determined by graduation lines at the side of the table. In order that the valve chamber will be at the proper vertical height after making this adjustment, the casting is originally set up in the machine so that the centers of the cylinder and valve chamber are in the same horizontal plane. Fig. 2 shows the position of the work when set for boring the valve chamber. The flanges are faced prior to boring, and the offset of the flanges with relation to the cylinder flanges, is tested by a special gage. The valve chambers are not bored to one diameter throughout, but have a shoulder at each end for locating the valve bushings or linings which are afterward forced into the bore. The piston-valve operates inside these bushings, which can readily be renewed when worn. As the steam ports are machined in the bushings, the latter must be accurately located lengthwise to bring the ports in the right position. The proper location for each bushing is secured by the shoulder previously referred to, in conjunction with corresponding shoulders on the bushings; hence this shoulder in the bore must be accurately located by another special gage.

Planing the Cylinders

After the cylinder is bored, the various surfaces on the saddle are planed. By the use of an ingenious set of fixtures, the castings are set up for the planing operations quickly and accurately. Fig. 5 shows the cylinder planer with these fixtures in place, and Figs. 6, 7, and 8 show different views of the work mounted on the fixtures. Three cylinders are placed in a row and planed simultaneously, and the fixtures are so arranged that the bores of the various cylinders are aligned with one another and with the planer platen. These fixtures consist of heavy brackets or standards *B* having flanges as shown. The end brackets have a single flange, whereas the two

* For information on locomotive building, at Altoona, previously published in MACHINERY, see "Machining Locomotive Frames," March, 1912; "Locomotive Building at Altoona—Driving Box Manufacture," July, 1910; "Erection Practice in the Juniata Shops," June, 1910, and articles there referred to.

† Associate Editor of MACHINERY.

which come between the cylinders are double flanged. There is a central pocket A in each flange face, and the distance from these pockets to the base is exactly the same for each bracket.

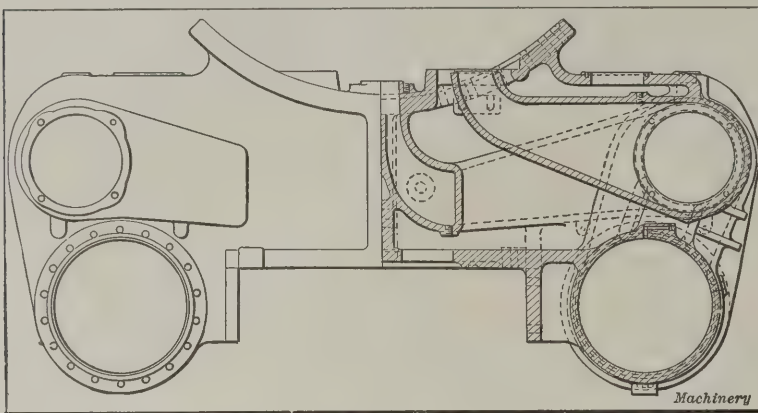

Fig. 3. Front View of Locomotive Cylinders of the Single-expansion Piston Valve Type

Each of the conical disks C which engage the counterbores of the cylinders, has a cylindrical boss D on the rear side which fits into any of the central pockets A. When a cylinder is to be set up for planing, one of these conical disks is clamped in each end of the counterbore by a bolt passing from one disk to the other. The brackets are also bolted to the planer platen in the proper position, as indicated in the illustration. The distance between the brackets is governed by the length between the outer faces of the disks after the latter are bolted in place, and the central pockets A are all brought into alignment, laterally, by tongue-pieces on the base of each bracket. The cylinder is next picked up by a crane and lowered until the disks have entered between the brackets. The temporary holding bolt for the disks is then removed and the work is lowered until the cylindrical bosses D on the disks, which slide through the vertical slots at E, rest in the central pockets A of the fixtures. When three cylinder castings have been set up in this way, the center line or axis of each cylinder bore will be in alignment.

the bore of the valve chamber by using hermaphrodite calipers. The casting is then adjusted vertically by the small supporting jacks seen in Fig. 8, until this center is the required distance below the center of the cylinder, as shown by an ordinary surface gage. The height from the platen to the center of the cylinder bore is accurately ascertained beforehand and remains constant for a given size fixture. After the three castings are set as described, clamping pieces which fit in the slots E, Fig. 5, are tightened against the hubs of the conical disks by clamps H. The cylinders are further secured by a long tie-bolt G, Fig. 6, which extends through the three castings and holds both the work and fixtures rigidly together. The side view, Fig. 7, clearly shows how the conical disks enter the cylinder counterbores and align the three castings. By referring to Figs. 6 and 8, it will be seen that these fixtures make it possible to hold the three cylinders with very few clamps; in fact, the four clamps seen in Fig. 8 are (with the exception of clamps H which are part of the fixture) the only ones required. These fixtures have not only effected a considerable reduction in the time required for setting the cylinders

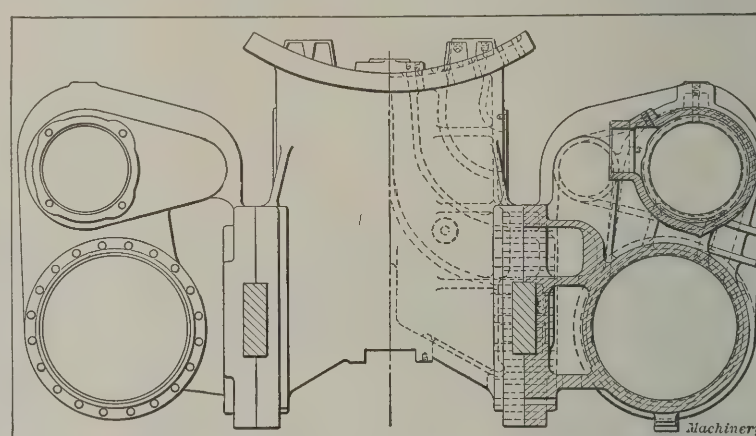

Fig. 4. Locomotive Cylinders having a Detached Saddle

prior to planing, but they also insure accurate and uniform work.

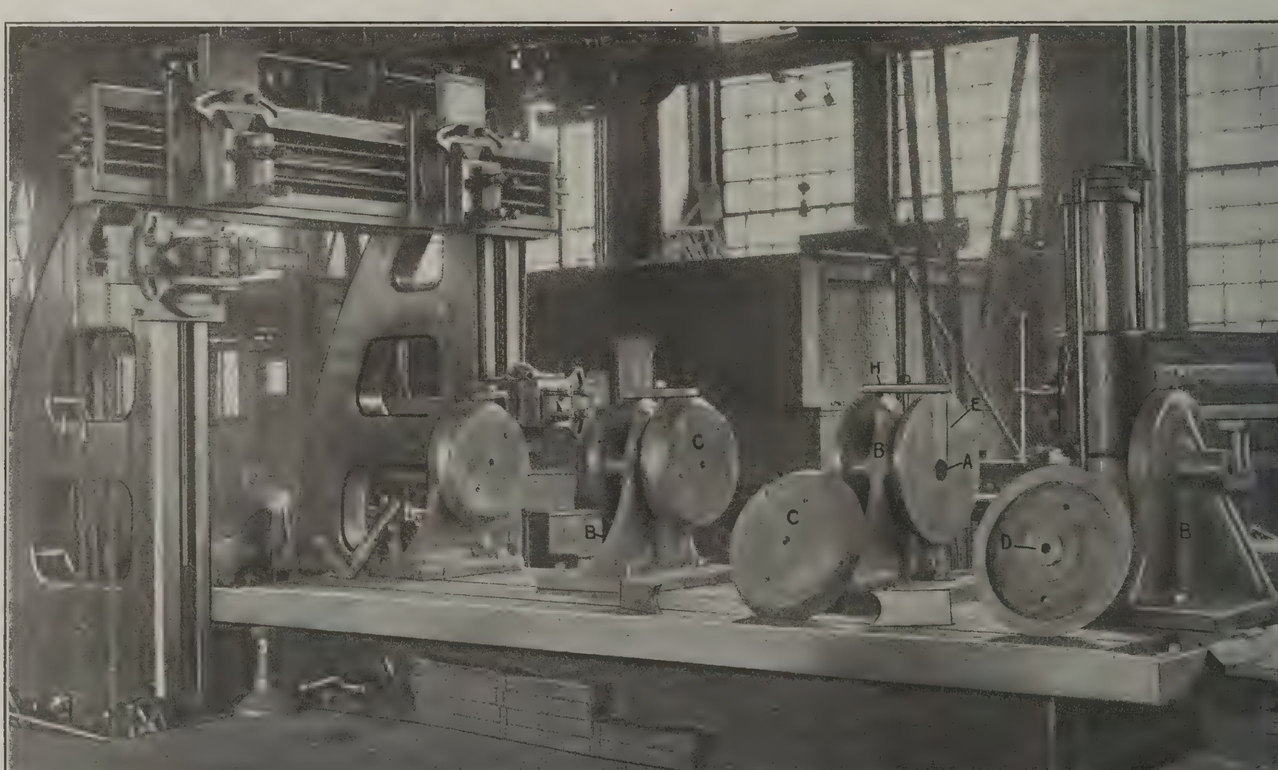

Fig. 5. Fixture for Holding Cylinders while Planing

The valve chamber is next set vertically with relation to the center of the cylinder. To obtain this setting, a spider F, Fig. 6, is placed in the valve chamber and its hub is centered with

After the cylinders are set as described, the top surface I, Fig. 6, which forms the joint between the right- and left-hand cylinders, is rough-planed by using the two tool-heads. This

surface is then finished with a broad tool which is set to the right height for the final cut by a special micrometer gage N. The cutting edge is adjusted to coincide with the top of this gage, which is graduated with reference to the centers of the fixtures so that heights from the center of the cylinder bore can be read directly. The side J is next roughed out and finished by using a side-head, and while this surface is being

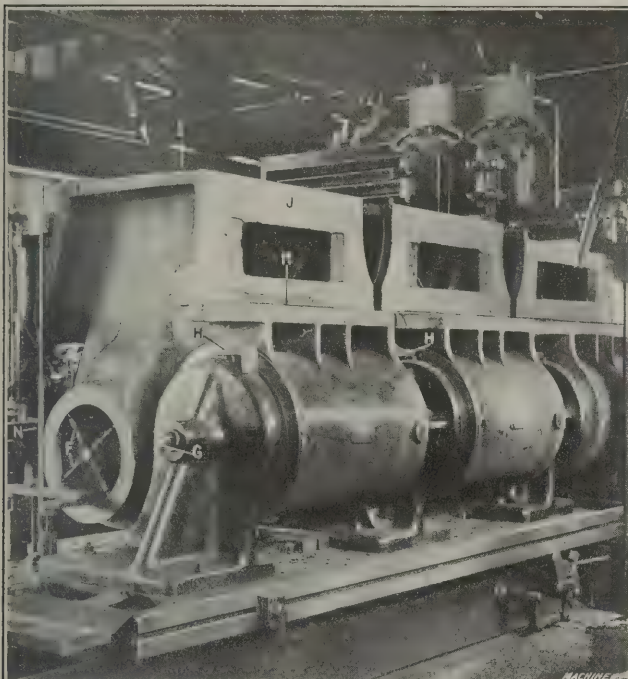

Fig. 6. Three Cylinders being planed simultaneously

planed, the seats K and L (Fig. 8) for the steam and exhaust pipes, are rough-planed with the opposite side-head. Side J is finished to a certain distance from the planer housing, the measurement being taken with a special vernier gage. By measuring directly from the housing, duplicate work is assured and the liability of mistakes is lessened. This method of

exhaust pipe, is gaged from the finished side J and the steam pipe seat L is finished with reference to the exhaust seat. The distance between surfaces I and M is measured by a special height gage. This practically completes the planer work. Of course, the order of the operations is governed entirely by the shape of the cylinder casting, and differs from that described in the foregoing, for other types of cylinders.

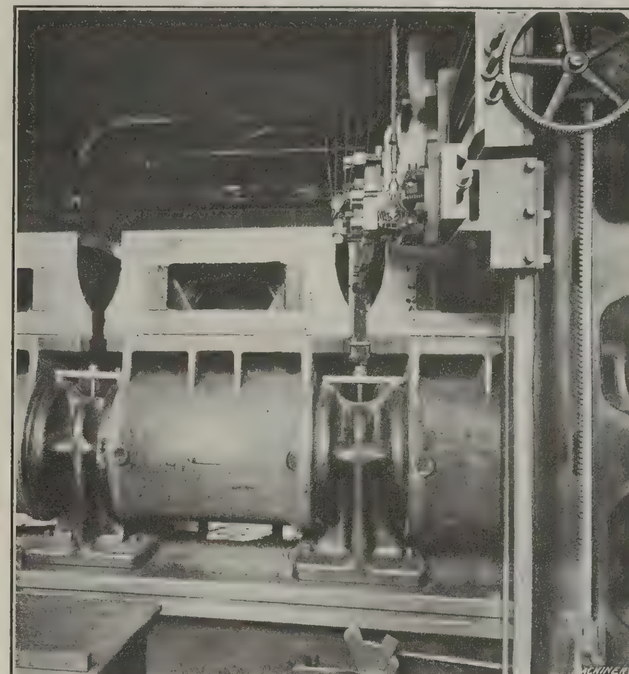

Fig. 7. Side View showing Arrangement of Planing Fixtures

Figs. 9 and 10 indicate the method of planing cylinders of the type illustrated in Fig. 4, which, as will be recalled, are bolted to the saddle. These castings are set up in the same way as described for the style illustrated in Fig. 8. The planer work on the cylinder proper, is more easily done owing to the shape of the casting. The illustrations show the two

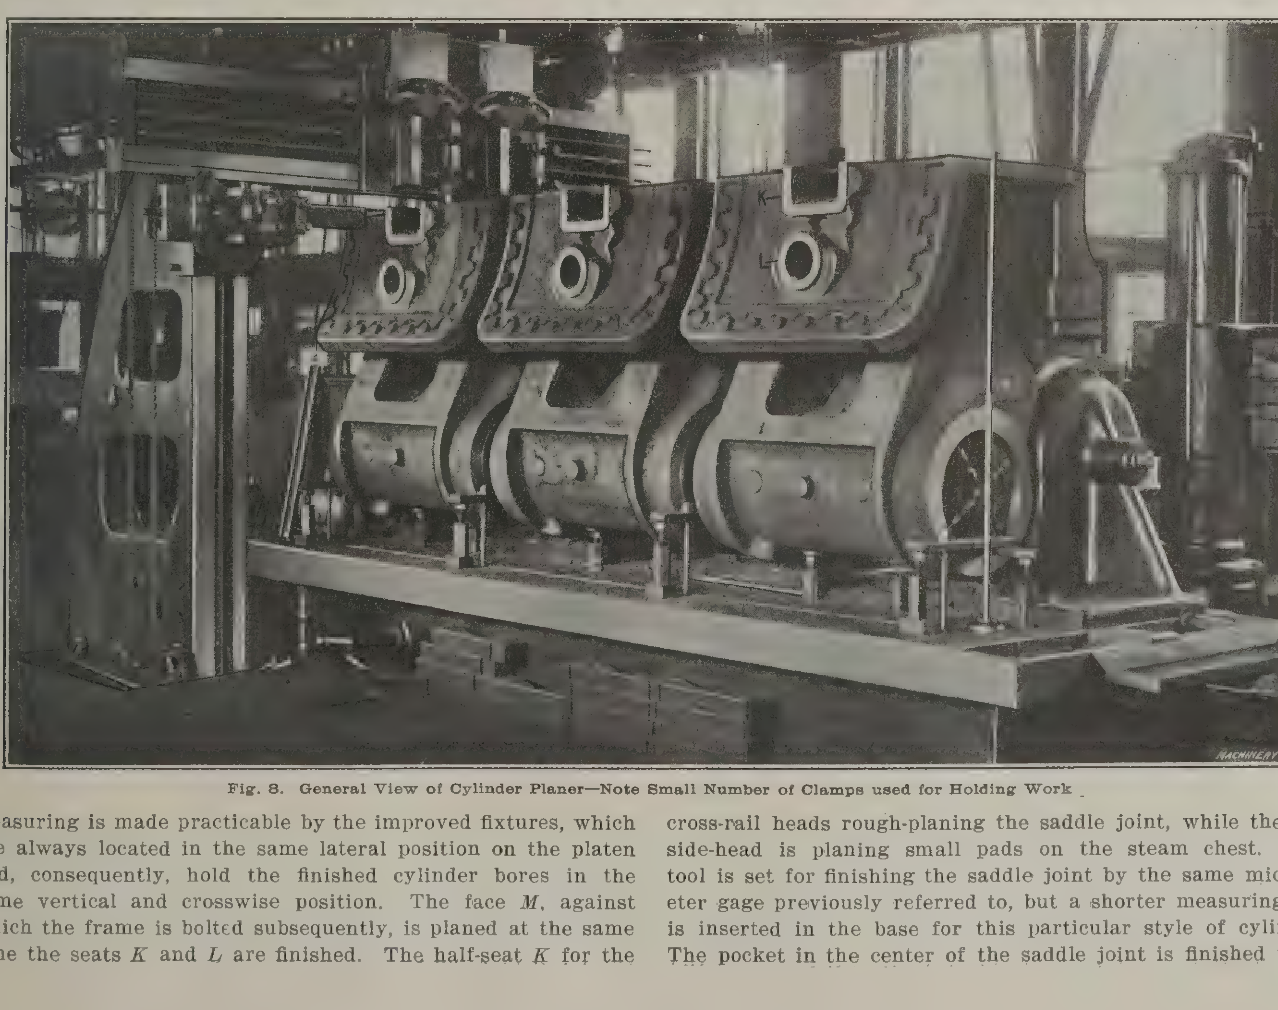

Fig. 8. General View of Cylinder Planer—Note Small Number of Clamps used for Holding Work

measuring is made practicable by the improved fixtures, which are always located in the same lateral position on the platen and, consequently, hold the finished cylinder bores in the same vertical and crosswise position. The face M, against which the frame is bolted subsequently, is planed at the same time the seats K and L are finished. The half-seat K for the

cross-rail heads rough-planing the saddle joint, while the left side-head is planing small pads on the steam chest. The tool is set for finishing the saddle joint by the same micrometer gage previously referred to, but a shorter measuring rod is inserted in the base for this particular style of cylinder. The pocket in the center of the saddle joint is finished to fit

the frame, and in the right relation to the cylinder bore. There are also corresponding pockets in each side of the saddle casting, and the frames pass through the rectangular opening or mortises thus formed, as indicated by the section lines in Fig. 4. The planing of this saddle joint and pocket, is practically all the planer work there is on a cylinder of this type. The nature of the planing operations on the saddle is clearly indicated by the drawing Fig. 4.

Laying Out and Drilling the Cylinders

After the cylinders are planed, the accuracy of the machine work previously done is tested and the casting is laid out for drilling holes that cannot conveniently be jig-drilled. Fig. 11 shows the method of testing the location of the cylinder bore and valve chamber, with relation to each other and to the finished central joint which is resting on the laying-out plate. The centering spiders shown are first accurately set in each bore and the respective heights of the cylinder and valve chamber are determined by using a tall surface gage. These heights are measured by comparing the gage pointer with a long steel scale held in a vertical position. While the use of the planing fixtures previously described, insures accurate work, it has been found advisable to check important dimensions so that the cylinders can be erected without delay due to imperfect work. After the height of each bore has been checked, as described, the distance from the face of the back cylinder flange to the finished projection A is carefully tested, as this projecting flange rests against the frame and determines the cylinder's fore-and-aft location.

Most of the holes in the cylinder are, of course, drilled by the use of jigs. There are, however, a few holes which cannot conveniently be drilled in this way and these are laid out at this time. For example, the small screw holes around the periphery of the flange, for fastening the cylinder jacket, as well as those for lubricator and indicator pipes, dripcocks, etc., are all laid out by hand. A center line L (see Fig. 15) is also drawn across the saddle face for locating the jig used when drilling the bolt holes for the steam and exhaust pipe seats at S and E. This line is exactly central with the front and back flange faces of the cylinder. A central point is first located at L_1, Fig. 12, by measuring from a long straightedge held across the front and back flanges. The cylinder is then turned over and this line is carried across the saddle joint by using a large square.

The drilling operations on the cylinder are of an obvious nature and therefore a detailed description of this work will be unnecessary. Practically all the holes are drilled by the use of jigs, in large radial machines. Fig. 13 shows a plate jig for drilling the frame bolt holes. This jig is located by the finished end A on the cylinder and the jig for drilling the corresponding holes in the frame is set by a shoulder which bears against end A, so that both sets of holes register closely when the cylinder and frame are assembled; consequently,

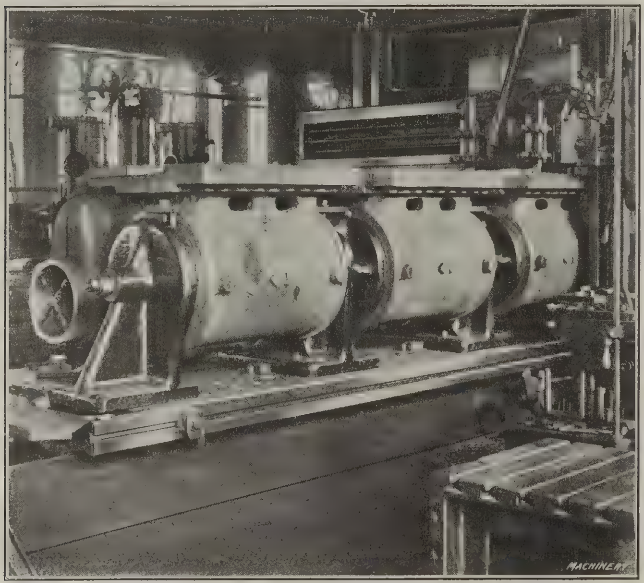

Fig. 9. Planing Cylinders of the "Three-piece" Type

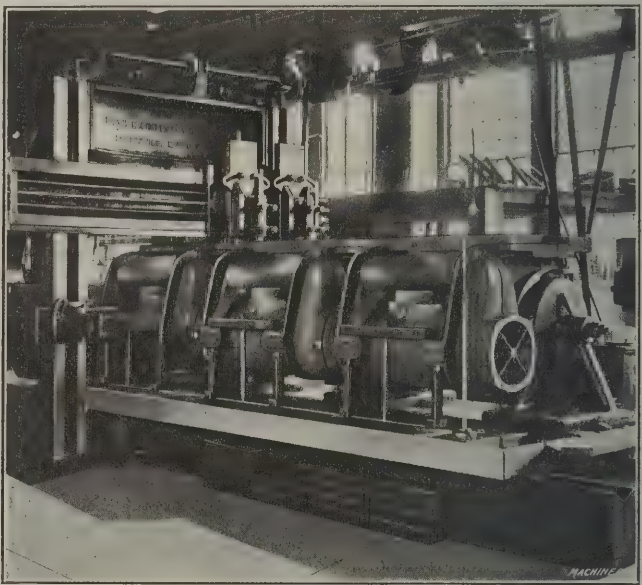

Fig. 10. Another View of the "Three-piece" Cylinders set up for Planing

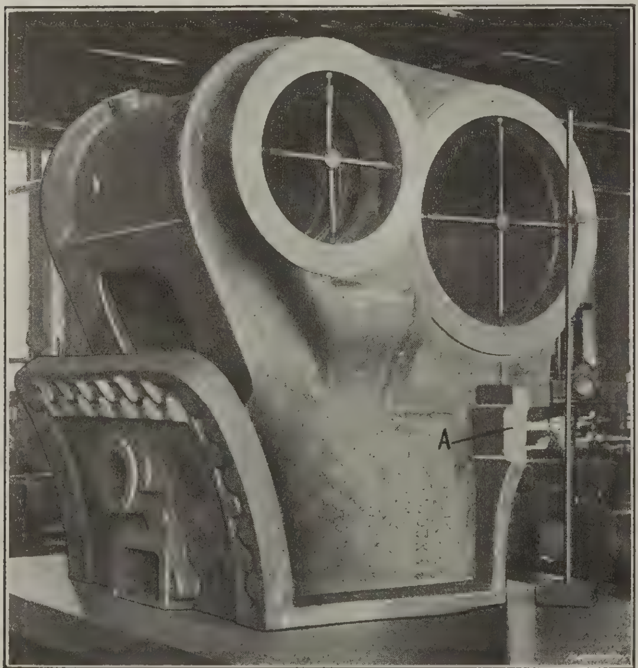

Fig. 11. Testing Height of Cylinder and Valve Chamber

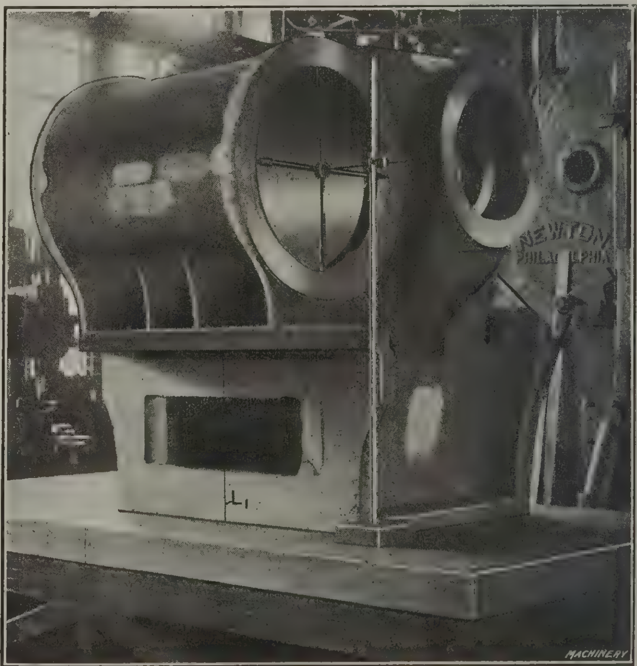

Fig. 12. Another View of Cylinder on Testing and Laying-out Plate

little reaming is necessary. The holes for the stud bolts which hold the cylinder and the steam chest heads in place, are drilled with ordinary ring jigs as indicated in Fig. 14. Fig. 15 shows the method of forming the seat for the steam pipe. This pipe is not clamped directly to the cylinder, but bears against a cast-iron ring having a flat face on one side and a spherical face on the other. The large reamer *R* forms this spherical seat, which is clearly shown in the view to the left, Fig. 16.

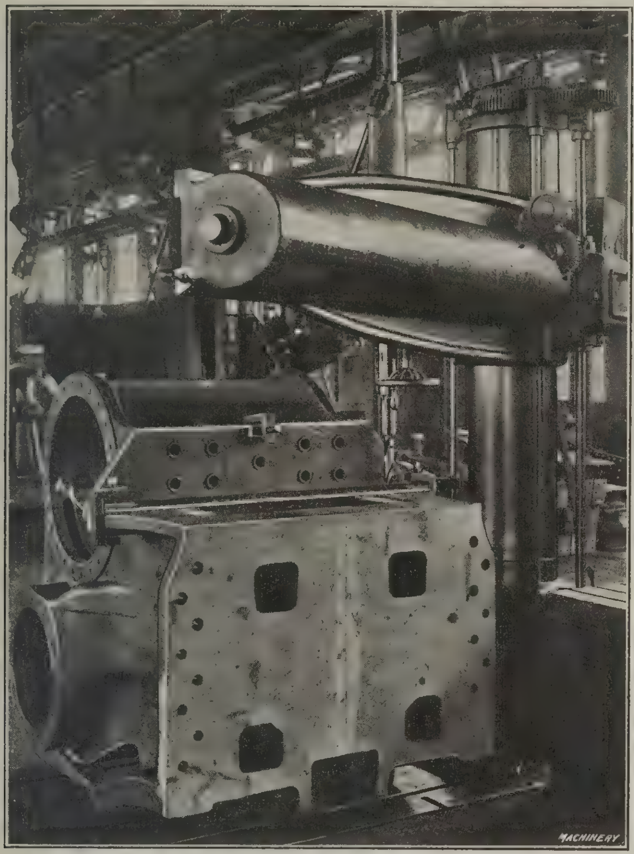

Fig. 13. Drilling Frame Bolt Holes

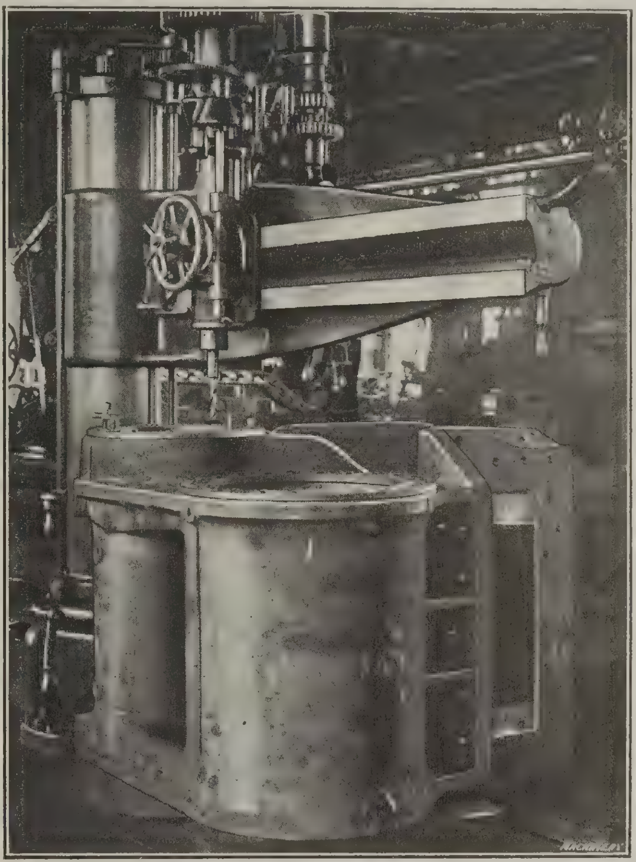

Fig. 14. Drilling Flanges

Erecting Cylinders—Piston-valve Bushings

When the drilling is completed the cylinders are ready for the erecting shop. The right- and left-hand cylinders which are to be mates, are set up and aligned as illustrated in the two views Fig. 16. The saddle bolts through the front and rear flanges *F* are then reamed and the tightly fitting taper bolts are inserted. The cylinders are now ready to be attached to the frames. They are first bolted to the frames temporarily, and their position is carefully tested. The bolt holes are next reamed and the right and left frame sections are bolted to their respective cylinders.

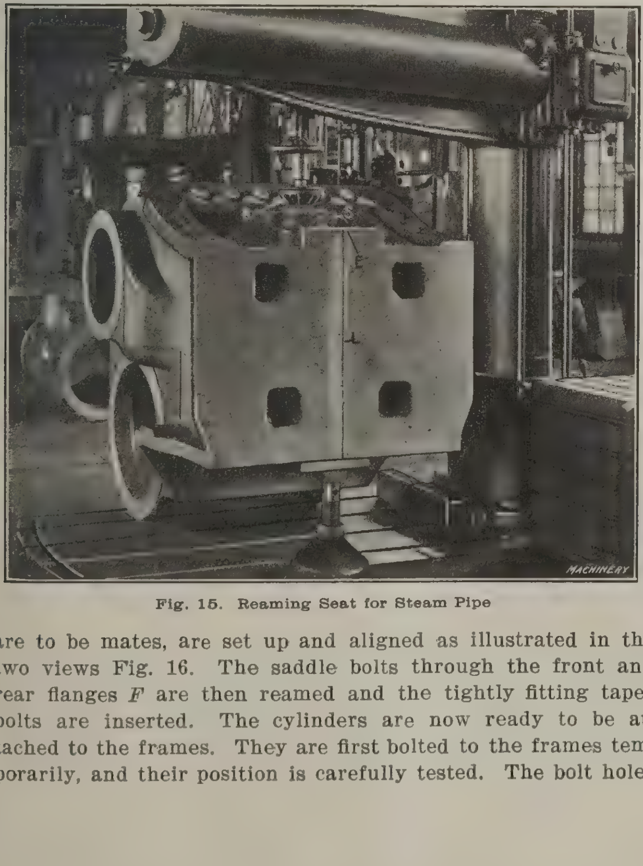

Fig. 15. Reaming Seat for Steam Pipe

Fig. 16. Cylinders aligned for Reaming Flange Bolt Holes

The bushings or linings for the valve chambers are also inserted at this time. There are two of these bushings in each cylinder, which are inserted from opposite ends of the valve chamber bore. The inside of the bushing is bored to fit the piston-valve, and the outside is turned to fit tightly into the cylinder. The boring is done in a vertical boring machine, and the outside is turned in a lathe (as indicated in Fig. 17), after the boring operation. The bushing is mounted on a large expanding mandrel, and it is turned from 0.005 to 0.008 inch larger than the bore of the valve chamber, in order to secure a tight fit. This allowance varies somewhat for bushings of different diameter. After the bushing is turned, the steam and exhaust ports, which are cored in the casting, are finished by milling. Two finished bushings are shown to the right in Fig. 17. The large ports *E* are for the exhaust and the smaller ports *S* register with the cylinder steam ports when

the bushings are in place. These ports are milled to a standard width by the use of gages. They are also located with reference to the shoulders L which, as previously stated, come against corresponding shoulders in the valve chamber, and determine the respective positions of the bushings. The distance between the steam ports is checked before the bushings are inserted in the cylinder. This preliminary test is made by placing the two bushings in line, with the shoulders L the same distance apart as the shoulders in the valve chamber. The distance between the inner edges of the steam ports is then measured with a large vernier scale V. A variation of only 0.004 inch is allowed for this dimension. As the distance

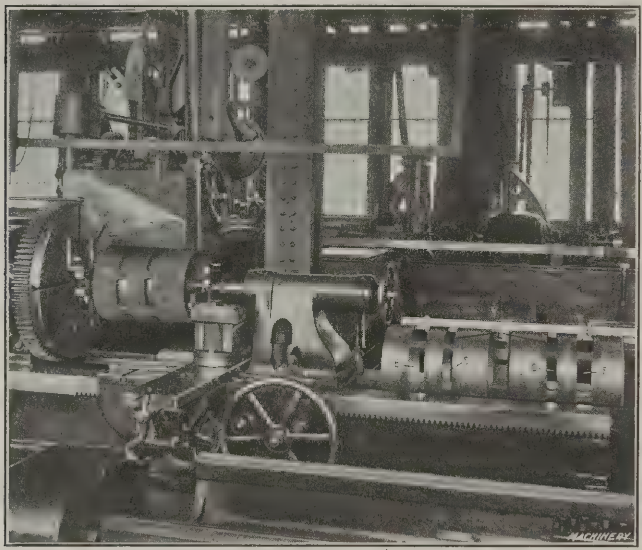

Fig. 17. Method of Turning Valve Bushings and Preliminary Test to determine Location of Steam Ports

between the packing rings of the piston-valves, and also the width of the rings, is accurately gaged, the proper relation between the valve and the steam ports is secured within close limits.

The finished bushings are drawn into the valve chamber by a screw and air motor as shown in Fig. 18. This particular illustration shows the motor arranged for drawing in the rear bushing. The screw, which is rotated by the motor, is prevented from moving longitudinally, by a heavy strap which

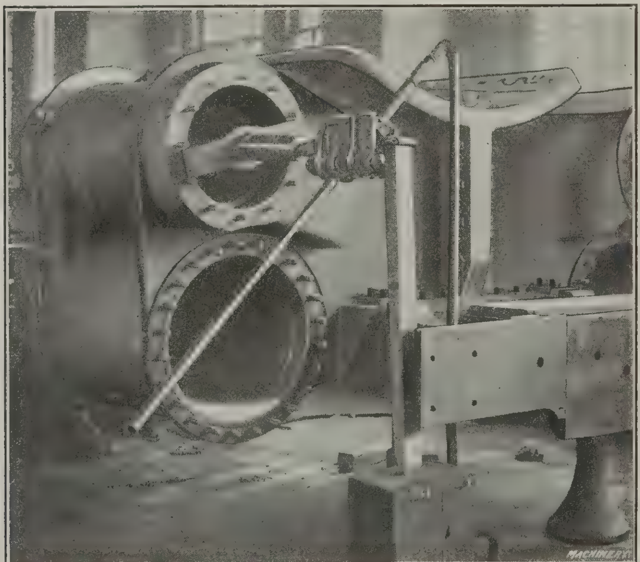

Fig. 18. Drawing in Valve Bushing with Air Motor

is placed across the flange as shown. After both bushings are drawn in against the shoulders, the distance between the steam ports is again tested with the vernier scale. This second measurement is taken to make sure that the bushings are not held away from their seats by small chips or dirt which may have been overlooked when the bore was cleaned.

Before the boiler can be erected, the curved seat or saddle formed by the two cylinders, must be fitted to the front of the smokebox. As the steel sheet which forms the smokebox, may not be exactly circular, the saddle is always fitted to the particular boiler for which it is intended. In order to obtain the required outline, the boiler is lowered by a crane onto the frames and cylinders. The boiler is then set level, both lengthwise and laterally, and it is also centered with the frames. The outline of the smokebox is then transferred to the saddle flanges, by using a scratch gage. This line represents the finished surface of the saddle, and it should be drawn just far enough from the top surface, to permit truing the entire saddle flange. When this line is scribed, the boiler is removed and a gang of men chip the flange down to the required outline. This chipping is done by pneumatic hammers. There are raised pads on the saddle flange as shown in the view to the left, Fig. 16, so that a comparatively small surface requires chipping. When the flange is finished, the boiler is permanently bolted to the cylinders, and when this stage is reached the erection of the locomotive proceeds rapidly. A detailed description of locomotive erection was published in MACHINERY, railway edition, June, 1910.

HIGHEST VOLTAGE DIRECT-CURRENT LOCOMOTIVE IN THE UNITED STATES

Recently the East Pittsburg Works of the Westinghouse Electric & Mfg. Co. completed equipping the locomotive illustrated, for the Piedmont Traction Co., which will operate an extensive railroad system in the Piedmont section in North Carolina and South Carolina. This locomotive is one of six to operate at a pressure of 1500 volts direct-current.

Baldwin-Westinghouse 55-ton 1500 Volt, Direct-current Locomotive for Piedmont Traction Co., equipped with four No. 308-B—5, 180 H. P. 700 Volt Railway Motors and Westinghouse HL Control

This voltage is the highest direct-current voltage used by any electric railway in the United States. The mechanical parts were built by the Baldwin Works, Philadelphia, Pa. The locomotives weigh 55 tons each and are equipped with four Westinghouse motors which have a rating of 180 horsepower. Each locomotive is able to haul 40 freight cars weighing 45 tons each with load, at 20.5 miles per hour on a straight level track, or nine cars at the same speed on a 1 per cent grade. The motor equipment is controlled by the Westinghouse electro-pneumatic, unit switch type of control. Steel construction is used throughout. The under-framing is built of steel channels and the cab-sheets are mounted on a steel angle-iron frame. Electric power for operating the Piedmont properties will be supplied by the Southern Power Co., Charlotte, N. C.

* * *

A well-constructed locomotive leaf spring is made with the ends of the leaves tapered in thickness to a comparatively thin edge, the object being to make the outline approximate the parabolic curve of the theoretical spring. The tapering of the ends entails considerable labor, and in some railway repair shops the theoretical consideration in spring-making is being sacrificed by leaving the ends of the leaves square. The extra stock required for a spring end is lost, but this is more than balanced by the saving of labor. Springs made in this way are not as efficient, however, as when the leaves are tapered.

REPAIRING PLANERS AND SHAPERS*

By EDWARD K. HAMMOND†

The wearing of parts of a machine, through use or misuse, necessarily disturbs its alignment and makes accurate work impossible. In such cases, the wear in each individual member need not be great, because the errors produced are cumulative in their effect, and negligible amounts of error in the different members combine to result in a serious inaccuracy in the work produced by the machine. The average mechanic, experienced in the operation of machinery, is familiar with these facts, but when he attempts to adjust a machine to compensate for wear, he is more than likely to fail. This failure is generally due to the use of improper methods of doing the work.

The firm of A. O. Walworth & Co., 30 S. Clinton St., Chicago, Ill., makes a specialty of rebuilding machinery, and,

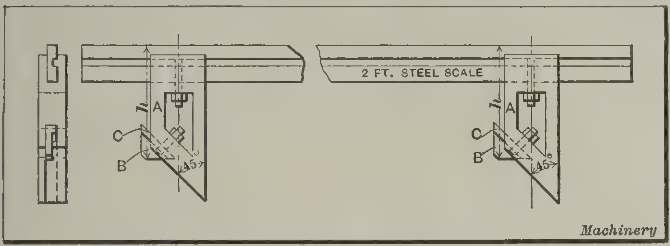

Fig. 1. Special Gage used for Testing Planer Beds and Tables

as the result of a wide experience in this work, special methods have been developed to compensate for the wear in used machine tools. These methods enable a badly worn machine to be adjusted to practically the same degree of accuracy that it possessed when new, and in this article, the practice of this company in the adjustment of planers and shapers will be described. While these methods are all of a special character, they will be readily understood by any mechanic, and their use will make it possible to put machines back into such a condition as to fit them for the production of accurate work.

Method of Adjusting a Worn Planer

In starting upon the adjustment of a planer, the first step is to completely dismantle the machine, in order that the

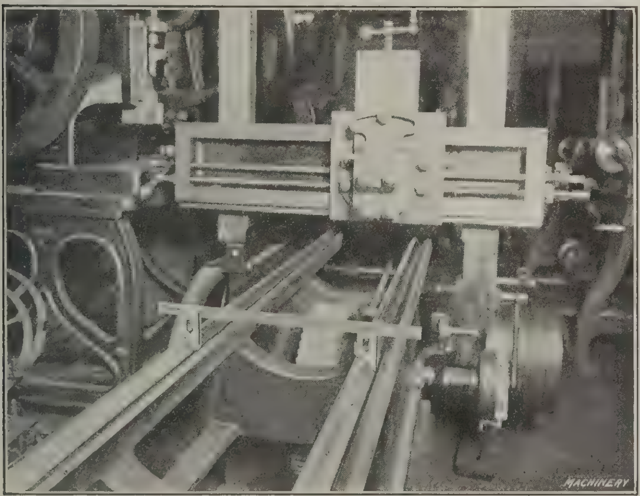

Fig. 2. Testing the Distance between Corresponding Surfaces of the Vees

condition of each part may be determined by tests and inspection. The class of service for which the planer has been used necessarily determines the amount of wear and the points where it will have been produced. In general, however, it may be stated that the table and its bearings in the bed, the crossrail, the saddle bearing on the crossrail, and the shaft bearings, are the points where the most serious inaccuracy is likely to be found.

Planer tables are frequently sprung out of shape as the result of poor judgment on the part of the operators in clamping down the work. When the clamping bolts are tightened to such an extent that the table is drawn out of shape, and the work and table are then allowed to stand in this way for a number of hours, a permanent set is more than likely to be produced. This is especially true if tools or other heavy objects are dropped on the table while it is in this strained condition. In such a case a vibration is set up which causes the metal to readjust itself to the new shape. Where inaccuracy of this kind occurs, it will usually be found that the middle of the table has become high, the amount of the deformation being easily determined with a straightedge. The error in planer tables from this cause is often a very serious matter, an instance having been brought to the writer's attention where an 8-foot planer table was ½ inch higher at the middle than at either end.

In adjusting a table that has been sprung out of shape in this way, it must be remembered that the thickness has originally been properly proportioned to the length and width. Consequently, if any considerable amount of metal is removed by planing, the table will be too thin. This difficulty has been overcome by reversing the process which caused the deformation of the table, in bringing it back into proper alignment. A heavy iron floor-plate is used for this purpose, provided with bolt holes for clamping down the work. The planer table is laid on this plate, face down, and is then clamped tightly against the surface of the plate. After remaining in this position for two or three days, it will be found that most of the inaccuracy has been removed. During the time that

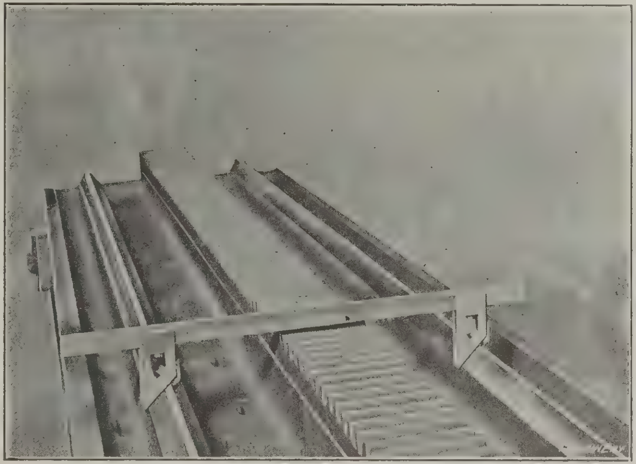

Fig. 3. Testing the Distance between the Planer Table Bearings

the table is clamped to the floor-plate, work can be progressing on other parts of the planer.

Improper methods of oiling often cause serious wear in the vees in the bed and on the table bearings which run in them. Where the bearings have worn quite smooth, there is little chance for proper lubrication, as the oil cannot be held between them. This cause of wear can be easily overcome by taking off the table about once a year, and scraping the vees and bearings. The scraper marks form small pockets which hold the oil and allow it to be distributed over the bearings as required. The bed is tested for inaccuracy of this kind with a straightedge, and if there is found to be any serious amount of wear in the vees, it must be placed on a planer and planed down to approximate accuracy, before scraping to a final finish.

The special gage shown in Fig. 1 is used to maintain the proper distance between the vees during the re-finishing operations. The blade of this gage is a 2-foot steel scale of the kind used on the Brown & Sharpe combination square. The position of the blocks *A*, at either end of the gage, can be adjusted to meet the requirements on different sizes of planer beds and tables; these blocks are secured in any desired position by means of the binding nuts shown. The angle at the bottom is 45 degrees, to fit the standard form of vee. The small triangular plates *B* slide in grooves cut in the inclined edges of the gage blocks, and can be secured in any desired position by means of the binding nuts provided for this purpose. These nuts are carried by bolts which have a slot milled in their sides to fit over the flanges *C* on the plates *B*. In adjusting this gage for use on a given planer bed, blocks *A* are set so that their inclined edges are at the same distance apart as the corresponding sides of the vees, the graduations on the

* See also MACHINERY, July, 1911, "Repairing Lathes and Milling Machines."
† Address: 9620 Hoyne Ave., Chicago, Ill.

blade of the gage being used for this purpose. The plates *B* are then adjusted with a micrometer caliper so that the distance *h*, from the top of the blade to the bottom of the plates, is the same at each end of the gage. It will be seen in Fig. 2 that plates *B* rest on the top of the bed, the purpose being to steady the gage and bring the blocks *A* into proper alignment with the sides of the vees.

In starting to re-finish the bed, the first step is to plane and scrape the horizontal surfaces at the top of the vees. Accuracy in two directions is necessary; each surface must be finished so that it tests up to a straightedge, and all four surfaces must be in transverse alignment. After each of these surfaces has been accurately finished, their transverse alignment is tested with the dial test indicator, which is mounted

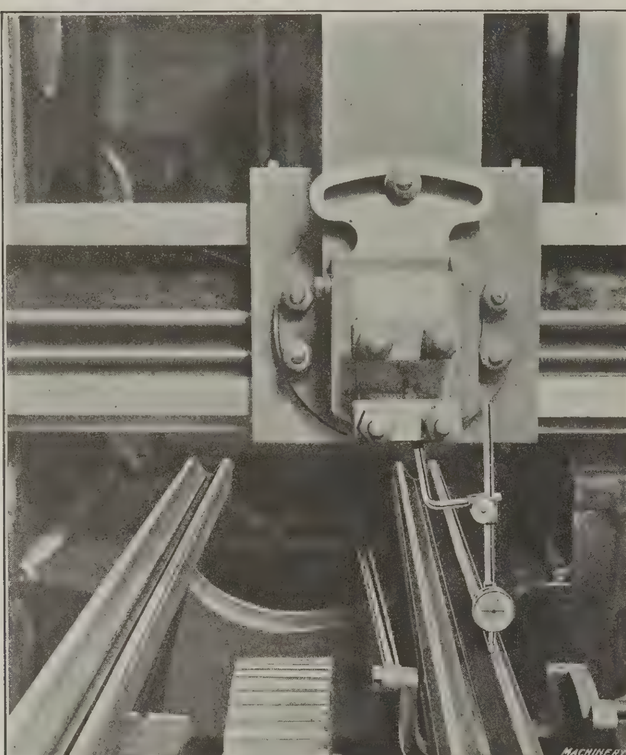

Fig. 4. Method of Aligning the Crossrail with the Planer Bed

in the planer head. The indicator is traversed over each of the four surfaces, and if the proper alignment has been secured, its reading will be the same for each surface; if either surface is found to be too high, however, it must be scraped down until the test gives satisfactory results. The accuracy obtained in this operation is important, because these surfaces of the bed are used in adjusting the housings and to bring the crossrail into proper alignment with the table.

It is only in extreme cases that it is necessary to resort to planing the vees in the bed; the wear at this point is usually so slight that it can be removed by scraping. In performing this operation, the outside surface of one vee is scraped down and tested with a straightedge, and this surface is then used as a standard of reference for the gage in re-finishing the corresponding surface of the other vee. The method of using the gage for this purpose is shown in Fig. 2, the gage being moved along the bed to determine the amount of metal which must be removed at different points. The surface is then scraped down to an accurate finish, as determined with the straightedge, the gage being used at frequent intervals to make sure that too much metal is not removed. The opposite sides of the vees are then re-finishd in exactly the same manner—the surface of one vee is first scraped down to a straightedge and is then used as a standard for the gage in re-finishing the remaining side of the other vee. It is evident that the gage need only be turned end for end to make it available for this operation.

The same general method of procedure is followed in re-finishing the table bearings, the use of the gage providing a method of obtaining exactly the same distance between them as that between the vees; this insures having the table fit properly on the bed. The table is removed from the floor-plate and mounted on the table of a planer, where the bearings are lined up with the dial test indicator to determine the amount of inaccuracy which still exists. If this inaccuracy is great enough to require planing, care must be taken not to remove any more metal than is absolutely necessary. The outside surface of one of the bearings is then scraped and tested with a straightedge, and this surface is then used as the standard of reference for the gage in re-finishing the corresponding surface of the other bearing, as shown in Fig. 3. This latter surface is scraped down to a straightedge, the distance between the bearings being maintained constant with the gage, as previously described for the vees in the bed. The opposite sides of the bearings are then re-finished in exactly the same way.

It is evident that the use of this special gage for both the table bearings ana the vees in the bed, assures that they will fit together with absolute accuracy. Far greater precision is attainable in this way than when male and female templets are used on these operations. If any considerable amount of metal has to be removed from the table bearings, it will bring the rack too low to mesh properly with the driving pinion. In such cases, the rack must be removed from the table and have a corresponding amount of metal planed from its bearing.

The crossrail and the bearing of the saddle upon it are subject to uneven wear, owing to the fact that most planer work is done with the head near the center of the rail. To remove the error produced in this way, the crossrail is planed on its face and sides, and then scraped until the re-finished surfaces line up properly when tested by the dial test indicator. The saddle bearing is then scraped to an accurate fit on the re-finished crossrail.

The planer housings are not often subject to any appreciable amount of wear, but their adjustment is sometimes inaccurate, thus throwing the crossrail out of alignment with the table.

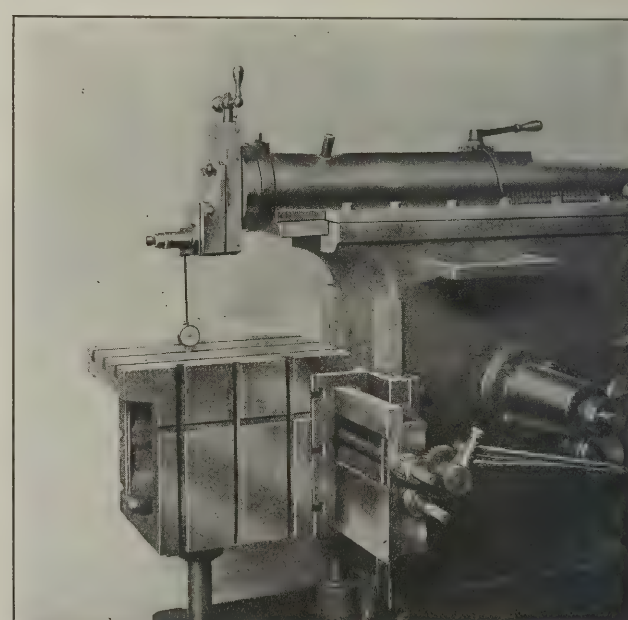

Fig. 5. Proving the Accuracy of a Re-finished Shaper Table

In re-assembling the planer, the re-finished surfaces at the top of the vees in the bed are used as a standard of reference in adjusting the housings, a millwright's steel square being used to bring them into a perpendicular position. After making these adjustments, the bearings of the crossrail are scraped to an accurate fit on the housings; the crossrail is then mounted in position and lined up with the bed. The dial test indicator is used for this purpose, as shown in Fig. 4, the indicator being brought into contact with the surfaces at the top of the vees, first at one side of the bed and then at the other. Corresponding readings of the indicator show the rail to be in proper alignment, but if this test cannot be made with satisfactory results, it is necessary to readjust the housings. The test is then repeated and further adjustments are made on the housings, if necessary, until the proper alignment of the

crossrail has been secured. It is, of course, understood that this alignment of the crossrail with the bed provides for having the table and the crossrail in proper alignment with each other.

Any inaccuracy in the bearings which carry the driving shafts will set up a vibration which manifests itself in an uneven finish on the work. Where such inaccuracy has been caused by wear in the bearings, it must be removed—by scraping, if possible, or by re-bushing the bearings, if they have been too badly worn to be adjusted by scraping.

A small amount of wear on either the rack or driving pinion is not a serious matter, as it does not impair the smooth running properties of the drive. Owing to the greater speed of the pinion, however, it will frequently be worn to a point where the smoothness of the drive is impaired, and in such cases, a new pinion must be provided. Where individual teeth of either the rack or pinion have been damaged, they can be economically repaired by adding metal with an autogenous welding torch and then recutting the teeth. This plan can be followed by sending the work out to a shop which makes a specialty of welding operations, if a torch is not included in the equipment of the plant in which the planer is being rebuilt.

After all of these operations have been completed, the planer is ready to be re-assembled. The machine is then placed in operation to plane down the face of its own table for removing any inaccuracy which exists. The lightest possible cut is taken, and when the operation is completed, the accuracy of the finish is tested by means of the dial test indicator held in the planer head. When these methods are carefully followed, a machine which is so badly worn that it is practically worthless, can be put into condition to produce accurate work.

Method of Adjusting a Worn Shaper

In starting to adjust a shaper for the inaccuracies which have been produced from the wear of its parts, the same general steps are followed that were outlined for a planer. After dismantling the machine, all of the bearings which take part in transmitting power to the ram are examined for wear, and they are either scraped or re-bushed to meet the requirements of individual cases. Where a shaper has been subjected to severe service for a considerable length of time, it will usually be found that the pinion which drives the bull-wheel is badly worn. If this is the case, this pinion must be replaced by a new one.

The ram and its bearings in the frame of the machine are the points where the greatest wear is likely to occur. In compensating for the inaccuracy which is found in these parts, the bearings in the frame are first scraped to a straightedge. The ram is then planed down just enough to remove the wear which has developed, the dial test indicator being used to insure proper alignment of the re-finished surfaces. The ram is then scraped to fit accurately in the bearings in the frame of the shaper.

The crossrail is next mounted on the planer, where it is first planed and then scraped to an accurate finish, as determined by means of the dial test indicator. After this operation has been completed, the saddle bearing is scraped to an accurate fit on the crossrail.

The completion of these operations provides for the smooth operation of the machine. After re-assembling, a light cut is taken over the surface of the table, to provide for having it in proper alignment with the ram, any inaccuracy in the alignment of the crossrail being compensated for in this way. The precision of the finish obtained on the table is proved with the dial test indicator, as shown in Fig. 5; the table is then scraped, if necessary, until an accurate finish has been secured.

It cannot be too strongly emphasized that the greater part of the wear which develops in machinery is due to improper operating conditions. This is particularly true when machine tools are operated by men who are not trained mechanics, and in such cases, careful inspection should be made at frequent intervals to see that every machine is properly oiled, and that it is not exposed to unnecessary strains. The methods described for proving the accuracy of different planer and shaper parts, can also be used to advantage in detecting wear in the different members of the machines, and when this is discovered before it has assumed serious proportions, it can easily be remedied by a little scraping. Such a course will add greatly to the life of all classes of machinery.

* * *

A. L. A. M. SCREW STANDARD AS REVISED BY THE S. A. E.

The Society of Automobile Engineers has announced the details of the S. A. E. screw standard, which supplants the A. L. A. M. screw standard adopted by the Association of Licensed Automobile Manufacturers in April, 1906. (See MACHINERY'S Data Sheet, No. 63, November, 1906.) The revised list is given in the accompanying table. The only changes which have been made are the distances across the flats of 1/4-, 7/16-, and 3/4-inch screws and nuts, the changes being from 3/8 to 7/16 inch, from 11/16 to 5/8 inch, and from 1 1/8 to 1 1/16 inch, respectively. The A.L.A.M. screw standard did not go beyond 1 inch in diameter for standard screws, but the S. A. E. standard proceeds by eighths of an inch for screws over 1 inch up to and including 1½ inch in diameter.

The material from which the screws and nuts are made is steel having a tensile strength not less than 100,000 pounds per square inch, and an elastic limit of not less than 60,000 pounds per square inch. The screws as well as the screw-heads are to be left soft, and the plain nuts are to be left soft, but the castle nuts are to be casehardened. It is assumed that when screws are to be used in soft materials, such as cast iron, bronze or aluminum, U. S. standard pitches will be used.

ERICSSON'S MEMORY HONORED

The American Society of Swedish Engineers celebrated the near fiftieth anniversary of the battle between the *Monitor* and the *Merrimac* in connection with its annual dinner at the society's house in Brooklyn, N. Y., February 17. The celebration commemorated Capt. John Ericsson, the famous Swedish-American engineer who invented and designed the *Monitor*. Mr. Erik Oberg, associate editor of MACHINERY, spoke on "John Ericsson the Man," and W. L. Axel Warn, Albany correspondent of the New York *Times*, briefly described the famous engagement between the two vessels which took place in Hampton Roads, Va., March 9, 1862.

THE MANUFACTURE OF STEEL BALLS

INSPECTING, GAGING AND TESTING

By ROBERT H. GRANT*

In the previous articles on the making of steel balls in the February and March numbers, the making of the blanks, the rough-grinding, the hardening and the finish-grinding of steel balls has been taken up. In the present article it is proposed

Fig. 1. Inspecting the Balls

to treat of the inspection, grading, gaging, and testing of the balls, and also to review the various uses of steel balls, as well as to give some advice to purchasers and users regarding the quality of balls.

The Burnishing and Tumbling Processes

When the balls come from the oil grinders, they have a dull finish and must be burnished or tumbled. The burnishing can be done in the oil grinder with a set of rings having grooves in them the exact size of the balls. A light oil is used, and after a very short run of the machines, a finely polished surface will be produced. This process, however, is expensive, and the ordinary tumbling method is most generally used. The tumbling barrel universally adopted is of is most generally used. The tumbling barrel universally adopted is of the regular iron tilting type. The balls are placed in the barrel in sufficient quantities so that, when they roll over and over, their weight will cause enough friction between them to polish them. A polishing material is placed in the barrel, and the latter is allowed to run at least ten hours to produce a good surface. The balls are then cleaned off by tumbling them in sawdust, and are later placed in another barrel with finely cut kid leather. This final tumbling brings out the high polish.

Inspection

The balls are now ready to be inspected, which is done almost exclusively by girls. The skill and rapidity which can be obtained in doing this work is certainly most remarkable. One girl can inspect fifty thousand ¼-inch balls, picking out seven or eight different grades, in ten hours. This inspection, as indicated in Fig. 1, is done on glass plates which are about ten inches square and inserted in a frame so that the balls cannot roll off. The under side of the glass is painted so as to reflect the light. The plate is about half filled with balls and is placed upon a box which is tilted slightly towards the inspector. This causes the balls to always roll to the front. The inspector holds in her hand a magnet resembling in shape a knitting needle. The end is sufficiently magnetized to raise one ball of the size being inspected from the glass. In the other hand the inspector holds a piece of heavy white paper 4 inches wide by 8 inches long, which she slides under the balls. This makes the balls revolve, and with the magnet defective balls are picked out. The defects consist of pits, bands, dents, scale, rough grinding marks, etc.

The different grades are separated in boxes, placed to the right of the inspector, and they are used for different purposes according to the requirements placed on the balls. It is evident that different grades of balls may be used when it is remembered that ball bearings are employed in so many different kinds of devices, such as bicycles, clothes-wringers, hand trucks, sash pulleys, hinges, etc.

After the balls have been inspected for defects they are rolled back and forth on the glass plate in order that those that are out of round may be picked out. As the balls which are not perfectly spherical will take a zigzag motion when rolling down the plate, and the true balls will run straight, it is comparatively easy for the inspector to pick out the imperfect ones. An expert inspector does not stop each time she picks up a ball to place it in the boxes, but will usually toss it into the palm of her hand, which will generally hold all of one grade that she will pick out from the batch of balls on the plate. Balls larger than ¾ inch in diameter are generally taken up by hand and looked over. Those that are out of round in the larger sizes are taken out while measuring the balls.

Grades of Balls

Balls are generally graded into four main classes, known as alloy, and A, B, and C grades. The steel for the alloy balls contains chromium, and these balls have the greatest crushing strength. They must be absolutely free from defects as regards material and finish, and must not vary in size more than 0.0001 inch. Balls classified as A-grade are made from

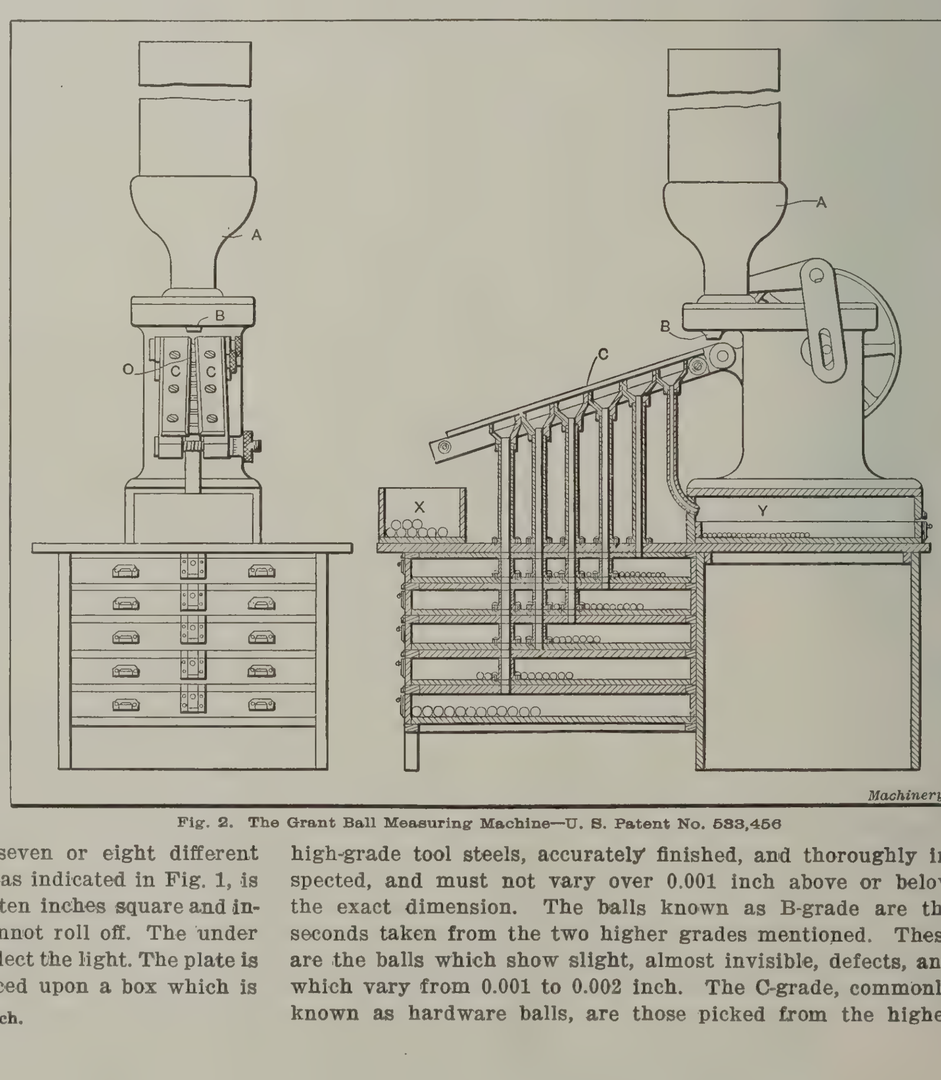

Fig. 2. The Grant Ball Measuring Machine—U. S. Patent No. 533,456

high-grade tool steels, accurately finished, and thoroughly inspected, and must not vary over 0.001 inch above or below the exact dimension. The balls known as B-grade are the seconds taken from the two higher grades mentioned. These are the balls which show slight, almost invisible, defects, and which vary from 0.001 to 0.002 inch. The C-grade, commonly known as hardware balls, are those picked from the higher

* Address: 912 Oakland Ave., Ann Arbor, Mich.

grades when these show a defective surface. Whether these balls are gaged or not depends upon the use to which they are to be put.

The Gaging of the Balls

After the inspection, the balls are automatically gaged, the gaging being done in a gaging machine in which the balls are fed from a hopper and allowed to roll down between two hardened straightedges and to fall into tubes which carry them to the proper drawer, as indicated in Fig. 2. This illustration shows the Grant ball measuring machine. At *A* is shown the automatic dropping machine, and at *B* the delivery spout through which the balls drop into the measuring slides *C*, provided with a longitudinal slot or opening *O* between them. The sides of the slot may be accurately separated any desired amount by the micrometer adjusting screws provided at both ends. Consequently, the flare of the slot may be adjusted so that it is possible to determine exactly what the diameter is of the balls that will drop into each of the tubes and drawers beneath the measuring slide as the balls roll down along it.

Fig. 3. A Battery of Grant Gaging Machines

As is clearly shown in the illustration, pockets are arranged successively beneath the inclined slot, and are connected by pipes with the drawers of the cabinet underneath. It is evident that in this way balls of the same size will go into the same drawer each time, the balls that go into the middle drawer being those of correct size, those that go into the upper drawers being those that are too small, while the large balls will go into the lower drawers. The balls that are entirely too large will run down the full length of the measuring slide and will be deposited in the box *X*. Those that are deposited in the drawers of the cabinet will be from 0.0025 to 0.005 inch too large or too small, according to the setting of the slides.

The exact arrangement of these measuring devices varies somewhat. In Fig. 3 is shown a group of the type of machines just described. A rack is run through the center of the machine. In this rack, directly under the hopper, there is a hole having a bushing in it of the size of the ball to be gaged. The ball drops from the hopper into this bushing and is carried forward until it comes to an opening which is connected with a tube for carrying the ball to the measuring slides. The rack is operated by a sector of a gear mounted on a shaft having an eccentric pin on one end and a pulley on the other. Inside of the hopper there is a small tube which is operated up and down by two levers, one being attached to the eccentric pin and the other to the tube. This arrangement prevents the balls from clogging so that the bushing in the rack is always ready with a ball to carry forward, thereby constantly feeding balls to the measuring slides.

In Fig. 4 is shown the writer's machine with the measuring slides removed. This particular machine is worked by a worm and worm-wheel instead of by a rack. There are two disks, beneath the balls in the hopper, the upper one of which is keyed to the shaft fastened to the worm-wheel and hence revolves. This disk has a series of holes drilled near the periphery, these holes being 0.005 inch larger than the ball to be gaged. The lower plate has a hole in it directly above the measuring slide, so that when the upper disk carrying the balls presents a hole directly above the hole in the lower disk, the ball will drop through the hole and tube onto the measuring slide. As the hopper is full of balls there is a liability of clogging, because two balls may have a tendency to drop through the hole at once when the opening is presented. The clogging tendency is overcome by a cut-off made of a thin piece of tool steel with beveled edges, which covers two holes in the revolving disk, the holes covered being the one directly over the lower disk and the one next to follow. This prevents jamming of the balls. The remainder of the machine and cabinet is substantially the same as the machine shown in Fig. 2.

In the Putnam gaging machine the hopper is worked practically the same as in a machine for slotting screws. Fingers raise the ball, allowing it to fall into a trough, and then through a tube onto the measuring slides.

This mechanical gaging and sorting of balls is applied to all sizes up to and including ⅝ inch. The large sizes are measured by hand by micrometers. The girls employed for this work pick them up one by one and measure each ball separately over several diameters, throwing them into small boxes placed before them, each of the boxes containing a certain size of balls between the limits of measurements adopted. This work is very rapidly done, as the operators become very skillful.

Counting the Balls

The next operation is the counting and boxing of the balls which at first sight might be assumed to be a tedious and very slow operation. So it would be were it not for the mechanical means adopted for doing this work. Balls up to ⅜ inch in diameter are counted by means of a counting board, as indicated in Fig. 5, which has holes sunk in it 0.010 inch larger than the ball. Around the board is tacked a narrow strip of wood to prevent the balls from rolling off.

Fig. 4. A Modified Type of Grant Measuring Machine, with Gaging Slides removed

The balls are then poured upon the board and all balls which do not find a hole to enter are allowed to run off. As there is an exact known number of holes in the board, the counter immediately knows how many balls she has, and she transfers them immediately from the counting board into a pasteboard box in which the balls are packed. In this way one girl can easily count a million balls a day and do other work besides.

The pasteboard boxes are made of a telescoping form and lined with paper which is free from acid and which has previously been soaked in an anti-rust compound. The balls, which have a very high polish, would otherwise easily rust on account of sweating, which is caused by the difference in temperature of extreme heat and cold. It is very essential that steel balls should be kept in a room properly heated.

The Testing of Balls

The testing of a steel ball for crushing strength should be done between hardened plates by placing three balls in a

tube into which they nearly fit. The center ball is the one that will be tested. The upper and lower balls will, of course, sink into the plates, and this will give them more of a surface bearing than the middle ball, which bears only in two points upon the upper and lower balls; hence the middle ball will ordinarily give way first. As the pressure is applied, a double pressure cone will be formed inside of the ball, this cone having its apexes where the outside balls bear on the middle ball. If properly hardened, a ball will break into several pieces. This method is the proper way to test a ball, but there seldom are two balls that will stand exactly the same load when tested. This is caused largely by the methods in which the ball blank is made. As will be remembered from the description of the making of the blanks in the February number of MACHINERY, the balls in the forging process are much more dense at what might be called the "poles," that is, where they join the next ball forged, than at the "equator." Therefore, if the center ball being tested has the point of contact on the "equator," it will not stand within ten or twenty per cent of the load that it would stand if the points of contact were at the "poles." The same method of reasoning may be applied to stamped and turned balls.

Through the means of this testing operation and the appearance of the fracture, it can be determined whether the balls have been properly hardened. Every batch of steel, no matter how carefully made, usually requires a slightly different

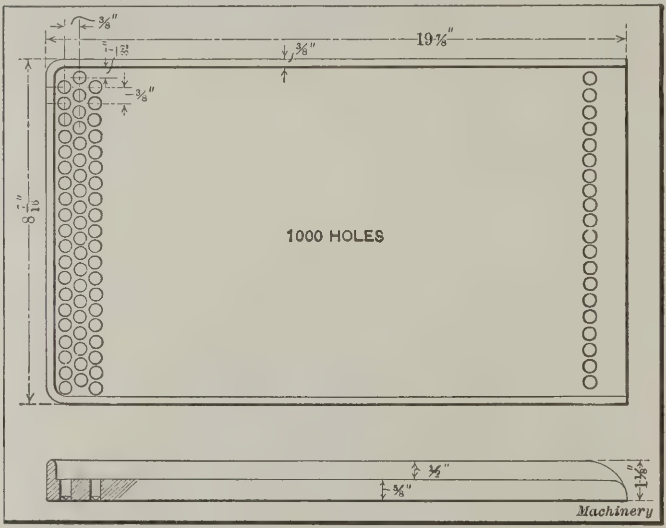

Fig. 5. Counting Board for 5/16-inch Balls

treatment in hardening, and what this treatment is must be determined by the man responsible for the hardening work. The accompanying table shows the crushing load ordinarily required by ball manufacturers for regular tool-steel balls.

Size of Ball in Inches	Ultimate Strength of Ball in Pounds	Size of Ball in Inches	Ultimate Strength of Ball in Pounds
1/16	390	5/8	39,000
3/32	875	3/4	56,250
7/64	1,562	13/16	66,000
1/8	2,450	7/8	76,000
3/16	3,496	15/16	88,000
7/32	4,780	1	100,000
1/4	6,215	1 1/8	125,000
5/16	9,940	1 1/4	156,000
3/8	14,000	1 1/2	225,000
7/16	19,100	1 5/8	263,000
1/2	25,000	1 3/4	306,000
9/16	31,500	2	400,000

The figures above have been adopted after a great many years of testing and are considered by the manufacturers safe figures with which to calculate. Of course, in selecting a ball for a bearing, a factor of safety of ten should always be adopted unless the bearing is used in an extremely narrow space. The grooves in which the balls run when heavy loads are imposed should be round instead of V-form. No figures can be given relating to tests of balls made from alloy steel, because these steels give such irregular results that the manufacturers have been unable to compile any data that would be in any way satisfactory. It is, however, safe to state that the alloy-steel balls will stand from 25 to 50 per cent more than the regular tool-steel balls.

Balls of Other Materials than Steel

Balls are made of a great many other materials, brass and bronze, for instance, being used extensively for oil-well devices where acid is found in the crude oil. Such balls are also used in valves where the material to be pumped will rust steel balls and cause corrosion, and also in electrical work. German silver balls are used in Yale locks to prevent corrosion when used on shipboard or in other places where they would be subjected to the damp sea air. Casehardened machine steel balls are used extensively in agricultural implements and similar apparatus on account of being inexpensive. Chilled cast-iron balls are used in turntables, trucks, and for similar requirements.

The Uses of Steel Balls

It may be said without exaggeration that balls are used in nearly every kind of article that it is possible to name provided it revolves. They are used in the cheapest kind of hardware and in the finest mechanisms and surveyors' instruments. Balls 1/16 inch in diameter are used in electric meters and typewriters. The number of balls being used for these purposes alone is from fifty to seventy-five millions per year. German silver balls 3/32 inch in diameter are used under the tumblers of a Yale lock to prevent the tumblers from becoming worn by the constant sliding of the key into the lock. Steel balls 1/8 inch in diameter are most extensively used in bicycle pedals. Some people think that the bicycle industry is no longer of the importance that it once was. This is a mistake. More bicycles are made at the present time than ever before, and about fifty million steel balls are used yearly in the pedals alone.

Sewing machines are now being provided with ball bearings. Millions of 3/16-inch balls are used for this purpose yearly. Some fifty million 1/4-inch balls are used every year in clothes-wringers; 1/4- and 5/16-inch balls are used exclusively for bicycle bearings, and the quantity used runs into hundreds of millions per year. Balls of the same size are used in thrust bearings in motor boats. Balls from 3/8-inch to 3/4-inch diameter are used extensively in automobiles. The quantity of balls so used is estimated at not less than five hundred millions a year. Larger balls of, say, 1 1/8 inch in diameter are used in oil-well pumps, road rollers and traction engines. The quantity being used for these purposes is not less than five hundred thousand a year. One of the most important uses for 1 1/4-inch balls is that in the side bearings on trucks for steam and electric cars. Still larger balls are used for a great many other purposes, including water-wheels, step bearings, locomotive cranes, drawbridges, etc.

Balls are made up to six inches in diameter, and some are used in very peculiar places. Balls of from 4 to 6 inches in diameter are now used by a Canadian concern in a whistling buoy. This buoy has a large tube in which the ball is placed, evenly balanced on the top. The end of the tube has a whistle. The ball, as the tube dips on account of the waves, rolls to the lower end, compressing the air by its weight, and thus blows the whistle. Then it rolls to the opposite end and causes the whistle to blow again.

As already mentioned, brass and bronze balls are used extensively in valves, electrical meters, and bearings where dampness or acid is liable to come in contact with the balls. The number of balls made from these materials is not less than fifty millions per year.

Points for the User and Purchaser of Steel Balls

In the following the essential points relating to the manufacture of balls which should be kept in mind by a purchasing agent or consumer are given. Nothing but a tool-steel ball should be used for high-grade work, and it is very important that it be properly heat-treated. Do not be deceived by a finely polished ball, as high polish and deep scratches (which show only under a magnifying glass) do not necessarily indicate a good ball. In fact, the outside appearance has little or nothing to do with the wear of a ball, for a dull looking ball may be just as good as one with the highest polish. The polish is merely the result of the tumbling process.

The first requirement is that the right material has gone into the balls. It costs but little to have the steel analyzed so that the purchaser may know whether he is getting a tool-

steel ball or a machine-steel ball. The fact that the ball has only a point bearing makes it the more important that it be made from good material in order to stand the pressure to which it may be subjected. Casehardened machine-steel balls ought not to be used when heavy duty is required. Naturally there is some difference in the quality of the steel that costs thirty-five dollars per ton from that which costs one-hundred-fifty dollars per ton.

It is true that a ball can be casehardened very deeply, in fact, almost through to the center, but it should be remembered that casehardening implies adding carbon to the steel under a high heat, which causes the pores in the steel to open so that the carbon can enter. The process, however, does not remove the injurious elements, such as phosphorus, sulphur and silicon, of which the cheaper steel contains a large percentage. It is, of course, perfectly satisfactory to use casehardened balls for many purposes, but when it comes to a really high-grade article, the highest class of steel is to be preferred.

In order to determine whether a ball has been properly heat-treated, place the finished ball in a piece of waste on an anvil and break it open with a heavy blow. The waste prevents the pieces from flying around. If the ball is properly heat-treated, the break will show a soft silky-appearing surface—the grain of the steel being fine. If it has not been heat-treated, it will look coarse and granular, having more the appearance of cast iron. As a further illustration of why the ball should be heat-treated, the following tests made by the writer when with the New Departure Mfg. Co., may be of interest. The balls tested were made of tool steel; they were ¼ inch in diameter and drawn to 420 degrees F.

Ground; not Annealed before Hardening	Headed and not Ground; Annealed before Hardening
4800	7500
5700	8150
6300	8200
6150	7200
5800	6880
5600	7300

It will be found that the average crushing load of the balls that were not annealed before hardening is 5725 pounds, while the average crushing load of the balls that had been annealed before hardening is 7538 pounds; hence the heat-treated ball is some 1800 pounds or nearly 30 per cent stronger than the balls which were not heat-treated. The heat-treatment not only strengthens the balls, but prevents them from flaking off, crumbling, etc. It distributes the molecules so that the steel is at rest.

If during the test the ball should break in half, it would indicate that it had not been properly drawn after hardening, but was still subjected to internal stresses. If such a ball is placed in a bearing, it would easily break if subjected to a severe shock or strain. If a ball has been properly drawn it can be touched with a fine Swiss file, and under the blows of a heavy hammer it will dent slightly and break into several pieces.

Balls over 5/16 inch in diameter that have been turned or headed should not be used for heavy duty, as they are not as good as balls for which the blanks have been forged. The headed ball, on account of the severe shock to which the metal is subjected when cold, cannot be treated so as to stand the strain that the forged ball will stand. A turned ball is cut from a rod which is rolled, so that the grain of the steel is in a lengthwise direction; hence when a ball is turned from this bar the surface of the ball consists of a mass of exposed fibers. When put under a heavy strain, as in a thrust bearing, it will pit and flake off. The surface of the ball should be smooth, that is, all the marks from the rough-grinding process should have been removed in the finish-grinding. If this has been done it can be readily determined by a magnifying glass.

A ball made from a forged blank cannot be hardened properly unless the decarbonized surface has been wholly removed. Some manufacturers attempt to keep the forgings as small as possible in order to save material and time in grinding, and in many cases it is then impossible to remove all of the decarbonized surface. Hence when the ball is hardened, rough marks and soft spots can be detected. The soft spots are much brighter than the properly hardened surface.

If balls are to be used for special purposes, this should be designated in the order sent to the ball manufacturer. In order to be able to supply a ball that will give satisfaction, it is necessary that he be furnished with information as to what the ball is to be used for, the speed and load at which it will be used, and the kind of bearing employed. Then the balls can be drawn to a degree of temper adapted to the particular purpose in view, and thus satisfaction can be guaranteed to the purchaser. It is also very important to see that the balls that are furnished are not out of round, as this would cause the bearings to "catch" and "jump." The resulting bearing will run unsatisfactorily, and will rattle on account of the fact that the balls are loose at one point and tight at another. The actual size of the ball does not make a great deal of difference, provided the balls are all of the same size. In other words, in a lot of one-hundred-thousand balls, if they are found to be 0.0005 or 0.001 inch under size they will give satisfaction if they are all used before the next shipment can get mixed up with them.

It has already been mentioned that the temperature of the room in which the balls are stored must not be too low. The temperature of the stock-room should be kept the same at all times, and on Sundays and holidays, when the factory is closed, it should be especially heated, for a ball which becomes very cold and then is brought back to a warm temperature will soon begin to rust and cause a great deal of trouble.

Summary of Ball-making Processes

In order to fix in the reader's mind the various processes that a ball passes through, from the time that the blank is produced from the rough stock until the finished ball enters the stock-room, a general summary of the processes described in the three articles comprising the present treatise on the manufacture of steel balls will be given.

There are several methods for producing the ball blank. One is that of turning the ball blanks in a special automatic machine. This method is rapid and makes it possible to produce a blank which requires less grinding than the blanks produced by other methods, but on account of the fact that the fibers of the stock from which the blank is turned are cut and exposed at the surface, a ball so made is of inferior strength after hardening as compared with balls the blanks of which are made by other methods.

Another method commonly used for producing ball blanks is to form the blank in a heading machine. A bar is fed into the machine and pieces of the required length are cut off and headed between dies to a ball shape. This is a very rapid method, and balls up to, say, 5/16 or 3/8 inch in diameter can be made advantageously by this process. As there is no waste, this process for smaller sizes of balls must be deemed the best as well as the cheapest of the methods used at the present time.

The best method of making ball blanks from 3/8 inch to 2 inches in diameter is known as string forging. This method is very extensively used and the balls so produced, when properly heat-treated, are strong and tough in their structure. The balls which have been produced by the heading or forging process must have the fin or flash ground off before they pass to the grinding machines. The process by means of which the fin is removed is called "flashing," and the machine in which it is done is ordinarily termed a "rotary" file. Large balls are flashed separately in a special fixture by an ordinary emery wheel.

The balls are now ready for the dry-grinding process, the grinding being done by an emery wheel acting upon the balls which are held and rotated by suitable means. After being dry-ground, the balls are annealed and then hardened, the smaller balls being quenched in cotton-seed oil, while the larger ones are immersed in brine. After hardening, the balls are washed in boiling soda and then tempered in oil.

After the tempering the balls are ready to return to the finish dry-grinding department, and are finish dry-ground in machines of the kind that performed the rough dry-grinding, but a finer grade of emery wheel is used. From the finishing dry-grinders the balls pass to the oil grinders, where the final grinding operation is performed and where the balls

are brought to exact size. The oil grinding operation is practically a lapping process, no grinding wheel being used. The machine has merely two plates, one of which is grooved, between which the balls roll. The grinding medium is fine emery and oil.

When the balls have been brought to size in the oil grinders, they are given their final finish either by burnishing them in machines similar to the oil grinders, or by being tumbled in a tumbling barrel with a polishing medium. Next they are tumbled in sawdust, and finally in a barrel with cut-up kid leather to obtain the high polish. The balls are then inspected, graded and gaged. The smaller balls are gaged in gaging machines, while the larger are measured by micrometers. Next the balls are counted and packed into boxes and sent to the store-room, which finishes the operations.

* * *

DOURTE VALVELESS PUMP

The pump which is illustrated in Fig. 1 has no suction or discharge valves and is designed especially to handle very trashy matter. Weeds, pieces of rope and other foreign material which may be drawn into the pump are sheared off by the edges of the ports which are located in the piston. This type is being used to pump trashy water out of irrigation ditches and to handle slimes in reduction works. It is also planned to use this pump for handling syrup and heavy oils. The sectional view, Fig. 2, of one of the cylinders of a horizontal type, shows the general arrangement of the piston and ports. A miter gear keyed on the end of the crankpin meshes with the mating gear keyed to the end of the connecting-rod, and the latter is attached to the piston by means of a universal coupling. This mechanism imparts a constant rotary movement to the piston in addition to the reciprocating action. The piston is of the trunk type with an opening at both ends and a partition in the middle. The head end at the left of the partition has a port, as the illustration shows, which alternately registers with the suction and delivery ports. When

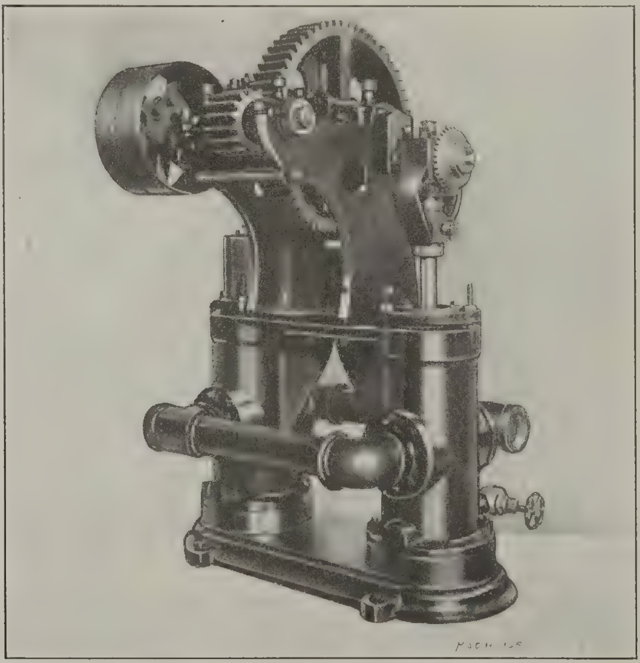

Fig. 1. Duplex Pump without Suction or Discharge Valves

the piston is in the position shown, both ports are closed, but as soon as the pump rotates in the direction indicated by the arrow, the suction port begins to open. When the crank has moved 90 degrees and is on the "top quarter," the piston port will be exactly over the suction port, and when the opposite "dead center" is reached, both ports will again be closed. When the crank is on the bottom quarter, the piston port will be exactly under the delivery port. It will thus be seen that the piston by its rotary movement regulates the suction and discharge openings. If the pump is reversed or one miter gear is turned through 180 degrees, the pump will operate from the delivery to the suction side or, in other words, the flow will be reversed. The delivery port is formed in a separate saddle which rides on the piston and is held down by adjustable spiral springs, as shown. The suction port is cut

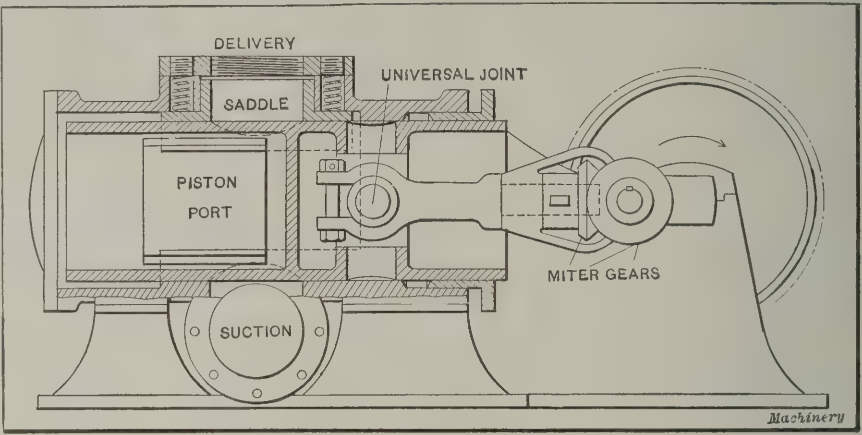

Fig. 2. Sectional View of Valveless Pump of Horizontal Type

out of the solid cylinder. This pump is made at Longmont, Col., and was designed by George L. Sullivan, Bozeman, Mont.

* * *

ENERGY THE MOVING FORCE

Many business concerns that have been organized with ample capital and to outward appearance well equipped to succeed, in the course of a few years have gone into the hands of receivers. Other concerns have started with very small capital, under adverse conditions and have prospered. What was the difference in the organization of these typical concerns which meant success for one and failure for the other? Largely brains and energy.

An incident from the career of a well-known machine tool manufacturer in the Middle West is an illustration of the point. Thirty years ago this manufacturer started in business with a small capital, and his hostages to fortune were "a wife and two kiddies on the hill." His money was soon tied up in the business, and no immediate cash returns were in sight. In the emergency he solicited some job work from a large concern and was "turned down," but being insistent and forceful finally secured an order for two hundred flask-pins at ten cents each. They had to be tapered at one end, turned down, shouldered and threaded at the other end, and provided with a hexagon nut. This was before the days of automatics, and after the order was taken the job hunter realized that he was in for a loss if he followed the regular method of production, so he set his brain to work. He went to a dealer in bar iron, got two hundred pieces cut off while he waited, took them in a box on his shoulder to his shop and then rigged up an engine lathe for the job. A boy hired at fifty cents a day, who had never worked in a shop, with the aid of simple tools and the expert assistance of the boss, turned out the job complete in a day at a cost of $2 for stock, 50 cents for nuts and 50 cents for labor, making the total cost $3, not including a small overhead expense.

The brains and energy used in this case were characteristic of the man and the concern he organized. Starting out in this small way it showed $7000 in assets at the end of the first year, and $32,000 the second year, increasing until the investment now represents over a million dollars, and its product is known and used all over the world.

* * *

A user of high-speed drills complained to the maker that he could not get results. The production was not much higher than with carbon steel drills, and much time was lost in grinding. Examination showed that the cutting speed was high, but the feed very fine. The speed was reduced and the feed doubled, the result being that the output of drilled holes was doubled and the squealing and heating of the drills disappeared entirely.

VARIATION IN MACHINE TOOL POWERS

By T. BARTON*

The wide divergence in the power put into machine tools by different makers is a fact not often commented upon, but a walk through any average shop will reveal many instances of it. The writer recently noticed an 18-inch turret lathe on chuck work, with a single-pulley drive, having a pulley 12 inches in diameter for a 5-inch belt, running at 200 R.P.M. Close by was a 2-inch bar lathe, having exactly the same size pulley, but running at 500 R.P.M. It will be seen at a glance that the bar lathe has two and one-half times the power of the turret lathe. Is not this somewhat of an anomaly? The bar lathe operates on work of small diameter, has only one tool cutting at a time, and that tool has a very keen cutting edge. The turret lathe handles work of large diameter, has frequently several tools in action simultaneously, and the cutting edge of the tools is not as keen. Either one machine is under-powered, or the other has a surplus of power which it can never hope to convert into useful work. Both these machines are of standard make, are good sellers, and do good work.

If the power of a machine is in reasonable proportion to the work to be done, then if anything goes wrong, the belt will slip or be thrown off, but if it is very much over-powered, this safeguard is lost. If a machine has twice the power that it needs, it means that, as the driving gears have to be strong enough for the belt, they must be made twice the width otherwise required. This increases the distance between the bearings, and consequently the diameter of the shafts must be increased to retain stiffness. In short, the whole machine must be made larger and heavier, and the belt up-keep cost is increased. The contrast between these two machines led the writer to investigate more thoroughly. Some of the results of this investigation are given in the following: A 3½-inch bar lathe was driven by a 10 H. P. motor; a 3-inch bar lathe was satisfied with a 3 H.P. motor. A 2-inch bar lathe had an 8 H.P. motor; another make of 2-inch bar lathe was content with a 2½ H.P. motor. It will be seen that here is a difference of over 3 to 1 on two machines made for doing identically the same size and class of work.

The increase in belt speed, and use of wider belts, which a geared drive allows, permits a great increase of power, compared with the old cone pulley drives, and in some cases it would appear to be the practice, when cone-driven machines are converted into single pulley drives, to put on a pulley as large in diameter, and as wide as the machine will stand, and run it at the highest permissible speed, without comparing the power thus obtained with that given by the old cone drive, which has probably stood up well to its work.

Below are given particulars of a few single-pulley machines. The first three figures have been multiplied together, giving a result which facilitates comparison:

	Diam. of Pulley, A	Width of Belt, B	R.P.M., C	$A \times B \times C$
2 -inch Bar lathe	12	5	500	30,000
18 -inch Turret lathe	12	5	200	12,000
3 -inch Bar lathe	10	3	800	24,000
3½-inch Bar lathe	14	5½	500	38,500
3½-inch Bar lathe	10½	4½	300	14,175
18 -inch High speed lathe	13	4½	300	17,550
21 -inch High speed lathe	16	5	300	24,000
22 -inch Combination turret lathe	10	4½	450	20,250
30 -inch Boring and turning mill	12	3½	400	16,800
4 -foot Boring and turning mill	12	4	575	27,600
4-foot 6-inch Boring and turning mill	13	5	400	26,000

* Address: 22 Augustus Rd., Coventry, England.

From this it will be seen that 50 per cent more power is put into a 3½-inch bar lathe than into a 4-foot 6-inch boring and turning mill. The weight of the work and table of a boring and turning mill is considerable, and the machine itself is less efficient, the power being taken through one, and often through two pairs of bevel gears.

To obtain the same tool pressure, or take the same cuts, at the same surface speed, would, neglecting the increased friction of the larger machines, require the same horsepower on any diameter; but as larger machines take heavier cuts, and the weight of the moving parts is greatly increased, they, of course, require more power. From the figures given in the foregoing, however, the reverse would appear to be the case in some instances.

STANDARD HEADS FOR SMALL SCREWS

The Engineering Standards Committee (Great Britain) has issued report No. 57, dealing with standard heads for small screws. The report standardizes the heads for small screws in five classes—countersunk, instrument, round, cheese, and fillister. For all classes of screws, the diameter of the head has been fixed at 1.75 times the full diameter of the thread. The committee recommends the adoption of a standard angle of 90 degrees for both countersunk and instrument heads. The depth of the coned portion has been determined at 0.375 times the full diameter of the thread. For instrument-head screws the committee recommends that the radius forming the curved surface of the upper portion of the head be equal to twice the full diameter of the thread. It follows from this that the depth of the curved portion of the head will be approximately equal to 0.2 times the full diameter of the thread. In the case of screws with round, cheese or fillister heads the committee recommends that a plain cylindrical portion having a length not exceeding twice the pitch, be left on the shank immediately underneath the heads of the screws. When determining the depths of the saw cuts or screw-driver slots the committee has endeavored to follow existing practice as far as possible, and has grouped them together in convenient sizes according to the gage of the metal from which the saws used are manufactured. The committee recommends a standard depth of saw cut equal to half the total depth of the head in all cases, this depth to be measured at the center of the head.

MACHINERY

RAILWAY EDITION

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS

49-55 LAFAYETTE STREET, NEW YORK CITY

27, CHANCERY LANE, LONDON, W. C., ENGLAND

Alexander Luchars, President and Treasurer
Matthew J. O'Neill, Secretary

Fred E. Rogers, Editor
Erik Oberg, Franklin D. Jones, Douglas T. Hamilton, Chester L. Lucas, Associate Editors

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

APRIL, 1912

PAID CIRCULATION FOR MARCH, 1912, 24,986 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

THE UNIT SYSTEM OF MACHINE CONSTRUCTION

A feature of machine construction that has been widely adopted during the past decade, especially in machine tools, is the so-called "unit system." The principle of the system is simply that of dividing a machine into groups of closely related mechanisms and constructing them with independent frames or boxes in which the shafts, studs, clutches, gears, etc., are assembled. These units of mechanisms are assembled on the main frame to form the complete machine. The natural divisions of the engine lathe, for example, are the headstock, tailstock, carriage, apron, feed-box, change-gear box, etc. These, mounted on the bed, require only the lead-screw, feed-rod and legs to complete the lathe. This admirable system has several marked advantages.

In the first place it is the logical development of the interchangeable system of manufacture which has so greatly reduced the cost and improved the quality of manufactured products. The units are made independently in departments suited to the character of the work, by men who, specializing on each particular unit, become experts. Refinements of design and construction are developed that could hardly come into existence in a building shop.

In the second place the units being interchangeable can be replaced by the user in case of accident with a minimum of trouble; they can be removed, returned to the factory for repairs at small expense for freight and handling.

A third advantage to the machine tool builder is the ease with which units can be incorporated in various designs. The builder, say of milling machines, can use the same feed-box in several sizes and styles, thus enabling him to produce a variety of designs at a minimum cost for jigs and fixtures, all in harmony with the general design.

These advantages, particularly the last, are slowly being grasped by the builders of special machine tools. This business, as everyone knows who has ever been in it, is conducted on a close margin of profit, and its returns, when compared to straight manufacturing, are hardly commensurate with the thought and energy required for success. More of the manufacturing element can be introduced by the development of unit designs of speed- and feed-boxes, tool-slides, elevating mechanism, etc., which can be worked into special designs with little trouble. These units can be made in lots of fifty or a hundred, using jigs and labor-saving appliances that are out of the question when making up parts specially for each machine. The reduction in cost and the more even distribution of labor over a given period incident to the unit system should make the conditions of special machinery building easier than they are now.

CLEAR THINKING AND WRITING

Given good ability, the one faculty that an ambitious man should cultivate is that of expressing his thoughts clearly in speaking and writing. Compared with one of equal ability who cannot express his ideas clearly, the possessor of a good vocabulary has a great advantage. This fact has been recognized in all times, and yet it is not as fully appreciated by many who are striving to rise in the world as it should be. The successful salesman sells goods because of his ability to secure an audience with buyers and to hold their attention. He holds attention because his story is interesting. He talks of the quality of his goods, how they are made, when they can be delivered, the terms of sale, meets arguments in a kindly spirit, and overcomes opposition by attractive manner and expression. That ability is certainly a great asset to any man. Not all of us can be salesmen in the sense of selling goods, but most of us have to market our abilities in some form of service. The man who can make his service appear to the best advantage usually gets the highest wages, other things being equal.

The machinist who can turn out a perfect piece of work in the average time or less, is a man whose ability will be recognized in most shops in the highest wages paid to journeymen. If he possesses the ability to plan a job and to tell how to perform it he will stand still higher and will, in fact, be rated as having executive ability, simply because he can tell someone else what to do.

With the foreman the telling of what to do and how to do it is the principal part of the day's work. The journeyman who aspires to fill higher positions must cultivate the faculty of imparting knowledge to others. If he practices writing out the plan of procedure for all the jobs that come under his observation, he will be surprised to find that the simplest piece of work is generally made up of several elements, each of which must be clearly known before the work can be carried to a successful conclusion. Describing a piece of machinery either orally or in writing develops logical thinking and leads to investigations of the principles of elements which are the fundamentals of all machines.

With understanding comes the joy of mastery and the common desire of broad-minded men to impart their knowledge to others. That imparting knowledge is profitable to the giver is common experience. It is proved by the rapid advancement of many contributors of MACHINERY who have started in a humble way to tell the readers about some interesting piece of machinery and how it was made. Their mental horizons expanded rapidly, and with expansion of mind came better appreciation of the meaning of what they read and the ability to assimilate ideas and use them. Soon, to our regret, they have ceased to write, because their time and energies have become absorbed in the duties of the executive positions to which they have been promoted.

* * *

One of the fascinating subjects to the theoretical engineer is the Schiele curve as applied to step bearings. The curve is a beautiful design in theory to equalize the wear on all parts of a thrust bearing. In practice, however, it is another story. The cost of producing it compared with an approximate form is so high that its advantages are *nil*. A well-known builder of boring mills formerly made the spindle bearings of his mill tables with the Schiele curve, and fitted up at heavy expense to produce them accurately. But after using the Schiele curve bearing for a few years it was abandoned for a conical bearing and plain step, the two approximating the shape of the Schiele curve spindle. The result has been entirely satisfactory and the cost is much reduced.

TARIFF REFORM

Although many American industries have attained their present strength under protection, this result has been accompanied by abuses from which consumers have suffered, and the majority of voters want a reform. They will have their way; but business men who favor a reduction want it brought about in a businesslike way, by a competent tariff commission not composed of politicians. Our machine tool builders in 1908 not only consented to, but favored, a reduction in the tariff on machine tools, and if a similar policy had been adopted by manufacturers generally the present disturbance to business might have been avoided.

There is a marked difference between the position occupied by machinery manufacturers and almost any other American industry, in that a machine usually represents years of thought, labor, experiment and outlay before a single one is sold. Yet this is hardly on the market before its vital points are imitated by foreign manufacturers who, except for the tariff, would be able to undersell the originator in his own market on account of the difference in the labor cost. Freights also favor the foreign manufacturer as the rates to New York City from almost any of the English or German industrial centers are less than from Cincinnati.

Our tariffs should be reduced; but the changes should extend over a period of years so as to enable our manufacturers to readjust their prices and methods to the new conditions. Any radical change in the tariff on machine tools, such as the proposed one to place them on the free list, would result in disaster to the entire machinery and allied industries; and the losses would fall as heavily on the workman as on the employers. Immediate free trade in this industry would mean destruction, not reform.

TURNING SHAFTS IN TURRET LATHES

Some manufacturers of machinery who have put turret lathes to all possible uses have occasionally met with serious difficulties when trying to turn shafts, say, 1 inch diameter and 30 inches long. The shape of the shaft at the chuck end where the cut is started will be turned round and true; but as the tool travels away from the chuck a quasi-hexagon, octagon or other polygonal shape may be developed under certain conditions, which gradually grows worse, until it is so pronounced at the finish end that ordinary allowances for grinding may not be sufficient to remove the tool marks. Although this is an old trouble, and the causes, and means for eliminating them, were discovered long ago, a knowledge of the facts is not as common as it should be in view of the widespread use of the turret lathe.

Where roller back-rests are in use, the first surmise of course is that one of the rollers is eccentric or worn flat, but other elements more obscure may cause the trouble. A well-known turret lathe builder states that the trouble is wholly overcome by using a back-rest of the old style, which embraces about half the cylinder and is of a dimension fairly close to the size to be turned. But these back-rests are not adjustable, and are subject to roughing up, which becomes a serious trouble. The V back-rests and roller back-rests seem to be superior, notwithstanding the possibility of the work's becoming slightly polygonal at times.

One of the principal elements in establishing the tendency to turn polygonal is produced by the varying depth of cut, which of course is the result of eccentricity of the stock. The effect of varying the depth of chip can be almost wholly neutralized by setting the cutting face of the tool perfectly square to the travel or a trifle "under," so that the variation in radial thrust is reduced to a minimum. The surface of the back-rest should make contact very close to the front edge, and the cutting tool should be set slightly in advance of the back-rest. If the back-rest does not touch the stock at the front, because of being a trifle bell-mouthed, or if the tool stands too far ahead of the back-rest, or again, if the tool is beveled so that the outer edge is in advance of the point, then the stock will spring away from the tool under the heaviest part of the cut. A round-nose tool, or a tool in which the point is behind the cutting edge, of course gives the greatest variation in radial resistance when the depth of the cut varies. This applies to turning cylindrical work in either direction, but the action is especially pronounced in turning away from the chuck when the outer end of the stock runs free.

Attention to these details of setting the tools and back-rests will generally eliminate the tendency to turn polygonal shapes entirely. The case is but another of many in machine shop practice in which apparently minor adjustments play an all-important part in producing satisfactory work.

THE DISAPPEARING TOOL-CHEST

By A. P. PRESS

Those of us whose heads are white well remember what was the first thing to be done after we had got a new job. That was to hunt up an express man to move the tool-chest. The machinist who did not possess a good set of tools and a good looking chest, even if it did not contain a "mike" or a vernier caliper, was considered a "poor stick."

One of the first requisites for the tool-chest was a pair of good stout handles for each end—handles that would stand a strain of 100 pounds or more. Inside of the chest you would find a 2-pound chipping hammer, a 1-pound or a 1½-pound light hammer, three or four smaller riveting hammers, most of which were homemade; three or four cape chisels, and an equal number of broad-faced chisels for straight chipping; a 12-inch and a 6-inch monkey-wrench; a 24-inch straightedge about ¼ inch thick with one edge beveled down to 1/16 inch or less; and a 12-inch scale usually round at one end and square at the other. These scales were imported from England. A 24-inch scale was beyond the machinist's wildest dreams. Besides there would be in the tool-chest six or eight pairs of calipers; a surface gage with a 4-inch base that weighed about 2 pounds or more, and a standard not less than ⅜ inch in diameter; a hacksaw on which the teeth had to be filed every time it was to be used; and a box level (not a protractor).

If the man claimed to be a millwright as well, as many of the oldtimers were then, there would be an 18-inch level and a plumb-bob with a line around it. Under all circumstances there would be a box of drills or "flats," and one or two choice twist drills, besides an indescribable amount of scrap that invariably accumulated.

Now what does the new man that comes in to-day bring along? He has a little hand-bag, about the size my lady uses when she goes downtown shopping, and inside there will be one or two sets of "mikes" and possibly a full assortment of scales from 9 inches down. There will also be a bevel protractor and a pair of spring calipers, and possibly a chipping hammer about 1½ pound in weight. Of a dozen men to-day, not more than two will bring a tool-chest, and the foreman does not view them with approval. When you have only 3½ or 4 feet of bench room for each man, the space is too valuable to be taken up with a big tool-chest. There are several shops with which I am personally acquainted where the tool-chest is not tolerated unless it is kept under the bench, but it is preferred, by those in charge, to have it left at home.

STRENGTH OF THICK HOLLOW CYLINDERS

A formula for calculating the bursting pressure of thick hollow cylinders, which agrees closely with the results of experiments undertaken by Messrs. Cook and Robinson, is given in *Engineering*, issue of January 5, by F. van Iterson.

Let P = bursting pressure, in pounds per square inch,
F = ultimate strength of material, in pounds per square inch,
R = ratio of external to internal diameter.

Then

$$P = F \text{ hyp. log } R$$

This formula, of course, is not applicable for values of R which make hyp. log R greater than 1, as in that case the bursting pressure P would be greater than the ultimate strength of the material F.

NOTES AND COMMENT

One discriminating dealer in second-hand machinery pays more for Eastern tools, claiming that the harder iron used in the East gives appreciably longer life to lathe shears and other sliding parts. This dealer, however, handles only second-hand tools that are in prime condition—those that have been well used and employed on a variety of work which has given nearly uniform wear to the shears, etc.

Milling carbon steel at a peripheral speed of 500 feet a minute and producing a surface like polished silver is what the National Twist Drill & Tool Co., Detroit, Mich., is doing on small drills. A high-speed cutter about 3 inches in diameter, having teeth of 3/16-inch pitch and cut at an angle of 15 degrees, is run at the given speed to mill the drill clearances. The drill is supported directly beneath the cutter by a V-rest and the cutter rotates against the cut. Lard oil of the best quality is used for lubricating.

An international exhibition will be held at Liverpool, England, from May to October. The textile, electrical, machine building, general manufacturing, and shipping industries, as well as arts and crafts, will be represented. The exhibition, it is claimed, will be of international importance and similar to the successful exhibition at Glasgow, where the number of people attending exceeded 11,000,000. Copies of the prospectus and application forms for exhibit space may be secured from the Bureau of Manufactures, Department of Commerce and Labor, Washington, D. C.

A change in the equipment of modern drop-forging plants that is being made in the interests of greater efficiency and better product, is the substitution of steam drop-hammers for board or other free falling hammers. The steam hammers work quicker, are under better control and deliver a harder blow for the same weight of drop. They are not as efficient, however, in the use of power as the mechanically-operated hammers. The steam is not as effectively expanded as in an efficient engine cylinder and there are large wastes in steam lines due to condensation. The power cost is, however, a small item compared to the labor cost and general overhead charges.

Few mechanics have an adequate idea of the great cost of some experimental aeroplane engines that have been built to develop great power with low weight. One came to our notice lately that has cost over $12,000 and is not yet completed. The cylinders are made from solid chrome-nickel steel bars, and are marvels of fine and accurate machine work. The weight of the engine, complete, is about 180 pounds and it develops 65 horsepower when all the seven cylinders are chugging. The cost is in inverse ratio to the weight. To illustrate, take one part made of alloy steel which in the rough weighed 115 pounds; when finished, the weight was 6 pounds and the labor cost was over $250.

It is reported that the White Star Line has commissioned Harland & Wolff, Belfast, to build a transatlantic liner which will be 990 feet long, with a beam of approximately 110 feet, a displacement of 70,000 tons, and a gross tonnage of over 50,000 tons. The liner is to be named the *Gigantic*. It will have twelve or thirteen levels or decks, the highest of which will be 75 feet above the water line. The vessel is to be designed with accommodations for over 4000 passengers, 1000 of which can be carried in the first cabin. The new vessel will be a seven-day boat, provided with a combination of reciprocating and turbine engines. It is stated that a cricket field, tennis court, golf links (?), and ball-room will be included. The cost of the vessel will be nearly $10,000,000.

Pensions are granted by the American Steel & Wire Co. to employes who have reached the age of seventy, and who have been in the service of the company or any of its predecessors for ten years. A pension is also paid to employes who have reached the age of sixty and are physically disqualified for further service, provided they have been employed during the preceding ten successive years. The pensioners are allowed to seek employment elsewhere, should they so desire, and can live wherever they please. Some of the retired pensioners, it is said, are living in England, Ireland, and Sweden, besides in various parts of the United States. The pension fund is maintained entirely by the company without any form of contribution from the employes.

A correspondent of the *Frankfort Gazette* draws attention to what seems to be a rather common practice of some German steel-making concerns. It appears that machine tool builders are practically compelled to accept deliveries of steel, instead of cash payment, in return for orders of machine tools. The great iron and steel works thus place the machine tool makers in a difficult position, as the latter have often to choose between losing a contract or laying up a stock of material which they may not be able to use for a long time to come. Sometimes they are forced to use material which they perhaps otherwise would not employ.

The wonderful effect of harvesting and other farm machinery, on the world's food supply is but dimly appreciated by those who have given it only casual thought. A pamphlet called "The Story of Bread," published by the International Harvester Co., is authority for the following statement that almost staggers belief: "A modern farmer, with the practice of scientific knowledge, and the use of modern machines, can, with three months' labor, raise as much wheat as could an old Roman had he worked ten hours a day, six days a week, for all the weeks of his three score and ten years. In the time of Nero it took four and a half days' labor to raise a bushel of wheat; when the reaper was invented it took three hours; and in the time of Roosevelt it takes ten minutes."

For many years past there has been a tendency to mark cutlery and other goods similar to those produced in Sheffield, England, with the word "Sheffield," in order to convey to the purchaser the idea that they have actually been manufactured in or near Sheffield, and that they carry with them the traditional high quality of Sheffield goods. A fund of $55,000 has been raised, and has been placed at the disposal of prominent citizens of Sheffield to prosecute in all cases where the name "Sheffield" is being fraudulently used as a trademark. It is proposed to increase this fund as occasion may arise. The results of the prosecution will be widely advertised, especially in the localities where the firms using the fraudulent marks are located.

Specialization in industries effects innumerable economies and cheapens production. Centralization of some of the functions of a community increases their efficiency. An exception is electric lighting in the case of large buildings. Many of the office buildings, hotels and other large buildings of New York and other cities have their own lighting plants. The exhaust steam is used for heating in winter and carries nearly as many heat units as the same weight of steam used direct from the boilers. If the lighting is charged at the lowest rate that the central lighting plants will quote, the heat costs nothing; if the heating is charged at the cost of live steam as furnished by the boiler, the cost of the current for lighting and power drops to less than a cent a kilowatt in New York City.

A type of machine construction that is much used in Germany is that employing steel plates and structural shapes for the frames. Castings of simple form are placed between the plates to act as separators and give stiffness and strength where most needed. The advantage of this construction is greatest on special machines of rough character, such as boiler shop tools. The cost of large and complicated patterns is avoided, as is the delay incident to making them and getting the castings. A variety of castings that experience has shown can be largely used are kept in stock, and these are modified by machining where needed. Sometimes a large machine for shearing and punching structural shapes will be built up in this manner in a few days, using plates, angles and gussets principally, that would require weeks if built with cast-iron frames in the usual manner.

THE DIESEL ENGINE*

By S. M. HOWELL†

To save the first cost of the igniting devices used on internal combustion engines and to avoid the additional expense and trouble incident to their employment, is an attainment of great practical value; an engine that is self-igniting and which also embodies other important advantages, is certainly a very desirable form of construction. The fact that the heat of compression is capable of firing the charge in a gas engine cylinder is, of course, a self-evident proposition in the science of thermodynamics, as well as a matter of common experience, and the idea of its utilization for this purpose no doubt occurred to some early designers; but the first prominent example of a self-igniting gas engine was that of Rudolf Diesel, of Germany, and it is probable that his was the first engine in which ignition was thus effected. The Diesel system, however, is not the only method of operation which is capable of self-ignition. Several patents have been secured by other inventors since the date of the first Diesel patent, in which the heat of compression generated by means of an auxiliary high-pressure air pump is used to fire the charge in engines of the impulse or explosion type. In the original Diesel patent, No. 542,846, of July 16, 1895, the inventor does not claim this feature of his motor, but he afterward claimed it in combination with other elements in his patent, No. 736,944, of August 25, 1903. The self-ignition, however, in the Diesel engine, is merely an incident in the operation of the cycle. The motor as a whole differs in its operative principle from all other gas engines, belonging to that general class known as the continuous combustion type. This type was first exploited many years ago by a number

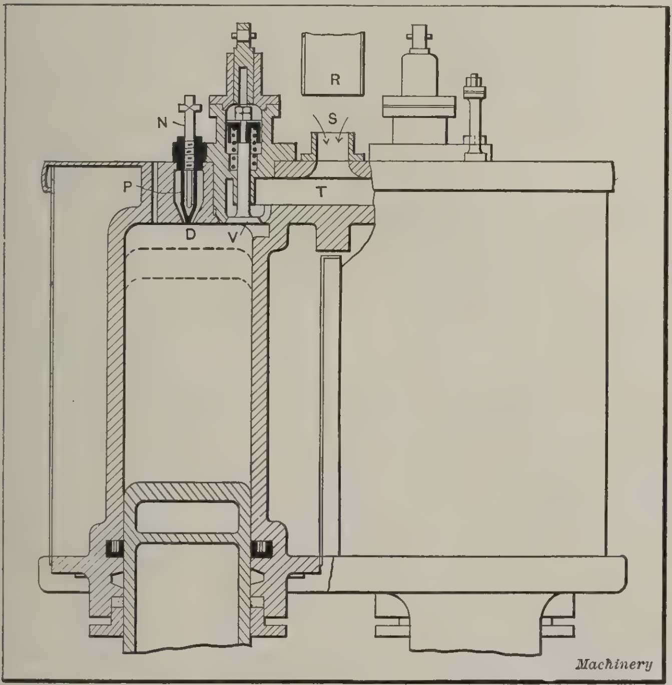

Fig. 1. Diesel Engine using Oil Fuel—U. S. Patent No. 542,846

of inventors whose productions never came into general use, and it was for a time displaced almost entirely by the impulse form of gas motor.

The primary idea of the Diesel system is to compress a charge of air by the in-stroke of the piston, to such a degree that the resulting heat will equal the highest temperature subsequently attained by the burning charge. The fuel is injected during a first fractional part of the power stroke, and is self-ignited and burned in a volume of air considerably in excess of the quantity actually required to consume it. By this means the mean working temperature of the cylinder is so reduced that the use of a water jacket is unnecessary. Thus the loss due to the abstraction of heat by water cooling, is avoided, and the highest degree of efficiency is secured from the thoroughly consumed fuel.

In considering the theory of this system of operation it would seem at first thought that to produce by means of compression alone a temperature equivalent to that of normal combustion, would require an excessive degree of pressure, so high indeed as to be altogether impracticable; and it may also seem that the heat generated by the combustion of the fuel would simply be added to that already existing in the body of compressed air, and that the resulting temperature would be still higher. Ordinarily this would be the case—that is, if the charge of fuel could be instantly introduced, but this action is not contemplated by the theory and does not occur in practice. Nor is the degree of initial compression as high as would be required to produce a temperature equal to that of combustion under ordinary conditions. The reasons for this are, first, that the burning charge is diluted,

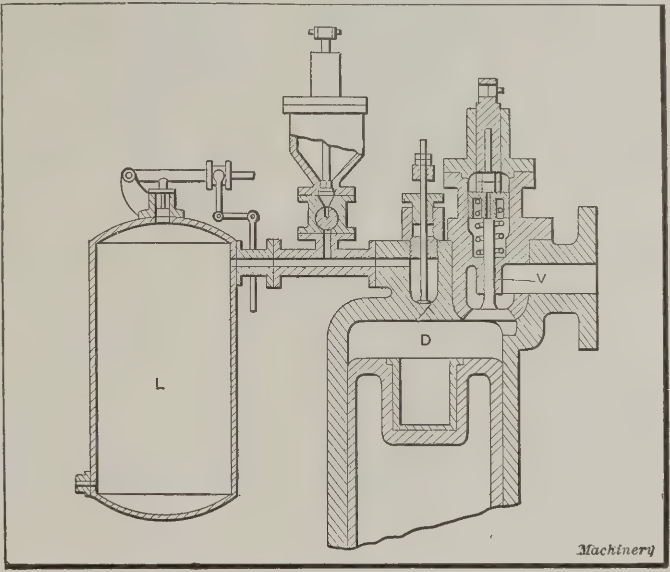

Fig. 2. Section of Diesel Engine having Compressed Air Tank for Starting

and the heat greatly modified by the superabundance of air, and second, that the fuel is forced into the cylinder while the charge is expanding on the power stroke, and is so regulated that the heat added by combustion is only sufficient to counterbalance that lost by expansion as the piston moves forward. Thus both the temperature and the pressure of the initial air charge are maintained, without material change, to the point of cut-off. This point is determined by the governor or control lever, and from thence to the end of the power stroke the pressure falls in an adiabatic curve, and the burnt gases are finally exhausted at the temperature of the atmosphere. The heat is absorbed and transformed into work by the expansion of the charge from the point of cut-off to the termination of the stroke.

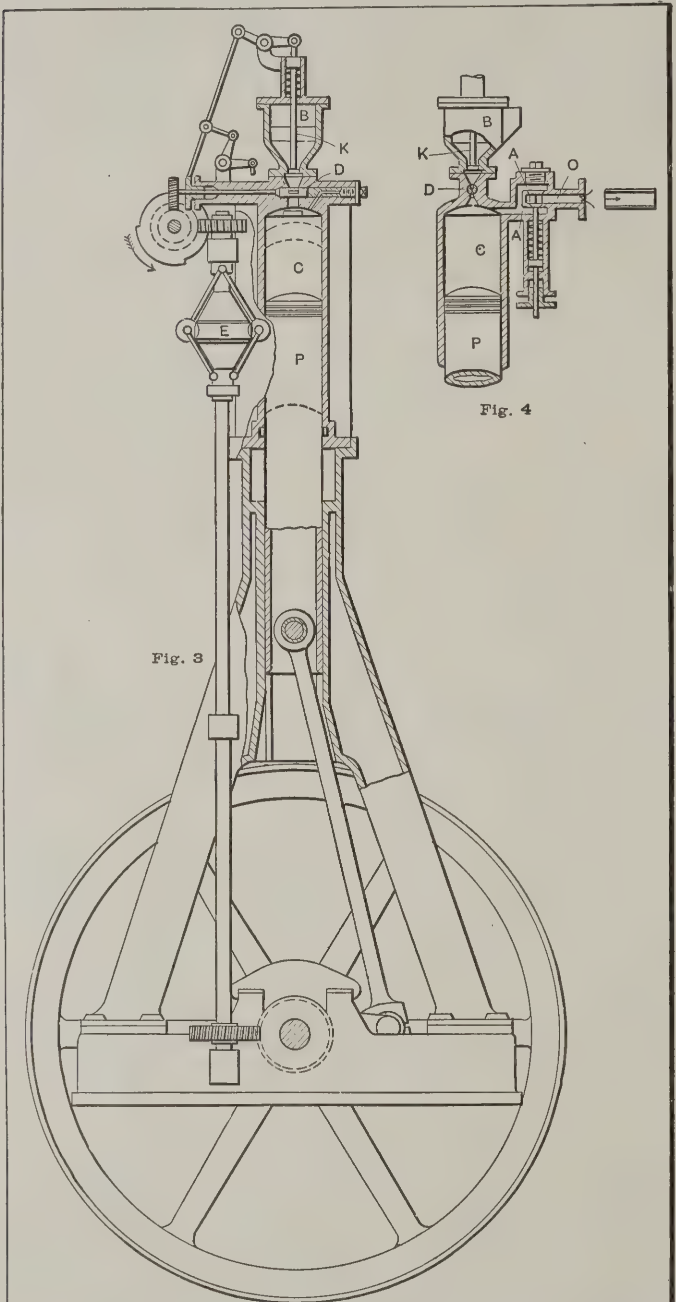
The object of the system is to promote a more perfect combustion, and to secure a working fluid of comparatively low temperature, expanded to the full limit of its useful effect. It should be observed, however, that while this is the theory of this celebrated motor, it is not fully carried out in the prevailing practice of the present day. A theory can seldom be accurately followed, and must always be subject to the requirements of practice. In the models originally demonstrated by the inventor, the initial air charge was compressed to 1500 pounds per square inch, with a resulting temperature of 1500 degrees F., and the fuel admission was accurately adjusted to maintain the theoretical conditions; but in many cases the Diesel engines now built depart somewhat from the first standard in this respect, and operate partly upon the system of the impulse or explosive cycle. The water jacket discarded by Diesel is now generally restored, and a pressure of 500 pounds per square inch is considered the proper degree of initial compression to secure the best all-around results in practical service. The thermal efficiency may be slightly reduced by this practice, but durability and ease of lubrication are improved by it, and commercial efficiency is secured to a more satisfactory extent than would be the case if the

* For further information on this and kindred subjects, see MACHINERY, February, 1912, engineering edition: "Points in the Design of Two-Stroke Cycle Engines," and also the previously published articles there referred to.

† Address: Oroville, Cal.

exact conditions demanded by theory were made the governing motive of the design.

For the purpose of automatic ignition, the extent to which the initial compression of the air charge should be carried depends upon the character of the fuel—that is the temperature at which it ignites; but as the fuel is usually crude oil or one of its heavy constituents, such as distillate or kerosene, there is but slight difference in the igniting points of these liquids. It is, of course, absolutely essential that the injection fuel be instantly and unfailingly ignited, and for obvious reasons it is certain that the compression of an engine in continuous use will not always be as high as when first



Figs. 3 and 4. Diesel Engine using Solid Fuel

installed. It is, therefore, good policy in designing a Diesel engine to take the safe side in this matter, by providing a degree of compression which is sufficiently high to include a margin of safety, in anticipation of the probable effect of wear and use under unfavorable conditions.

The manner in which this cycle differs from that of the more familiar impulse or explosion type of motor, and the chief reasons of its greater efficiency, may be seen at once by comparison. In the impulse motor the volume of the clearance space usually equals about one-third of the piston displacement. The in-stroke compresses the charge of mixed air and gas to, say, 75 pounds per square inch. At the moment this action is completed the charge is fired, and the pressure instantly rises to perhaps 300 pounds per square inch and a temperature as high as 3000 degrees F.; the gases are exhausted at the termination of the stroke at a temperature of at least 500 degrees. This makes the mean working temperature quite high, and a considerable portion of this heat must be absorbed by the water of the jacket in order to moderate the temperature of the cylinder and piston.

In a Diesel engine, however, the clearance does not exceed 7 per cent of the piston displacement, and the in-stroke forces the entire body of the air drawn in on the previous out-stroke into this space, at a pressure of 500 pounds and a temperature of about 1000 degrees. The injection of fuel begins with the power stroke and continues (if the engine is running under full load) until the piston has completed about one-fourth of its outward movement. The quantity of fuel is just sufficient to maintain the original pressure during the combustion interval, that is, from the beginning of the stroke to the point of cut-off. The volume of air is about double the amount required to consume the fuel, and the resulting temperature is correspondingly low. From the point of cut-off the charge expands to the end of the stroke, where it is exhausted at low temperature and pressure. As a result of this method of operation, the mean working temperature of the charge is lower than that of any other gas engine cycle. Consequently less heat is taken up by the jacket or lost by radiation, and a larger proportion of the heat energy of the fuel is utilized for the production of power.

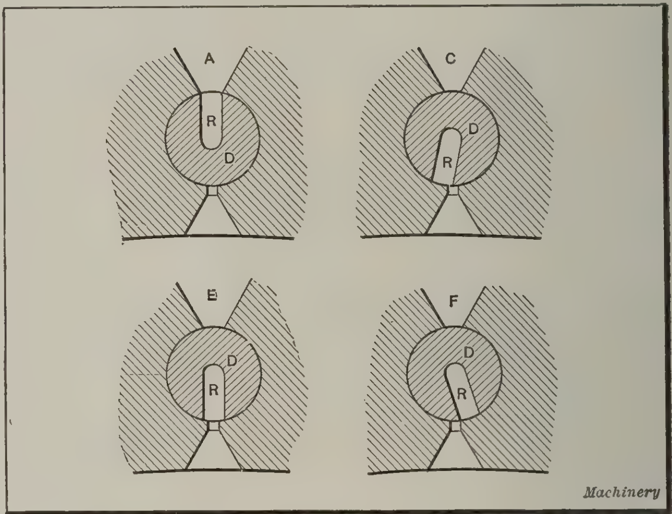


Fig. 5. Section showing Action of Valve D, Figs. 3 and 4

The means of introducing the fuel into the cylinder of a Diesel engine in a suitable physical condition and in a regulated amount is one of the most important features in the design and operation of the motor, and has received a large share of the attention given to the construction of these engines by engineers and inventors. Several methods have been devised by the original inventor of the engine, as well as by others, and two or three of these are now in use. In most cases the engine comprises an auxiliary air or injection pump, capable of producing a degree of pressure considerably in excess of the cylinder compression; this higher pressure is used to force in the liquid fuel through a minute opening controlled by a needle valve in the cylinder head. In one arrangement the fuel opening is located at the bottom of a cup-shaped chamber in the head of the cylinder, the stem of the needle valve standing in a vertical position. This chamber is in communication with the injection pump, the suction stroke of which draws a charge of oil fuel into the chamber. The lift of the needle valve is effected by a device operated by a cam on the main shaft of the engine, and the extent and duration of this lift, and also the quantity of fuel drawn into the chamber, is controlled by the governor. At the proper moment the needle valve opens and the high-pressure air drives the oil, in a finely divided spray, into the hot-air charge within the cylinder.

In the first American patent of Diesel, No. 542,846, the mechanism used for delivering the oil fuel is practically the same as that just described, and is shown in Fig. 1. This

illustration shows an engine with two cylinders just alike, and designed to be connected to the same shaft. The crankpins are in the same line, and the movements of the reciprocating parts are parallel. One cylinder is shown in section and the other in elevation. The spring closed valve *V* is used for both admission and exhaust; *R* is the exhaust pipe, and just below the open end of this pipe is the nozzle *S*, communicating with the passage *T* which leads to the valves *V* in both cylinders. Combustion takes place alternately in the cylinders, producing a working stroke at each revolution, and since the exhaust follows immediately after the drawing in of the air charge, the valve *V* remains open during a full revolution and is then closed during a full revolution. At *D* is shown the fuel nozzle; at *N* the needle valve; and at *P* the fuel cavity into which the charge of oil fuel and a small body of highly compressed air are first delivered by the injection pump and then passed through the nozzle *D* by the needle valve and sprayed into the heated air of the cylinder charge in the manner already described. The exhaust is nearly cold and of nearly even tension with the atmosphere, and the return of the piston drives out the products through the nozzle *S* into the open end of the exhaust pipe. The fresh air for the next stroke enters the same nozzle from the open space around it.

The claims of the American patent of July 16, 1895, were previously granted in England, April 14, 1892, and expired by limitation April 14, 1904. The three claims broadly covered the principles involved in the operation of the cycle as above described, and as the field is now open to all who wish to use the Diesel cycle in combination with their own designs, this patent is the key to the situation as far as general principles of operation are concerned. The specifications of this patent were largely devoted, however, to a description of certain methods of using solid fuel (coal dust), as then contemplated by the inventor, and we will consider this feature further on.

The second American patent of Diesel, Reissue No. 11,900, dated April 2, 1901, contemplated the employment of solid fuel injected with a mixture of gas and air in order to insure instantaneous ignition and more complete combustion. It also described a method of starting the engine with compressed air stored in tank *L* in Fig. 2, the compression having been effected by the engine on a previous run. In this arrangement, a lever-operated clutch controls a system of shifting cams, by which, when the engine is first started, the valve *V* is made to admit the compressed air from tank *L* to the cylinder at each out-stroke of the piston, and to exhaust the same upon the in-stroke. After a few revolutions the flywheel acquires sufficient momentum to effect the compression of the charge, and by a movement of the clutch-lever, the action of the cams is so altered that the valves are operated in the usual manner, and the regular cycle is taken up. This patent specification further provides for a method of automatic ignition without the use of the extra high-pressure air pump. In this modification ignition is effected as follows: The opening of the fuel valve is delayed until the piston has receded slightly from the dead point, and the pressure first produced by the initial compression of the air charge has fallen somewhat. The fuel valve then opens and the air previously compressed in tank *L* forces in the fuel charge as usual. The remainder of this patent specification is devoted to descriptions of burners, fuel spraying devices, etc., evidently designed in anticipation of their possible adoption by others, but probably never constructed.

The next Diesel patent is No. 708,029, dated September 2, 1902. The object of this specification is to reduce the usual size of the auxiliary air or fuel injection pump. For this purpose the pump receives its air from the compression space of the engine cylinder at a high pressure, and thus a pump of much smaller size may be employed than would otherwise be necessary. The next patent, No. 736,944, dated August 25, 1903, relates to the construction of a two-cycle engine and certain means of scavenging the cylinder of the burnt gases before the admission of the fresh air for the succeeding charge.

The last patent of this inventor, No. 890,620, dated June 16, 1908, deals with the introduction of the liquid fuel, the leading idea of this specification being to heat the oil fuel and to saturate it as far as possible with highly compressed air, prior to its admission to the cylinder of the engine, in order to facilitate atomization and promote a more thorough admixture of the fuel with the air of the charge. The oil fuel is continuously pumped into a receiver where it is submitted to the action of air at the working pressure of the engine, and then delivered to the cylinder by the means already described.

Figs. 3, 4 and 5 of patent No. 542,845 show the construction of the original Diesel engine designed for the use of solid fuel. The stroke is long in comparison with the bore, and the compression of the charge is very high. The air is drawn in on the suction stroke at valve *O* (as in the engine shown in Fig. 1), and this valve serves also for the exhaust. The powdered fuel is supplied to the hopper *B*, and is fed by valve *K*. The lift of this valve is controlled by the governor, and the consumption of fuel is thereby proportioned to the demand for power. The delivery of the fuel to the combustion chamber is effected by the rotating plug valve *D*, shown in Figs. 3 and 4, and in transverse section in Fig. 5. This valve has a slot *R*, on one side, and is revolved by the worm-gear shown in Fig. 3. When in position shown at *A*, in Fig. 5, the slot *R* receives a charge of fuel from valve *K*, and while in positions, *C*, *E*, and *F*, delivers the same to the cylinder during the combustion interval.

The inventor states in regard to the use of coal dust fuel that, "the residues of combustion being suspended in a finely divided state in the whirling gases are blown out with the same." If such an engine was ever successfully operated, however, it was probably run at a slow speed.

The Diesel cycle is easily adapted to the use of gas fuel of almost any description. The injection pump receives and compresses the gas to about 750 pounds per square inch, and the injection valve operated under control of the governor, delivers this compressed fuel to the cylinder.

* * *

AN ANALYSIS OF LATHE ACCIDENTS

The gathering of statistics by labor inspectors and inspectors of factories is accumulating a vast store of interesting information. In England, for example, a very complete report has been published covering facts elicited on inspection and in reports, in the Northeastern division of the work of factory inspection.

The total number of accidents reported with lathes in the year 1910 was 670. The classification of the sources of these accidents and the numbers in each group are given in the following table:

From the driving belt of the lathe	24
From the cone-pulley, or belt of the lathe proper	46
From spindle-gear and back-gear	17
From the change gears at the headstock	17
From other gears in apron and feed mechanism	8
From the driving dog	71
From the faceplate or chuck	23
From projecting set-screws about the lathe or work	8
From the tool point or article being turned	297
From the flying chips, or articles being turned flying out	127
From other causes, including falls upon the workmen	32
	670

It is interesting to notice that nearly one-third of these accidents occurred in connection with the work being turned; next to these are the accidents incident to the dog or driver catching the arm or clothing of the workman, and doubtless the chuck or faceplate accidents might be taken together, making up nearly 15 per cent of the entire list.—*The Journal of Industrial Safety.*

* * *

To illustrate the progress of the introduction of machinery in different manufacturing industries, a notable example is cited in a factory in Waterville, Me., where paper pie-plates such as are used by bakers are made in automatic machines that cut, form and emboss plates, turning them out at the rate of 840,000 per day.

PREVENTION OF INDUSTRIAL ACCIDENTS*

By FREDERICK REMSEN HUTTON†

Prof. Frederick Remsen Hutton‡

It should require no argument to prove that an accident in a shop or factory is an economic blunder. It costs the owner, the victim, and the community more to produce the staple article in that establishment than if accidents were prevented. The owner or manufacturer pays at least four costs.

1. The proper compensation of the victim who for a longer or shorter period is unable to earn wages.

2. The cost of litigation where questions arise respecting the responsibility for the accident; or the cost of liability insurance, if the owner follows this method of protecting himself from more costly attack.

3. The cost of the diminished rate of production which follows the nervous shock to everyone who witnessed the accident or ran to the help of the sufferer.

4. The cost of the time to train a new operative to the speed and skill of the disabled one, and such loss as there may be from defective work in that process.

If the seller properly charges these costs to the prime costs of production, he is unable to meet the competition of a rival who has no accidents. In the second place, the community as a whole wastes its resources in the care of the disabled one in the hospital and the charity doled out to any dependents he may have. The community suffers indirectly also, because the victim's children are held back from their full schooling in order to go to work. In the third place, the victim himself spends his savings, laid aside for old age, to say nothing of the pain, the sorrow, the disappointment, the broken spirit, and the quenched ambitions, which the victim has to bear.

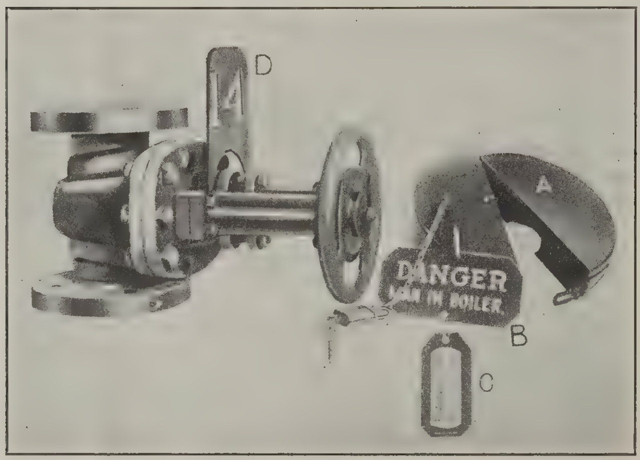

Fig. 1. Safety Lock for Steam Valves

Are industrial accidents preventable? The answer must be conditioned upon the definition given to an accident. An industrial accident may be defined as something which happens to a man, or to a machine, which incapacitates either for the process of production. The accident to the machine may involve an accident to its operator, or he may escape. So far as the operator is concerned, an industrial accident is one by which a mechanical force acts upon the non-resisting tissues or structure of the human body and wounds, bruises, lacerates, or crushes such parts of the body as are in the path of that force. It is the mechanical forces which are responsible for the injuries in industrial accidents. The accident to the machine may be the result of a poor design or of a failure in the material of a properly designed part, from an excessive stress. Prevention of accidents would therefore seem to be a matter which concerned the designer, the inspector, and the works-manager, foreman or superintendent.

The accidents outlined above are in the nature of a sudden disablement. It is no less the duty of the designer and manager to take steps to prevent a gradual disablement, or a premature wearing out of the wage-earning capacity, by slow physiological causes incident to the character of the work; or, to put this in other words, the producing interests need as an economic proposition, to have their human factors in the "pink" of physical condition. They should take care that no conditions in the works itself are responsible for lowered vitality.

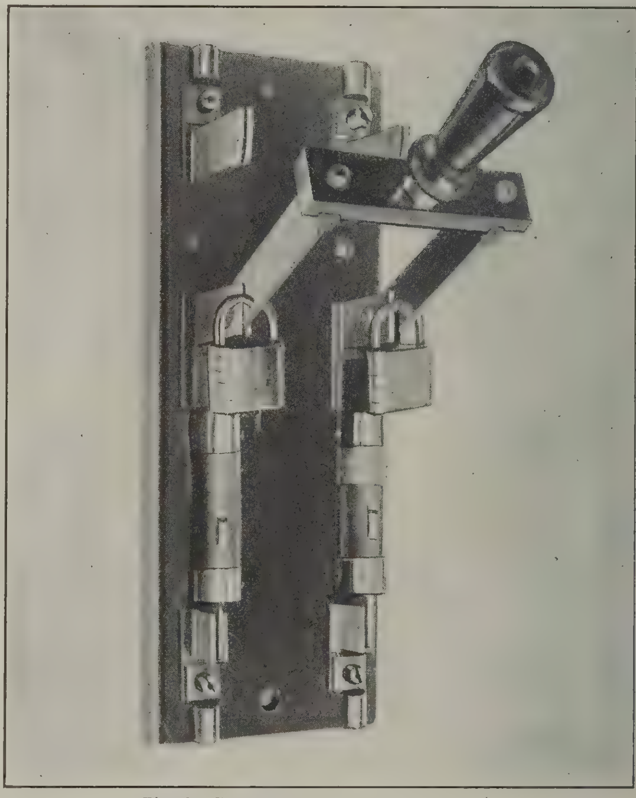

Fig. 2. Safety Lock for Electric Switch

Preventing Accidents in Boilers, and around Engines and Motors

If the foregoing contentions are sound, the motor energy on which all modern production is based, is the prime cause of industrial accidents. Accidents do not happen when the works are shut down. It is so common to surround the moving parts of the power plant by railings, that it seems scarcely necessary to illustrate safeguards in this class. A disaster, however, hangs over the workman around a boiler, which the safety device shown in Fig. 1 seeks to prevent, and against which it has been found entirely effective. This device for preventing a steam valve from being opened upon a line where

The illustrations used in this article have been furnished by the American Museum of Safety, 29 West 39th St., New York City.

† Emeritus Professor of Mechanical Engineering, Columbia University, New York. Address: 257 W. 86th St., New York City.

‡ Prof. Frederick Remsen Hutton graduated from Columbia University in 1876. From 1877 until 1907 he was professor of mechanical engineering in Columbia University. In that year, he was made professor emeritus and entered consulting engineering practice. From 1883 to 1906, he was secretary of the American Society of Mechanical Engineers and was president for the society year 1906-1907. He was then made honorary secretary of the society in recognition of his efforts and success in building up the society from its early beginnings until it moved to the great engineering building on 39th St., New York. He is the author of "The Mechanical Engineering of Power Plants" and "The Gas Engine." In 1911 he served the city of New York as consulting engineer, and is consulting engineer and chairman of the technical committee of the Automobile Club of America. He was one of the persons who early realized the significance of the protection of the workman from the accidents of his occupation in factory and shop. He is vice-president of the American Museum of Safety, chairman of its committee on exhibits and of its board of award of medals. He was for some time also president of the Industrial Safety Association, organized with a special view to the promotion of safety devices in the design of tools and machinery. He is much in demand as a lecturer on this special subject, particularly among the student branches of the American Society of Mechanical Engineers. He is also greatly interested in the problem of good roads and the philosophy of national highways.

people are at work, consists of a sheet-steel casing which fits around the handwheel. It is locked in place, and the key given to the man most interested. The engine down the line on which men are working cannot be started; steam cannot be turned into a boiler within which a man is working; acid cannot be turned into a tank or vat within which repairs are in progress; and a wide group of most distressing accidents are precluded where this safeguard is used.

Fig. 2 shows a safeguard identical in principle and operation where the danger may come from an unauthorized closing of an electrical switch which the repair-man opened when he went to work. The key of the padlock is, as before, in the pocket of the man most interested, and the current cannot be turned on the line until he unlocks the lock.

The next great avenue of disaster is to be found in the belts or gears through which power is passing. The main belt is usually massive enough to act as its own warning sign. The smaller transmissions, however, are those with which the workman is usually more intimate, and from which his greatest danger arises.

In Fig. 3 is illustrated a form of safeguarding against belt accidents, and, of course, the same principle can be extended

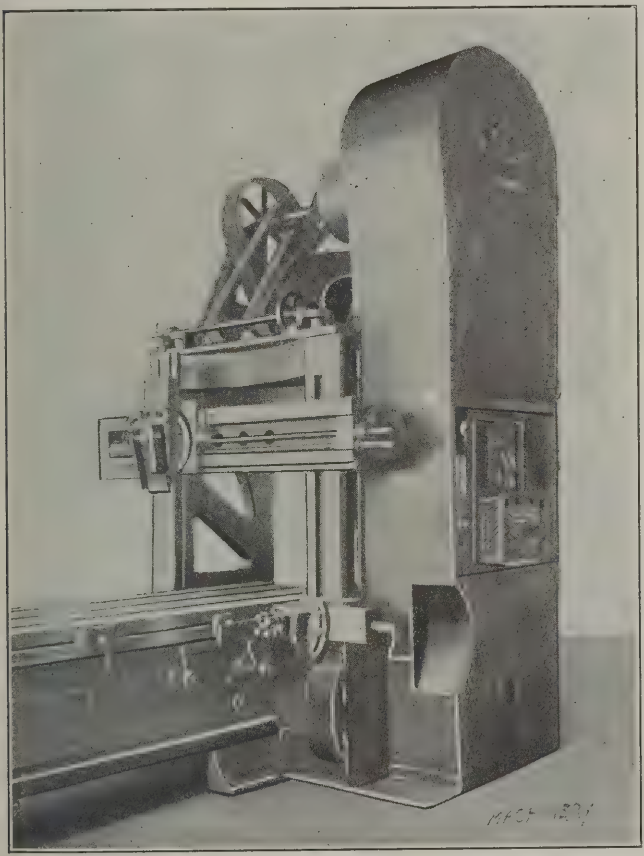

Fig. 3. Guard over Belting and Gears

to gears. A slippery floor or a loose end of a garment may be the cause of throwing a man into the path of the belt, and he may be maimed or killed before the motion can be stopped.

The wood-working or pattern shop is a place where dangerous cutting edges are moving at high speed. These conditions make the circular saw, the jointer or buzz-planer, the molder or sticker, and the band-saw, sources of most distressing accidents, which seem almost worse by reason of their suddenness of attack without warning. Fig. 4 illustrates the trend of modern prevention of accidents of this kind. The lower part of the band-saw is completely encased, and the upper wheel covered with a guard. The accident from the breakage of the saw, and the danger to the forehead of the workman are practically eliminated. He can still, however, lose a finger in the danger zone of the tool. Improved designs of cutter-heads for planers have greatly reduced the dangerous character of the accidents which happen about it, and many forms of guards for the villainous circular saw have been widely installed.

Preventing Accidents in Punch Presses

The punch for boiler and bridge plate is not in itself so very dangerous a tool, but Fig. 5 illustrates a principle of actuating such tools which will make them still safer. Without going into the detail of mechanical construction, it will be plain that by using the electrical wire to put the punch into commission, the fingers of the workman can be kept entirely outside of the danger zone, and he is much less liable to accident than when the design compels that the clutch be thrown in by a second man who may not know just exactly where

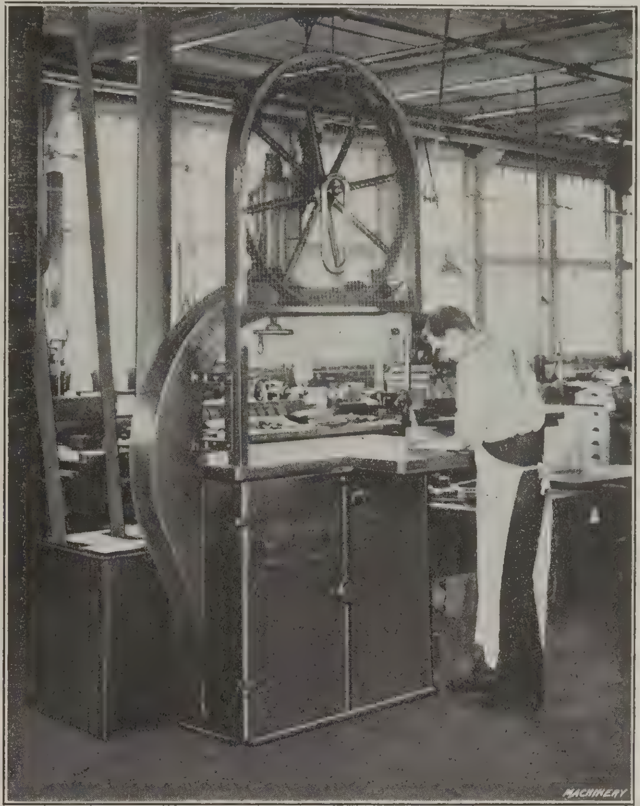

Fig. 4. Guards for a Band-saw

his comrade's fingers are. Probably, however, the most dangerous of the tools in the punching class are the ordinary punch presses used in stamping and drawing sheet metals and similar work. If the ram reciprocates continuously, and the workman feeds the stock by hand, there is always the danger that something will distract his attention, resulting in his leaving a finger where the stroke of the ram can catch it. The designs in Figs. 6 and 7 show a collapsible guard forming a safety device, the intention being that the fingers of the operator

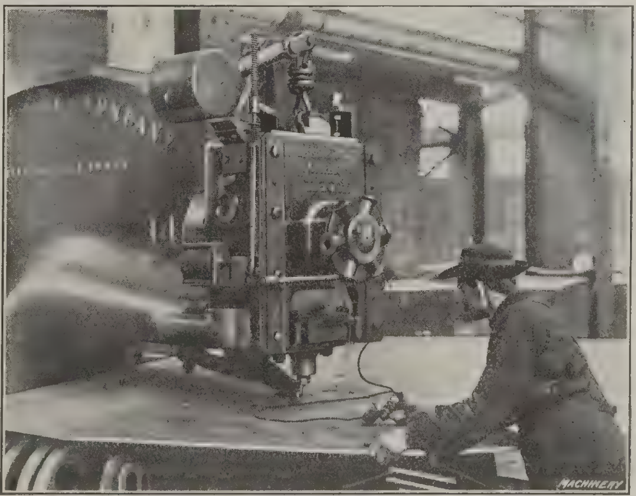

Fig. 5. Operating a Boiler-plate Punch by means of an Electric Hand-switch

shall never get within the guard, while it gives freedom for presenting the stock to the press. Other forms of safeguards cause a steel finger to sweep over the die of such a press, just as the ram descends, forcing the careless finger out of the danger area. A recent clever inventor has proposed to electrify the die as the punch starts to descend, so that any man whose fingers rest on it will get a sharp shock, and automatically draw the fingers away, due to the involuntary contraction of the muscles.

Guarding Emery-wheels

The emery-wheel is a dangerous center of possible accidents. The danger is first from a bursting of the wheel, either by the pressure of the work at the periphery of the wheel, or, more rarely, simply from the action of the centrifugal force. A two-fold safeguard against these accidents can be secured by the use of large disks or washers which grip the wheel at a considerable distance from the revolving axis. If, further, the wheel is thicker at the center than where the washers bear, the danger of a centrifugal flinging of the parts of a broken wheel is materially lessened. Furthermore, the wheel can be covered, except just at the working sector, by a steel guard strong enough to keep in any fragments of the wheel if it should burst.

Fig. 9 shows a safeguarded emery-wheel with the belt protected within a steel shield, and the eyes of the workman shielded by screens either of glass or of fine wire mesh. If

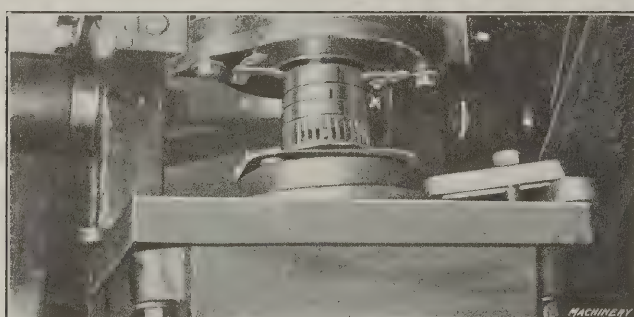

Fig. 6. Punch Press with Telescoping Guard

exhaust currents of sufficient strength to overcome the centrifugal tendency of abraded particles are led away from the wheel, the respiratory tract of the workman is saved from the slow deterioration which it would otherwise suffer.

Miscellaneous Safeguards

The lathe, working on small diameters, or with work in its chuck or on its faceplate, is particularly liable to entangle the sleeve of the workman and break or lacerate his arm. In Figs. 8 and 10 are shown two suggestions for safeguarding the man. The drum *A* in Fig. 8 should keep his clothing from the projecting points of the chuck or faceplate, while

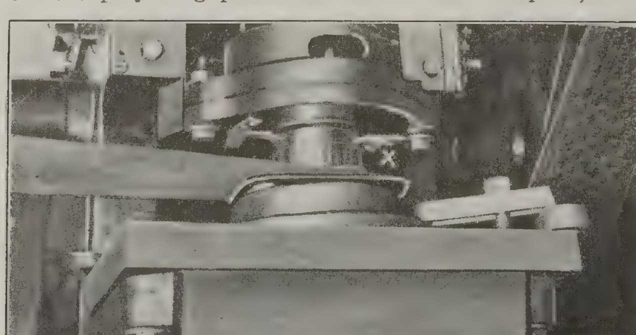

Fig. 7. Punch Press Guard in Fig. 6 with the Ram in its Lower Position

Fig. 10 shows how the common dog can be prevented from his vicious biting.

It is not the custom in the United States to make such common use of women in the shops as the German practice does. The safeguarding the women's hair from being caught in belts or other moving parts should, however, not be neglected. The electrical zone surrounding a fast moving belt is particularly fatal to loose strands, and the entanglement of hair between a belt and a pulley can result in a most distressing accident, which is usually severe enough to be fatal. The wearing of close-fitting caps, covering all of the hair, prevents accidents of this kind.

Accidents in the shop do not originate alone in the danger zone of a power driven tool. The process of chipping often sends a flying particle with considerable force over quite a distance, and the delicate tissues of the eye can easily be pierced by such a barbed missile. In Fig. 11 is shown a safeguard in simple form; a screen of burlap is stretched upon a light frame in the path of such steel particles. The fibrous character of the screen catches what is thrust against it, and the particles drop harmlessly to the ground.

It must not be overlooked that the mechanical force which may strike a man down is not alone manifest or developed at the operating point of the tool. The means of transportation within the shop and about the yard, when operated by power, can be as fatal as the machine tool. The door into

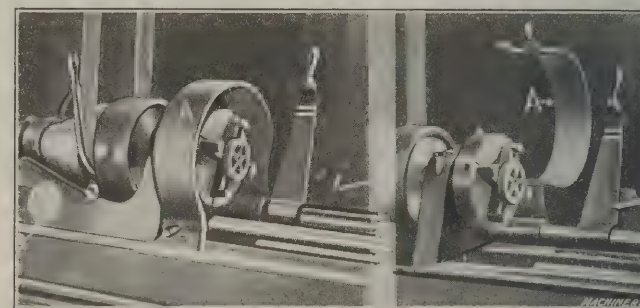

Fig. 8. Guard for the Lathe over Faceplate or Chucks

one of the plant buildings may open directly upon the line of a railway. On a stormy day when the wind is high, or late in the afternoon when the shop is bright, but outdoors is dark, a man may step from the door directly into the danger zone of the railway. He may be intently thinking of something

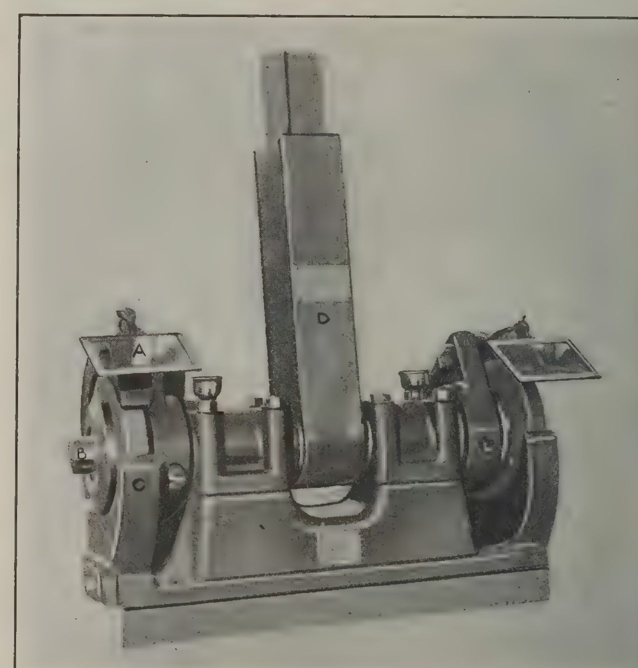

Fig. 9. Emery-wheel Head Effectively Guarded

else, or young lads may be full of the thought of release from toil at the end of the day. The simple expedient of a gate which shall compel a man who comes out through the door to turn and face parallel to the building before he attempts to cross, will at least direct his attention to the danger of the

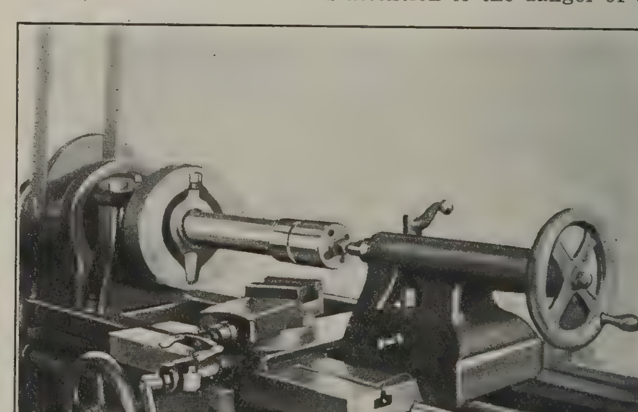

Fig. 10. Lathe Dog Guard

railway line by compelling him to pass around the end of the gate.

The workman whose business it is to oil shafting may meet with an accident by placing his ladder at rather an acute

angle with the floor, and a slippery surface may permit the ladder to fall, bringing the man and his tools to serious injury, particularly if he should fall into moving machinery. It is a good safety device to equip the foot of such a ladder with large contact areas (Fig. 12), and to fit this with a rubber or other surface of high frictional resistance. The protection of traveling cranes, of hoistways and hatches, and of safety hooks and gangway railings, all belong in this general class.

Interlocking Safety Devices

It will be apparent, however, from a consideration of most of the foregoing devices for safety that, even when they are

Fig. 11. Screen for Preventing Chips from flying around

used, it is entirely possible for industrial accidents to occur if the workman is careless or uninterested. The highest principle in safety devices is that which in other departments of engineering is called the "interlocking" principle; that is, it may be made mechanically impossible for the operator to have his fingers in the danger zone and have the tool set in motion while his fingers are there. This principle is introduced in two ways. The first is to have the engaging device require a concurrent action of both hands, in order that the machine

Fig. 12. Large Special Feet for Ladders, with Rubber Soles to increase Frictional Resistance

may function. In a press, for example, it may be arranged so that the belt has a tendency to pass to the loose pulley unless a counterweight attached to the shifter is held in a certain position by the right hand. When the right hand has gripped this one lever, it still requires that the left hand shall throw the clutch lever to make the machine operate. Obviously, the workman has no hand free to put in the path of the plunger of the press. The engagement may also be pneumatic, and require that two valves be opened, one of which is worked with the right hand and the other with the left.

The second interlocking principle is applied in centrifugals or kneading machines which are fitted with a cover. It can easily be made mechanically impossible to throw on the power until the protecting lid has been closed down over the working parts. When this has been done, the belt may be shifted or the clutch thrown in. Conversely, when the clutch is in or the belt is driving the machine, the lid cannot be lifted until the power has first been shut off. For the machines to which this principle can be applied, there is nothing additional to be desired in the way of a safety provision.

It is, however, impossible to apply interlocking to all machines, and there remains, therefore, the necessity for getting the workmen interested in preventing accidents. One of the most satisfactory agencies to this end has been the formation of Safety Committees in the works, of which the workmen themselves are made members in rotation, serving with a certain number who do not change from week to week. While it is true that no soldier makes a good captain until he has first served as a private, it is equally true that no man makes so good a private as one who has carried the burdens of a captain. Service on the Safety Committee and familiarity with the line of thought which reaches after safety, makes the men themselves far more willing to take precautions.

We need an educational process which shall, on the one hand, inform the manufacturer as to what safety devices and systems of shop rules have worked well in other plants, and on the other, instruct the men as to the precautions and safeguards which they have a right to expect in their plant. The labor union may very properly exert itself to protect its members by an insistence upon adequate provisions for safety. The factory inspector may properly insist that every works manager lives up to that standard in safety matters which has been found practical in other establishments of the state.

* * *

The Machine Tool and Engineering Association of Great Britain announced at its last annual meeting that eighty firms had joined the association. A communication had been received from the Home Office, one of the governmental departments in Great Britain, with respect to the question of adequately guarding the gears of machines. It was stated in this communication that British firms had lost several orders owing to the inadequacy of the guards over gears, and that machine tool manufacturers in other countries supplied their machines with better guards. A prominent man in the machine tool trade, speaking about the way in which some of the gears and parts were indiscriminately arranged around a machine, to the danger of the operator, suggested that the builders should look at the human frame as a model to which to build their machines, since in this all the important elements are carefully concealed within perfect guards. A designer, he intimated, should make a machine a pleasing thing to look at besides being an article of utility. Mr. Walter Deakin of Messrs. H. W. Ward & Co., Ltd., called attention to the fact that the reason why the British mechanical industries were not in the lead, as they had been in the past, was chiefly due to the narrow view that the members of the trade had entertained. They had, he said, rather kept to themselves and thought that it would be the best policy to cultivate their own little patch, without attempting to recognize the general bearing of questions concerning the whole industry. Evidences, however, indicate that this feeling is disappearing among British manufacturers.

* * *

Radium emits three kinds of rays which for convenience are called alpha, beta, and gamma rays. Of these the gamma rays, which greatly resemble the Roentgen or X-rays, are of tremendous penetrating power. It has been possible to obtain fine photographs with these rays through 12 inches of steel. The alpha rays emitted by radium are in reality small particles of matter that can be detected when the radium is exposed to a zinc sulphide screen; the bombardment of the screen by these particles, which travel at a very high velocity, produces scintillations which under a magnifying glass, look like millions of shooting stars or sparks. Through the constant giving off of particles, the radium atom gradually breaks up, but the process is so slow that only one-half of the atom is broken up in about 1300 years.

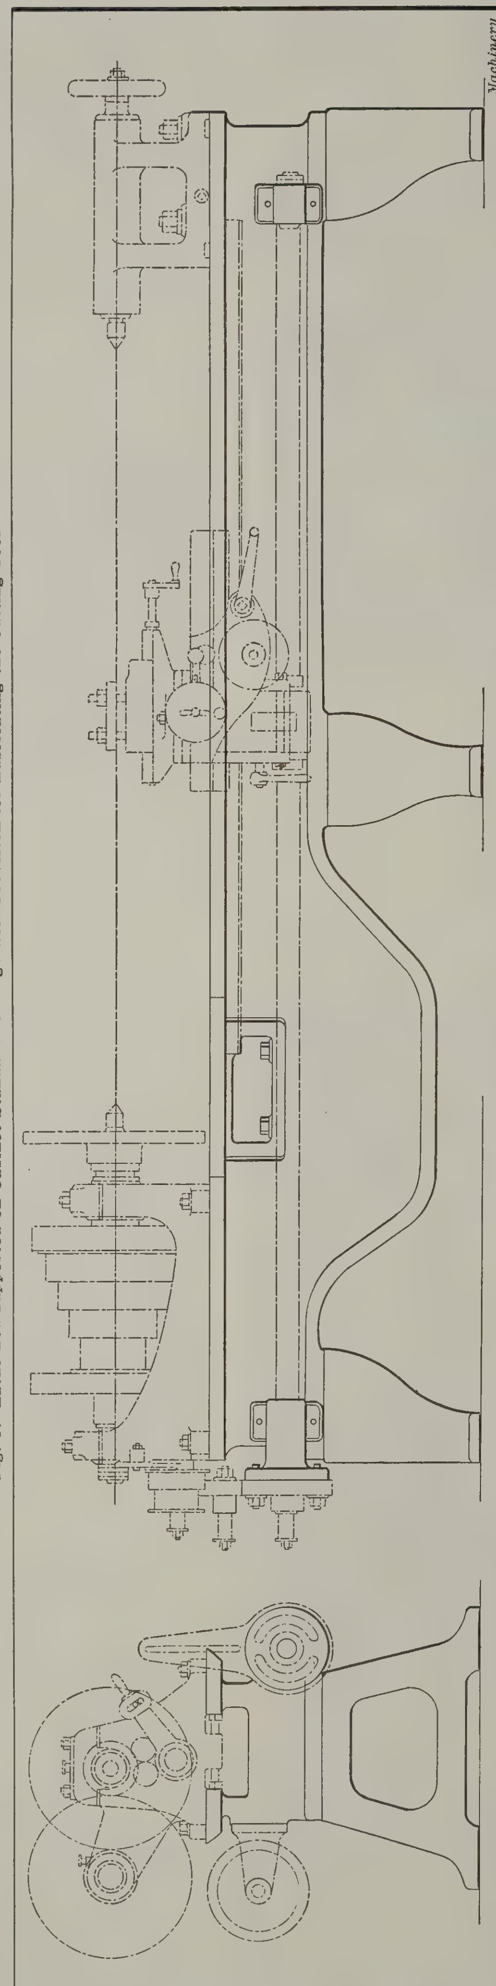

Fig. 2. Gap Bed supported on Three Legs

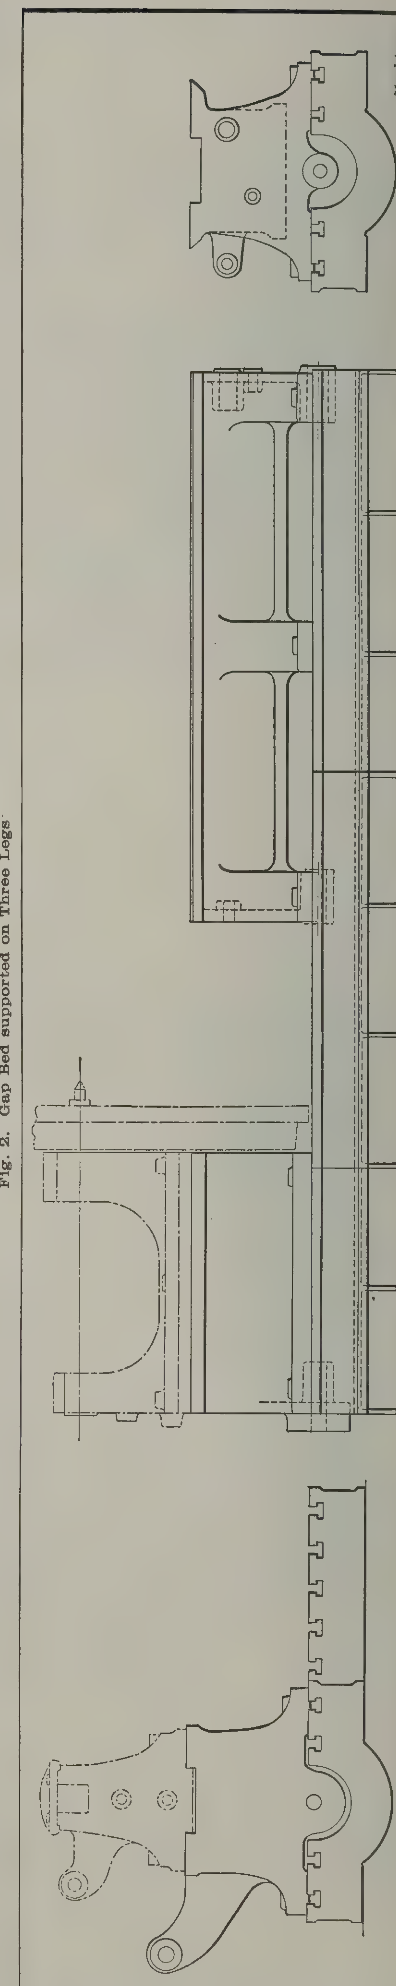

Fig. 3. Large Sliding Gap Bed

THE FORMS OF LATHE BEDS -3

THE LONGITUDINAL FORMS OF BEDS

By JOSEPH G. HORNER*

The remarks made in the previous installments relative to the flexure and torsion of lathe beds need not be repeated here, but we shall consider, with the aid of the representative illustrations, how flexure is best resisted, and how the longitudinal shapes are modified to serve different functions. The principal differences which are made in the forms of beds are those arising from variations in dimensions, while subsidiary differences are produced by special designs of lathes, or additional functions, or by the particular class of work which is done in the lathe. Thus, the shapes of beds of similar dimensions for ordinary screw-cutting or engine lathes and those for turret lathes are very often radically different. In the one case provision has to be included for the screw-cutting and feeding devices, for the carriage motions, and for the tailstock, while in many turret lathes these features are absent, and the bed is plainer, with provision only for clamping the turret base and the cross-slide. On the other hand, the arrangements for lubricating the cutting tools and work often introduce complications into the design of turret lathe beds, and the casting is of a more elaborate character below the bed proper—around the top of the legs or standards.

The length of a bed has an important influence upon its construction and the number of supporting points, and if a gap is included, this also modifies the form to a considerable degree. The number of supports ranges from the single cabinet standard in some small lathes, and the two standards or legs in those of ordinary dimensions, to the three or more supports in longer beds. A continuous bed of full depth for the whole length is employed in lathes for heavy work and large swing, and is supported solidly on concrete foundations. The truth and rigidity of a lathe bed depends to a certain extent upon how it is fastened down. Ordinarily, beds are bolted rigidly to their foundation, which may be a wooden floor or a stone or concrete base.

Many years ago Prof. Sweet suggested the adoption of a tripod support for lathe beds, and this suggestion has been acted upon in practice. One end of the lathe is bolted down by the usual means, and the other is pivoted on a pin which passes through lugs in the bed and in the leg. The only support at that end is the pin on which the leg is free to adjust itself. Many firms also adopt the three-point support principle without any pivoting device: sometimes there are three points of contact with the foundation, and sometimes the bed is united to the legs at three points. The effect of an untrue foundation is thereby neutralized. Another method of affording good support is that of casting the bed with, or bolting it to, a single column of box form, which makes the lathe self-contained, and obviates any risk of distortion or winding. This construction is employed both for small ordinary lathes, and for turret lathes up to fairly large dimensions.

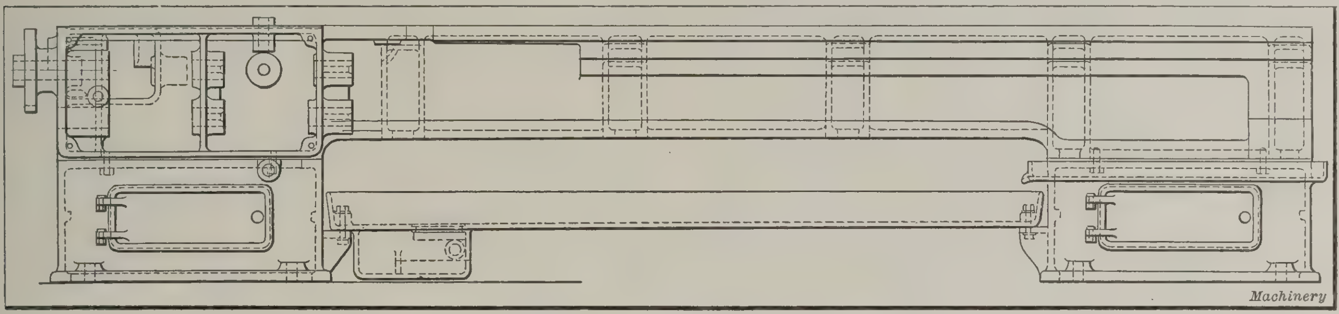

Fig. 4. Bed for 20-inch High-speed Lathe built by Smith & Coventry, Ltd., Manchester, England

Legs or Supports for Lathe Beds

When legs are used to support the bed, it is the custom of some makers to spread the legs under the head to a greater extent than those under the right-hand end, to resist the vibration, which is more pronounced at the headstock end. Other firms do not put ordinary ribbed legs at all under the headstock, but prefer a boxed cabinet support, even when there are legs at the other end. The principle of this seems faulty, since, if it is considered necessary to put a box support under the headstock end, the use of a flimsy support at the other end of a heavy bed appears unreasonable. Many makers view the matter in this light, and place the bed on equally solid and substantial supports at both ends; sometimes the supports are of identical pattern, but frequently they are a little larger at the headstock end, in order to afford more cupboard room for tools and appliances.

The practice of placing the supports a certain distance inward from the ends, mentioned in a previous installment, is followed in many instances, and a further development of this principle is found in the case of some lathes, particularly those with gaps, where the metal of the boxed bed is carried down to a considerable depth under the headstock, gradually tapering off towards the ends. A great many turret lathes have their supports placed some distance inward from the ends of the bed, and the under side of the latter is often tapered or curved upward from the outside of the legs to the ends of the bed.

Gap Lathes

The question of forming a gap in a lathe bed has long been the subject of controversy. A gap lathe bed is practically as common in England as a straight bed. Theoretical considerations have been urged against it, chiefly on the ground that the bed is weakened, because its continuity is broken; but an English lathe maker would argue that the metal which is removed can be more than compensated for by extra metal placed underneath and beyond the gap, and in the heavier lathes by metal brought down to the ground in the form of a broad foot. The real objection to a gap is its unalterable dimensions—it is wider than is required for some jobs, and not wide enough for others. The fitting of the bridge-piece is also liable to become slightly inaccurate when a lathe has done much service, but this can be rectified.

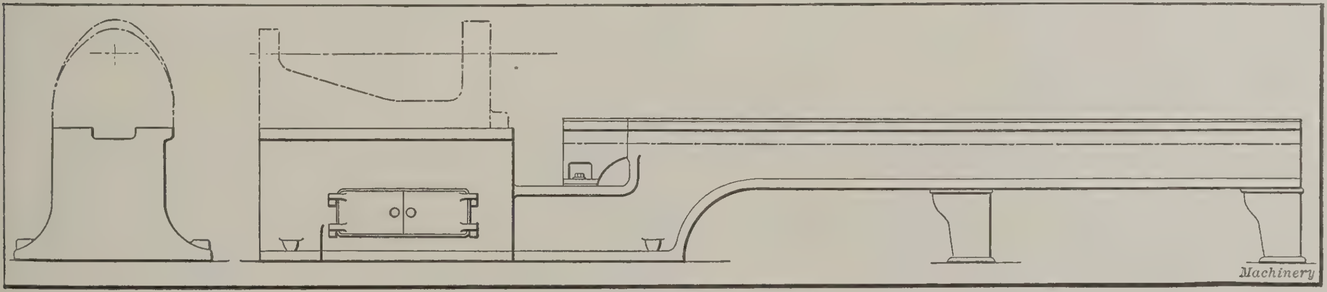

Fig. 5. Gap Bed with Support under the Gap

The gap is nevertheless a great favorite because of the gen-

* Address: 45 Sydney Buildings, Bath, England.

eral and miscellaneous character of the work which has to be handled in most shops. Thirty or forty years ago such lathes predominated over all others, but gradually, with the growth in specialization, they have been displaced, to some extent, by straight-bed lathes on the one hand, and by regular facing lathes, and vertical turning and boring mills, on the other. Nevertheless, the rigid gap bed retains an important place in nearly all English shops, and is likely to do so because of its adaptability to so many varied classes of work. Usually, the makers now supply identically the same lathe with and without the gap. In some designs a sort of compromise is made, in that the metal immediately in front of the headstock is recessed to a moderate depth and width, leaving a gap which very considerably increases the usefulness of the lathe, but no gap-piece is required. The metal removed at the recess is compensated for by carrying the bed down deeper underneath, or by casting it with a continuous foot extending from the end of the bed to a certain distance beyond the gap.

The movable-gap is used to a moderate extent, in medium and large sizes of lathes, and would be adopted more extensively but for the fact of the ever-growing specialization. The breadth of gap is adjustable within a wide range, or it may be closed up entirely, the object being, of course, to support the carriage as close as practicable to the cutting point of the tool under all conditions. The most serious defect in gap lathes, perhaps, is the fact that the lead-screw has to be kept low down to be out of the way. In the movable-gap lathes another difficulty arises in the driving of the lead-screw, which has to be done from gears at the right-hand end of the bed.

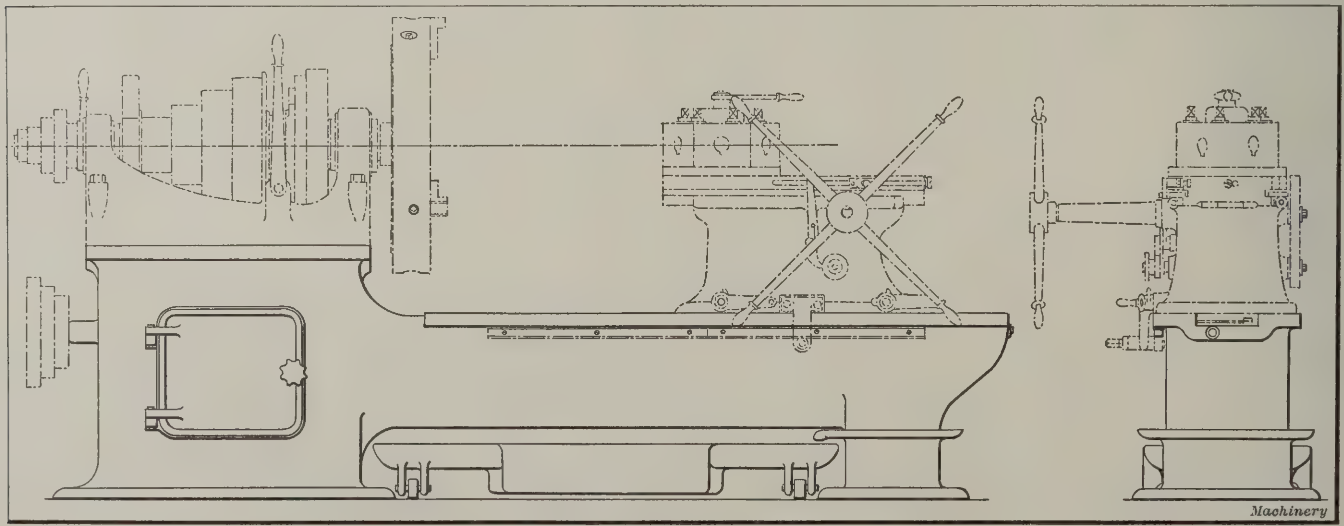

Fig. 8. Type of Bed used for Chucking Lathe

Types of Lathe Beds

The first illustration, Fig. 1, shows the form of a good type

of bed, supported on box standards at both ends. The bed is equipped for the use of cutting lubricant or oil, though not in such a perfect manner as some beds shown later. A more

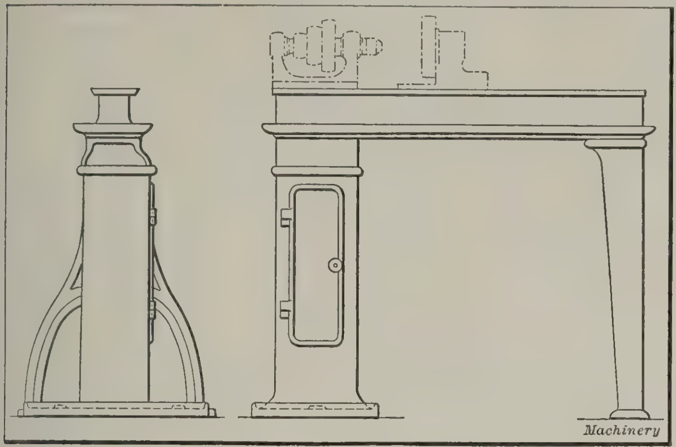

Fig. 9. Bed for Small Lathe

elaborate type of bed for a 20-inch high-speed lathe, built by Smith & Coventry, Ltd., of Manchester, England, is shown in Fig. 4. The cross-sectional shape of this bed was shown in a previous installment of this article. The details of the boxing and cross-ribbing and the joining of the bed to its standards will be observed. The right-hand standard is surrounded by an oil rim which conducts the lubricant into the trough, and at the top of the bed, close to the headstock, a space is left for the oil and chips to drop down into the trough.

The two principal designs of gap lathes are represented in Figs. 2 and 5, the first having the gap compensated for by the usual deepening underneath, and the other having a continuous base, such as is adopted for heavier lathes. In each case an intermediate leg is located under the bed, owing to its length. It will be noticed that in one case the gap-piece entirely fills the opening, while in the other it only partially does so, leaving a space for a large face-plate or chuck to remain in place, and still providing sufficient length for the support of the saddle.

Fig. 6 shows a French design of gap bed in which the metal is carried down in a graceful curve under the gap. The bed is well supported at this point on the wide cabinet base. An example of a straight bed supported on three equidistant bases is shown in Fig. 7, this being the bed of a Darling & Sellers' lathe, the section of the bed and saddle for which was shown in a previous installment. It will be noted, from the elevation, how the lower tier or guide rail would support the carriage if a gap were used. A design of bed for a chucking lathe is illustrated in Fig. 8; this is of the box type, with ample support underneath the headstock.

Two designs of beds which embody the same idea, with different proportions, are shown in Figs. 9 and 10, the first being for a small lathe, and the second for a larger one. A cabinet leg is used under the headstock end in each case. For beds of the proportions shown in Fig. 9 it is not generally the practice to use a cabinet base, but regular ribbed legs at both ends are used instead.

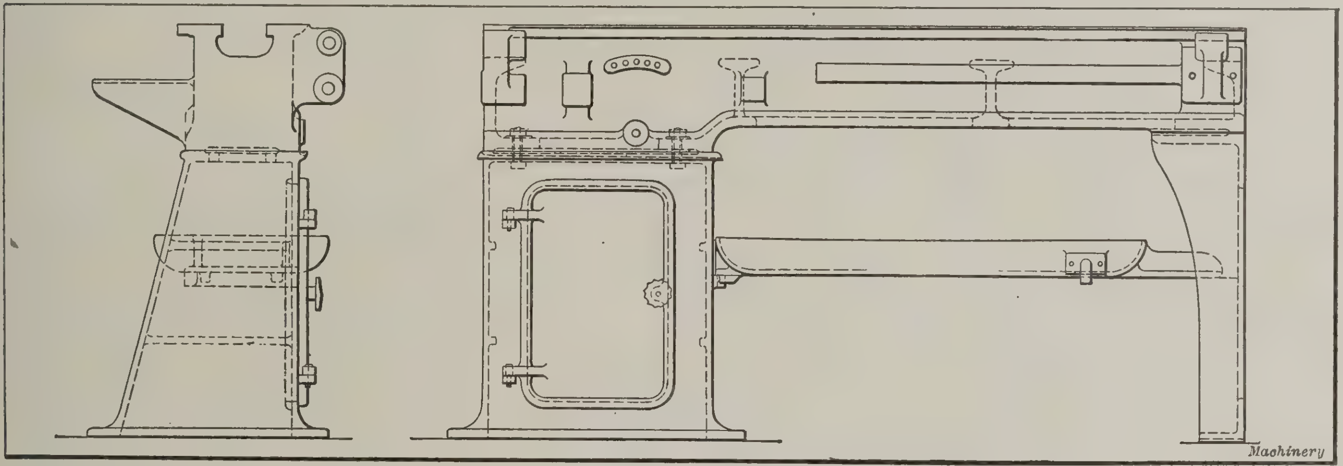

Fig. 10. Bed with Wide Cabinet Standard at One End

The arrangements for lubrication of the cutting tool and work, as mentioned before, affect the extent to which the bed is provided with oil-catching devices. The most complete method, short of placing the entire bed in a tray, is that represented in Fig. 11, with each base surrounded with an oil rim, leading into the trough between them. This arrangement does not provide for splashing, unless a sloping guard is fitted in front, or in both front and rear. A step further, as shown in Fig. 14, consists in fitting a single tray large enough

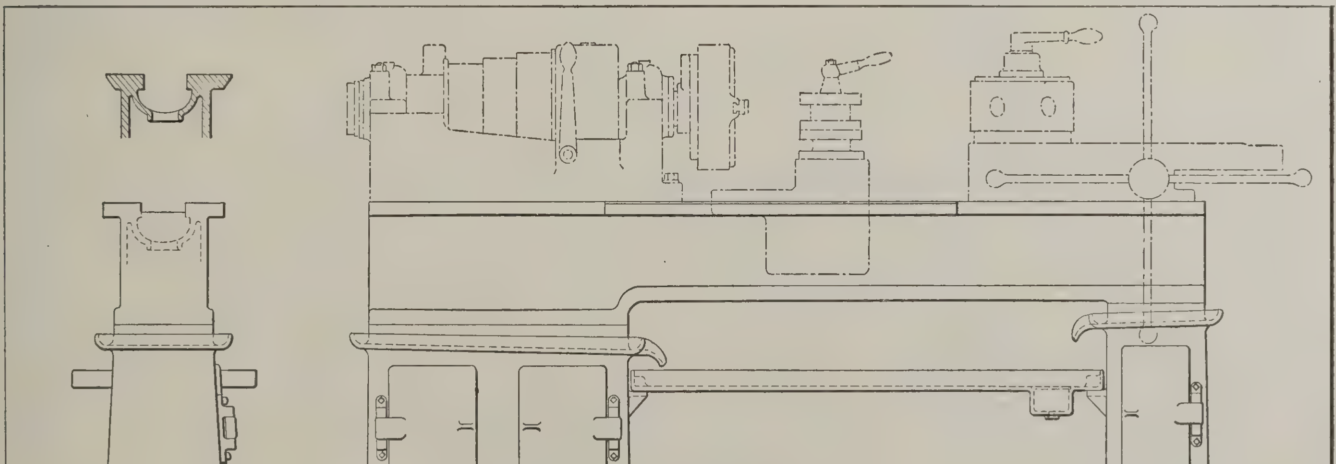

Fig. 11. Bed with Two Cabinet Standards of Unequal Size

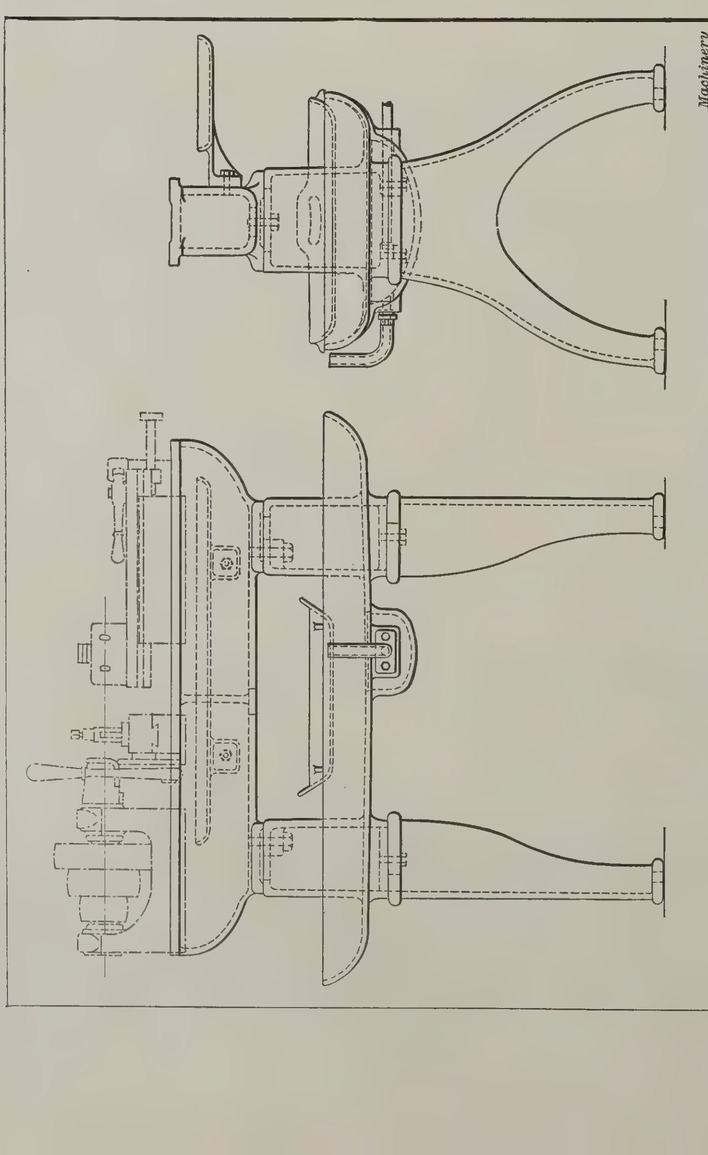

Fig. 12. Bed for Turret Lathe, showing Complete Cutting-tool Lubrication Arrangement

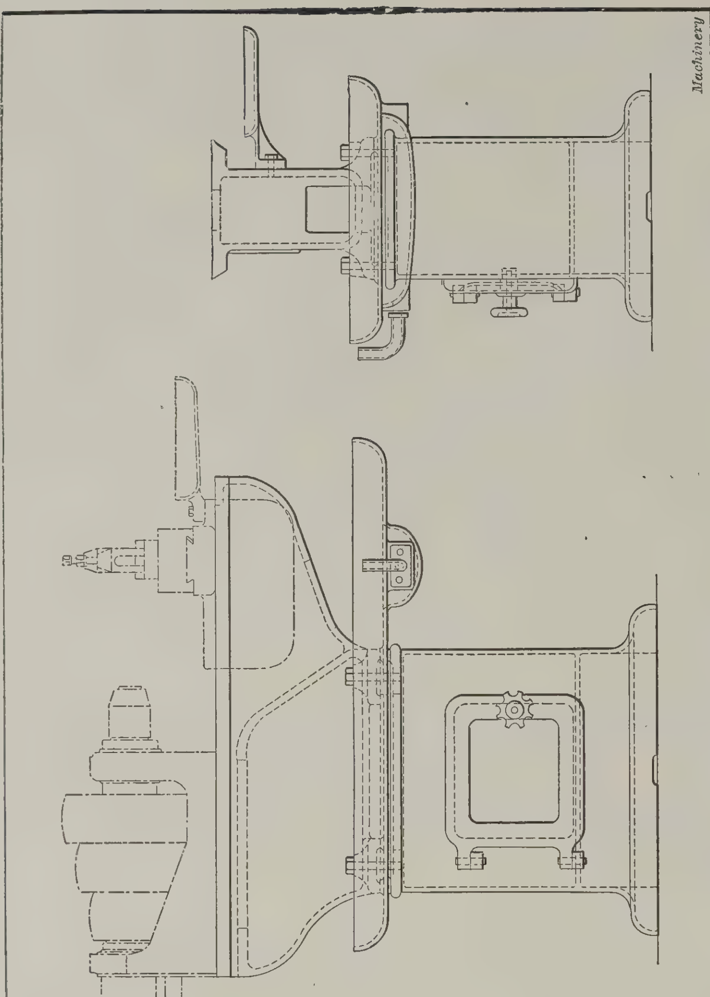

Fig. 13. Bed for Shaving Lathe with Single Cabinet Standard

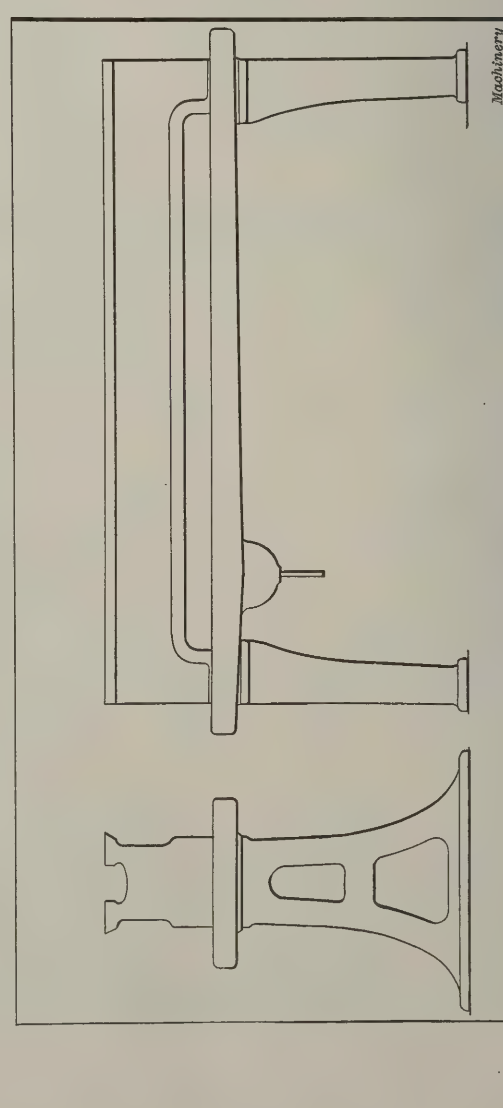

Fig. 14. Light Lathe Bed with Plain Leg Supports and Oil Tray

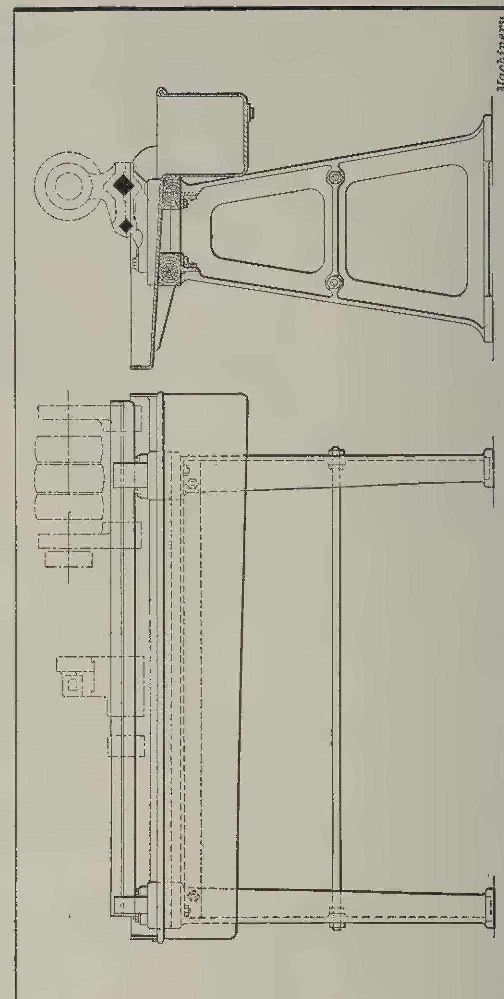

Fig. 15. Double-bar Type of Lathe as built by Brenot, Buronfosse & Cie., Paris, France

to extend around the entire bed. A more elaborate design is illustrated in Fig. 12, in which the tray is of ample capacity. An addition is sometimes made in the shape of sloping guards

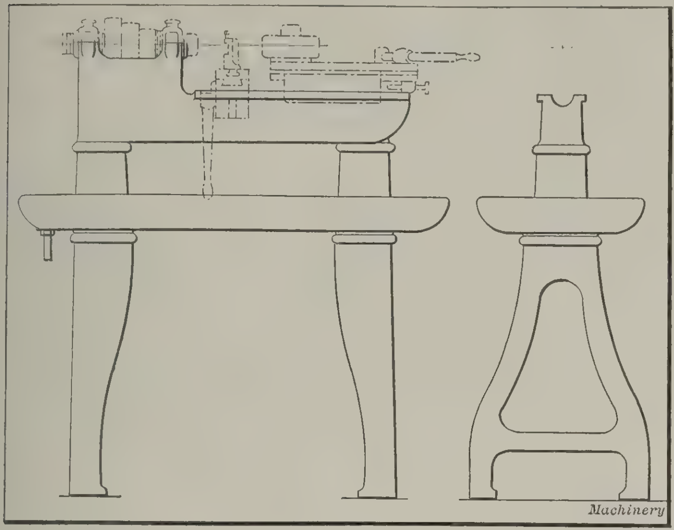

Fig. 16. Turret Lathe Bed with Head cast Solid with it

or oil catchers hung on the rim, not only at the front and the rear, but also at the ends. Single-standard beds, Fig. 13, are fitted in the manner shown, and for lathes of a size suitable for this design, are admirably adapted as regards steadiness and convenience.

The practice of casting the headstock in one piece with the bed is becoming more and more common both in ordinary lathes and in those of the turret type. It is not always cheaper than to make the head separately and bolt it on, but it may be so if quantities of similar beds are cast. In this case the machining will be cheaper also, provided there are proper facilities for dealing with the work. The principal idea, however is to gain greater rigidity and strength and consequent freedom from vibration. By carrying the webs up between the two bearings, as in Fig. 16, the two bearings are firmly tied together. This design is adopted largely in high-speed lathes with all-geared heads, the webbing extending up from the bed to form the lower half of the gear guards. There is then an opportunity of coring out a cavity large enough to receive big cone pulleys or gears, which could not be done if the head were made separately.

As a contrast to the foregoing examples, Fig. 15 seems like a reversion to primitive construction; this is the Brenot, Buronfosse & Cie screw-making lathe, with the two steel bars for a bed, illustrated in a previous installment. These bars are clamped in brackets at both ends; the brackets are supported on wooden bearers resting on A-shaped legs, tied together with distance bolts. The tray and tank are of galvanized plate.

A neat design of bed and head for a small lathe is shown in Fig. 17, cast with the tray for tools around it. Fig. 18 shows the bed used in some of the German Pittler turret lathes which are supported on a single box base arranged as shown with a strainer and trough for the lubricant and a receptacle for tools, etc. The cross-sectional view shows the jointing of the bed on the standard, and the section of the ways, which carry the turret saddle on vees. The dotted circle indicates the diameter of the vertical turret.

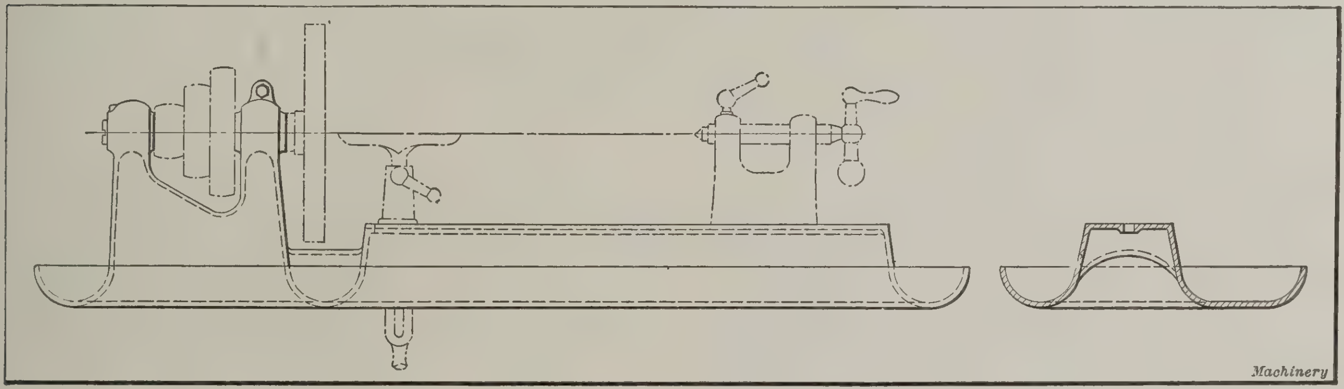

Fig. 17. Bed for Small Lathe with Head and Oil Pan cast Solid with it

Beds for lathes of large size embody the general principles which have been stated, but they are subject to a number of modifications which are not met with in those of medium and small size. Supporting legs are necessarily absent, the under side of the bed resting on its foundations for its whole length. Joints in the longitudinal direction as well as in the cross direction become necessary on account of convenience in casting, machining or transportation. Gaps or pits are

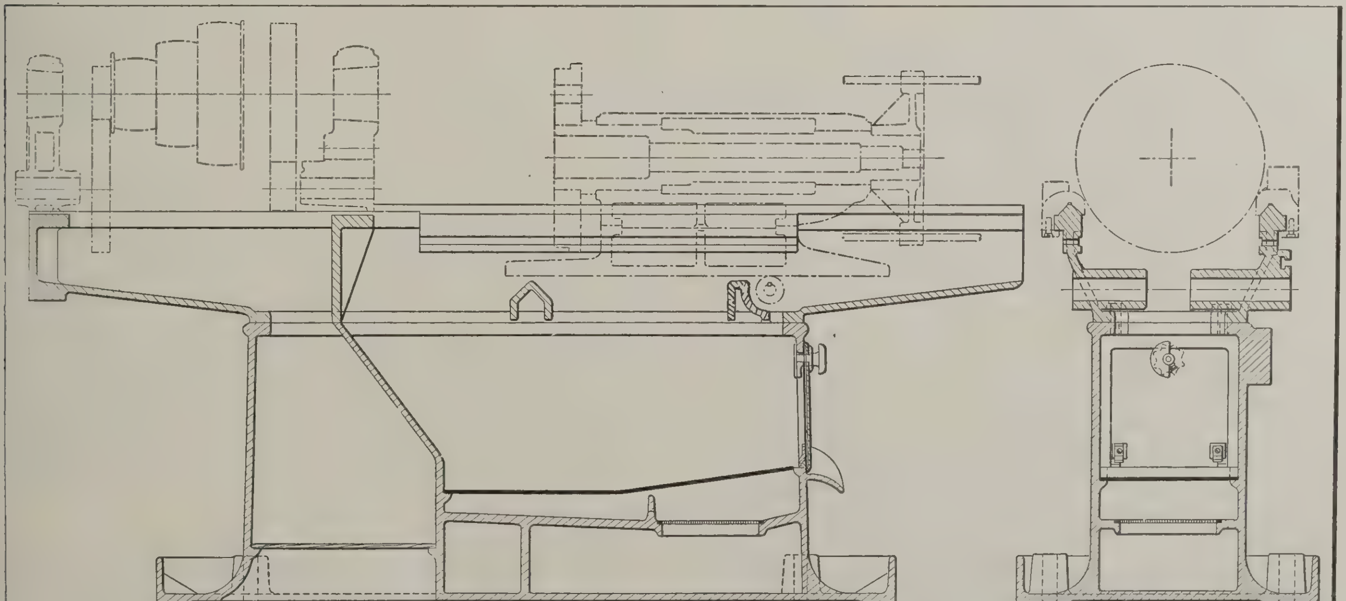

Fig. 18. Bed for the Pittler Turret Lathe as built by the Leipziger Werkzeug-maschinenfabrik, Leipzig-Wahren, Germany

used for lathes required for swinging large diameters, and sometimes the head is independent of the bed, except that it is mounted on the same foundation, that is, the cast-iron bed is not continuous. In some facing lathes the bed does not extend in the longitudinal direction, but comprises merely a support for the slide-rest. The slide movements are obtained only from the rests, and not from the bed. Sometimes the

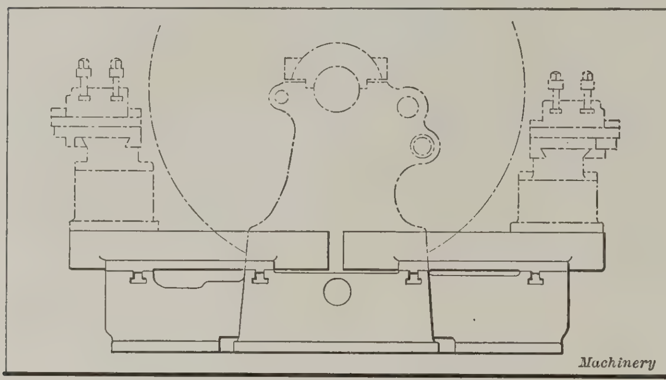

Fig. 19. End View of Bed for Wheel Lathe

longitudinal extension of the bed from the headstock carries only a tailstock or a boring head, and the rests are supported on wings extending toward front and back. In the sliding-gap lathes there is a pillar or pillars on the wings extending out from the front of the gap to carry rests, in addition to the regular saddle on the slide bed.

Figs. 19 and 20 show a bed for a wheel turning and boring lathe which has supplementary extensions to receive the four

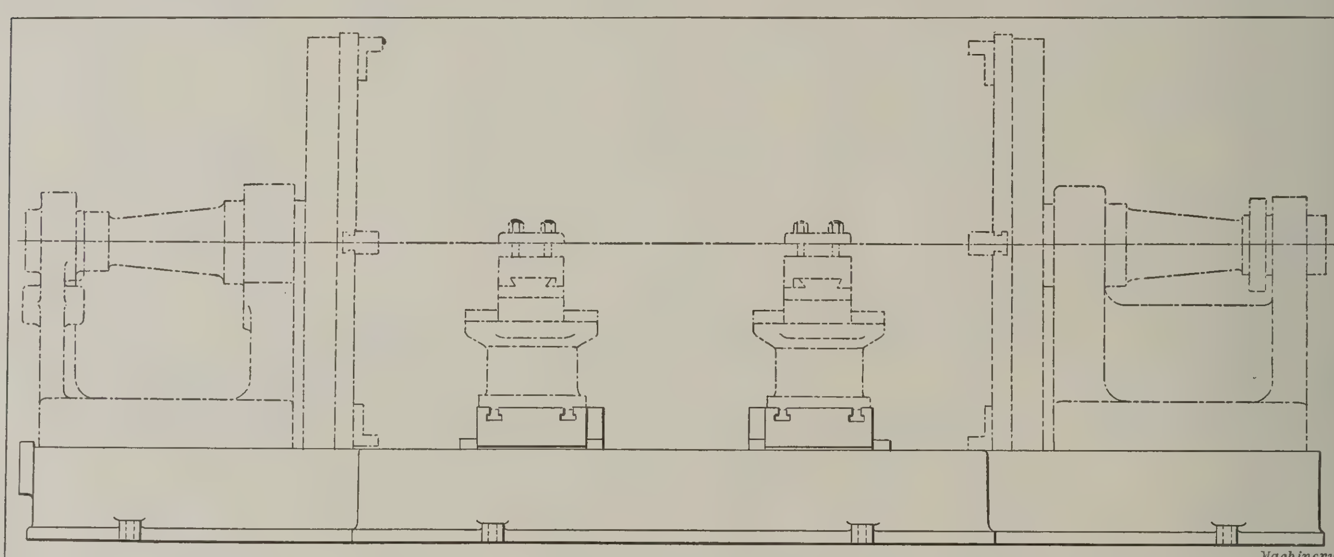

Fig. 20. Bed for Wheel Lathe

slide beds that carry the saddles. These beds are adjusted independently on the main bed; this is typical of a great many beds for different kinds of lathes.

Fig. 3 illustrates a built-up bed, with curved ribbing underneath, and a slide bed for carrying the tailstock and the saddle. The extension plate at the front carries the saddle of the rest for turning large work.

* * *

The laws passed by the legislatures of several states prohibiting the use of common drinking cups have created a large demand for collapsible and other forms of individual cups. Paper cups coated with paraffine are dispensed by automatic vending machines, the common cost being one cent each. But in many places it is not feasible to charge, although necessary to provide the sanitary cups. In order to provide for free distribution the cups must be made very cheaply. Automatic machinery has been developed which forms cups from paper disks, crimping the sides and forming a curved edge and coating them with paraffine at the rate of sixty a minute. The cups are packed automatically in cartons and human hands do not touch them at any stage of the manufacture. These cups are sold in sealed boxes containing ten for family use. at five cents. They are sold much cheaper in quantities to theaters, hotels, clubs, hospitals, etc.

ACTUAL AND CONSTRUCTIVE PATENT INFRINGEMENT—1

By E. D. SEWALL*

When entering upon the investigation of a subject at a point in its advanced development, there is a chance that one may reach erroneous conclusions by overlooking some fundamentals amid the intricacies of detail. It is well, therefore, to revert to the primer of patent law in seeking to discover what infringement of a patent is.

The Constitution authorizes Congress to secure for limited times to inventors the exclusive right to their discoveries. As ideas are not susceptible of exclusion from the apprehension of men who chance to perceive them, and as notions of natural justice do not admit of restraining the individual from putting the ideas he receives to innocent use, the exclusive right to a discovery can be secured only by affording inventors the aid of the public force to restrain all others over whom its authority extends from making practical use of the inventor's ideas.

This provision of the Constitution, Congress has sought to carry into effect by enacting that the patent right shall be conferred upon any person who has invented or discovered any new and useful art, machine, manufacture or composition of matter, under certain conditions, among others that he shall disclose clearly in writing the nature of his invention, and shall particularly point out and distinctly claim the part, improvement or combination which he claims as his invention or discovery; thereupon the government shall grant to him this right by an instrument under seal known as letters patent, for the term of seventeen years. (Sections 4886 and 4888, U. S. R. S.) This right, which does not exist except as created by statute, having been granted, becomes personal property, like other incorporeal chattels, except that, not being a common law right, it is not enforceable at common law, but only by enactment of the power that created it. Therefore, violations of the patent right, Congress has enacted, shall be remedied in the District Courts of the United States in the first instance, with appeal to the Circuit Courts of Appeal, and, in certain eventualities, in the Supreme Court of the United States, on *certiorari*. Damages for the infringement of any patent may be recovered by action on the case in the name of the owner of the patent; or injunctions may be had according to the course and principles of courts of equity, to prevent the violation of any right secured by a patent.

Nature of Patent Rights

The right secured by a patent, then, is an incorporeal right—a right of action in the U. S. courts to restrain others from making profitable use of the invention without the owner's consent, or for recovering damages for unauthorized use. It extends no further. All other rights in the property that may result from the invention remain to be adjudicated in the same manner as if this right created by Congress did not exist.

* Address: 2106 F St., N.W., Washington, D. C.

Of the nature of a patent right, the Supreme Court of the United States has thus spoken:

"Whenever this court has had occasion to speak, it has decided that an inventor receives from a patent the right to exclude others from its use for the time prescribed in the statute." (Marshall, C. J., Grant vs. Raymond, 6 Peters, 243.)

"The franchise which the patent grants consists altogether in the right to exclude every one from making, using or vending the thing patented, without the permission of the patentee. This is all he obtains from the patent." (Taney, C. J., Bloomer vs. McQuewan, 14 How., 539.)

"The right to sell [the patented manufacture] was not derived from the letters patent, but it existed and could have been exercised before they were issued, unless it was prohibited by valid local legislation. All which they primarily secure is the exclusive right in the discovery. That is an incorporeal right, or in the language of Lord Mansfield 'a property in a notion having no corporeal tangible existence.'" (Harlan, J., Patterson vs. Kentucky, 97 U. S., 501.)

"Congress by its legislation made in pursuance of the Constitution has guaranteed to him [the patentee] an exclusive right to it [the invention] for a limited term; and the purpose of the patent is to protect him in this monopoly, not to give him a use which save for the patent he did not have before, but only to separate to him an exclusive use." (Brewer, J., U. S. vs. Bell Telephone Co., 167 U. S., 224.)

Thus Mr. Justice Miller before elevation to the Supreme Court:

"It is to be observed that no constitutional or statutory provision of the United States was or ever has been necessary to the right of any person to make an invention, discovery, or machine, or to use it when made, or to sell it to some one else. Such right has always existed and would exist now if all patent laws were repealed. It is a right which may be called a natural right, and which so far as it may be regulated by law belongs to ordinary municipal legislation, and it is unaffected by anything in the Constitution or patent laws of the United States." (*In re* Brosnahan, 18 Fed. Rep., 62.)

Proper Tribunals for Cases Involving Patented Articles

Remedies for wrongs against patented property, then, may be had by the same procedure and in the same tribunals as remedies for wrongs against unpatented property; but wrongs against the "property in the notion," the right of exclusion, which is an artificial right created by Congress, may be remedied only in the way and by the tribunals designated by Congress. When one patents an invention, he has all the rights and remedies respecting the invention that he had before, and when these rights are invaded his remedy is at common law or equity; but when the government grants the patent, it undertakes, figuratively, to police the industrial territory reserved to him, by preventing others from making, selling and using the patented product without his consent. If no one else attempts to make, use or sell the patented product, the benefits derived from the invention are not augmented by reason of the patent, and wrongs to the property of the inventor may be redressed by the ordinary machinery of the law; but when others seek without authority to make, use and sell that product, thus encroaching upon the reserved territory, the government steps forward and, as it were, ejects them.

A patent right is inconsistent with the natural rights of individuals. It often denies to others the common right of utilizing the products of their independent inventions. Hence, as the patent law confers a privilege that is in derogation of natural right, it should be invoked only to enforce the right that it creates, namely, to restrain others from making, using, and vending without the patentee's consent that which the claim of the patent defines as the thing patented. "The taking away of rights is not favored by the law. Therefore, statutes in derogation of common right are in the construction kept within their express provisions." (Bishop on Written Laws, Sec. 19.)

There is therefore a distinct kind of property in the patent right, injuries to which will be remedied by the U. S. courts in a patent suit; and another distinct kind of property in the industrial process or product to which the patent right pertains, injuries to which will be remedied in the state or other courts wherein violations of rights relating to personal property generally are adjudicated. Each of these two kinds of property rights should be adjudicated in the particular tribunals provided and under the particular laws relating to them respectively, lest there be danger of confusing the two rights, and a failure of justice by reason of the application, to one right, of the law that was designed to have application solely to the other.

Infringement of Patents

Infringement, generally, is a violation of a legal right. Infringement, in the language of the patent law, is a violation of the patent right only, and the term is not appropriate, in speaking of patents, to an invasion of those rights which the patentee has aside from the patent. The only persons whose rights can be infringed under the patent law are the owners of the whole or a part of the patent; they are the patentees, and no one else may bring an action for infringement. The owner may be the inventor, or one or more persons to whom he has assigned the patent. A purchaser or lessee of a patented article, or one who has a permission to make, use and vend the patented thing, owns no interest in the patent, and has no power to sue for infringement.

Infringement of a patent right consists usually in making the thing patented without the consent of the patentee, and in selling or using a thing so made, or in so using a patented process. The thing patented is that which is defined in the claims. The claims measure the invention. "As the inventor is required to enumerate the elements of his claim, no one is an infringer unless he uses all the elements." (Cimriotti Unhairing Co. vs. American Fur Co., Day, J., 198 U. S., 399.) If one makes, uses or vends without permission the exact combination claimed in a valid patent, he infringes the patent; also, if without authority he makes, uses or vends that which contains as a part thereof the exact combination claimed; but if he takes only a part of that combination, he is not an infringer.

Contributory Infringement

There is, however, a wrong to patentees known in the patent law as contributory infringement. Prior to 1896 the text books and legal precedents taught that contributory infringement consisted in conspiring with another, or abetting or wilfully aiding another, to make, use or vend an instrument, or to use a process defined in the claims of a valid patent without permission from the patentee.

"An infringement of a patent is a tort analogous to trespass or trespass on the case. From the earliest times all who take part in a trespass either by actual participation therein or by aiding and abetting it, have been held to be jointly and severally liable for the injury inflicted. There must be some sort of concert of action between him who does the injury and him who is charged with aiding and abetting, before the latter can be held liable. When that is present, however, the joint liability of both the principal and the accomplice has been invariably enforced." (Thomson-Houston Co. *vs.* Ohio, 80 F. R., 712, Taft, J.)

Necessarily, an act of contributory infringement presupposes an act of principal infringement by another. One may become liable for contributory infringement by assisting in constructing or renewing a patented combination, by furnishing to one who has no authority from the patentee some of the necessary parts with intent that they shall form a part of the infringing thing. These parts may be common, unpatentable things of general utility, or they may have no known use except in the patented combination. If the parts are of general utility, the person furnishing them must be proven to have had knowledge that they were to be used in constructing the patented thing, otherwise he is no infringer. (Snyder *vs.* Bunnell, 29 F. R., 47; Bliss *vs.* Merrill, 33 F. R., 39.) If they have no use except in the patented combination, the infringing purpose of the person furnishing them will be presumed, and he will be deemed a contributory infringer without other proof. (Wallace *vs.* Holmes, 9 Blatch., 65; Thomson-Houston Co. *vs.* Ohio, *supra;* Alabastine Co. *vs.* Payne, 27 F. R., 559; Leeds & Catlin Co. *vs.* Victor Talking Machine Co., 213 U. S., 318, McKenna, J.)

The law of contributory infringement, in substantially the circumstances noted above, must be deemed to be settled, since the U. S. Supreme Court has upheld it in the talking machine case above cited, wherein defendant, charged with making nonpatented record disks of a kind particularly adapted to be used as a part of a patented combination comprising the record disk and a reproducing stylus in defined relation thereto, was held to be a contributory infringer. In the opinion it was said:

"A combination is a composition of elements . . . It is, however, the combination that is the invention, and is as much a unit in contemplation of law as a single or non-composite instrument. Whoever uses it without permission is an infringer of it. Whoever contributes to such use is an infringer of it . . . It can make no difference as to the infringement or non-infringement of a combination that one of its elements or all of its elements are unpatented."

Complicated Questions of Contributory Infringement

Although the law as above set forth is believed to be just, yet nice discrimination is often required to avoid stretching the law to restrict the common right of freedom of trade. Shall not only he who purposely makes and supplies the record disk to be assembled by an infringer with the motor and stylus to make a patented instrument, be liable as a contributor to the infringing act, but also he who furnishes the raw materials with knowledge that they are to be used to make such record disks?

Not only may infringement by a principal infringer be aided by one supplying necessary parts of the patented thing, but also by one providing an instrument with the purpose that it shall be used in practising a patented process without the consent of the patentee. Thus where a filter was furnished with the intent that it should be used in carrying out a patented process of filtering beer without the patentee's consent, and it was so used, the one furnishing the filter was held liable for contributory infringement of the process. (Loew Filter Co. *vs.* German-American Filter Co., 107 F. R., 949.) In such a case it must affirmatively appear that the one furnishing the instrument was knowingly a direct accomplice of the principal infringer, and the question is to be decided upon the particular facts of the case, for it cannot be deemed settled that the seller of a common mechanic's tool is guilty of infringement because he knows it is to be used in aiding to practise a patented process.

Case of the Commercial Acetylene Co. vs. Autolux Co.

One may also become liable as a contributor by supplying to a principal infringer an instrument adapted to aid in making a patented article. Here also the liability of him who supplies the instrument depends upon proof of intent to aid the principal in invading the patent right; and the circumstances that the instrument is a common one of general utility, or on the other hand of utility only in the manufacture of the patented product, may have effect one way or another on the liability of him charged as an accomplice. In the case of Commercial Acetylene Co., *et al.*, *vs.* Autolux Co., 181 F. R., 387, the complainants were the owners of patents granted to Claude and Hess for a package containing acetylene gas. Among the claims of the patents is the following: "A gas package comprising a holder or tight vessel; a contained charge of acetone; a volume or body of gas dissolved by and compressed and contained within the solvent, and a reducing valve applied to an opening extending to the interior of the holder above the level of the solvent." The invention was one of great commercial value. It provided a solution of the problem of safely storing acetylene in large or small quantities in condition for use as desired. The patent was not for a special tank but for a package of gas held under pressure in solution. An exclusive license to make, use and sell this package in the United States had been accorded to the Prest-O-Lite Co.

According to the text of the decision, one of the original officers and stockholders of the Prest-O-Lite Co. severed his relation therewith for the purpose of establishing a plant for the manufacture of an infringing device, and also for recharging the tanks made by the Prest-O-Lite Co. when the gas had been consumed by the individual users. He was actively engaged in committing direct infringing acts until enjoined by an order of the court, on final hearing, from making the infringing device, which was known as the autogas tank, or committing any other infringing act. The party thus enjoined and his associates then organized a new corporation under the name of the Autolux Manufacturing Co. for the purpose of manufacturing an apparatus known as a high pressure generator, which, the court said, had been extensively used in recharging Prest-O-Lite gas packages and other gas tanks used on automobiles.

Now, the Claude and Hess patents contained claims for a receptacle containing gas dissolved in acetone. When the gas had been consumed the combination was destroyed, and whoever again assembled or conspired with another to assemble that combination without the patentee's consent made the patented article and infringed the patent. The receptacle alone was not patentable, but only the receptacle containing the gas in solution. The recharging of the package was as much a making of the patented article as would be the reconstructing of a patented sewing machine, which had been worn out, by taking the unpatentable table, drive wheel, and treadle, and assembling therewith new parts to make a new machine. Although the court made the statement that the generator supplied by defendants was extensively used in recharging Prest-O-Lite *and other gas tanks used on automobiles*, it must have satisfied itself that the maker of these generators intended them to be used in reconstructing Prest-O-Lite gas packages and was guilty as an accomplice of the person who actually procured the recharging of such tanks without the permission of the Prest-O-Lite Co., thus deriving profit by aiding others to do that which the patent reserved to the patentees and their assigns and licensees.

The fact, assumed to have been proven, that the defendant company actively and directly assisted others in reproducing a patented article, was one ground of the decision in the Prest-O-Lite case, and appears to be in accordance with the long established principles of contributory infringement. Another ground of the decision is based upon a more recent extension of the doctrine, to be referred to later.

Summary

It appears, therefore, to be settled that not only he who makes, uses and sells a patented thing without permission from the patentee infringes the patent and may be sued under the patent laws, but also he who actively and knowingly assists in the unauthorized making of a patented thing; and probably also that he who actively and knowingly assists another person in selling or using a patented thing that has come into the possession of that other person *against the permission of the patentee* may be likewise liable under the patent laws. The fact that not all acts that aid more or less directly or indirectly in infringement by another can be deemed to be acts of contributory infringement does not affect in any way the point under consideration, which is that such acts as invade the *patent right* only, raise any question under the patent law. If the allegations of fact are that the act complained of invades the monopoly—narrows the reserved market of the patentee by aiding in the unauthorized manufacture, sale and use of the thing patented, and which the patent reserved to him—the case made is one to be tried under the patent law, because the common law and laws of the states make no provision for property in a right to restrain others from making and dealing in useful commodities, but only the patent laws.

Thus far it has been sought to show, no doubt with some repetition, what right a patent confers, when it is infringed, and where the remedy for infringement lies. It has also been asserted that rights regarding patented property which do not bring into question the patent right to exclude others, have the same adequate remedies under general law as other property rights, and it has been intimated that the adjudication of the one kind of right in the courts provided for adjudicating the other, or the attempt so to do, may result in the inappropriate or inadequate remedy, or none at all.

The Questions to be Decided in a Patent Case

Very briefly may be discussed the tests that may be applied to determine whether an alleged injury to a patentee's rights is an infringement of the patent right. A charge of infringement of a patent puts in issue either (1) the title of the patentee; (2) the validity of the patent; or (3) the identity of the alleged infringing product or process with that claimed in the patent. One charged with infringement may defend by (1) denying the validity of the patent; (2) denying the title of the patentee; (3) denying the identity of the thing alleged to be made, sold or used by him with that defined in the claims of the patent. If, on the other hand, the alleged infringer concedes all these, but alleges an agreement with the patentee or his nominee whereby he was permitted to use the

patented thing, a question of contract is raised out of the violation of which the wrong to the patentee, if any there be, proceeds, and which the ordinary law of contract is adapted to remedy. (Wilson *vs.* Sanford, above; Dale Tile Co. *vs.* Hyatt, 125 U. S., 46, Gray, J.)

If one surreptitiously destroys a patented still, because he deems the manufacturer of alcoholic liquor immoral, he does not thereby deny the title of the patentee, the validity of the patent, nor the identity of the still destroyed with that which is patented. The wrong complained of raises a question for the ordinary criminal law to deal with. So, if the patentee of a butter substitute seeks to sell it in a state the laws of which make the sale of a butter substitute of that character a penal offense, the action of the state in preventing the sale thereof is not a denial of the title of the patentee, the validity of the patent, nor the identity of the substance sold with the patented substance, but is a criminal prosecution and one in which the validity of the laws of the state may be put in issue. (*In re* Brosnahan, above; Patterson *vs.* Kentucky, above; Webber *vs.* Virginia, 103 U. S., 344, Field, J.)

If a patentee makes a shipment of patented articles and they become damaged *en route* by the fault of the common carrier or his agents, no question of title, validity of the patent, or identity arises, the injury being a simple tort cognizable in the state courts, or in the federal courts solely on the ground of amount involved, diversity of citizenship, or interstate commerce. If a patentee of a useful article makes a contract with a manufacturer of an inferior article having a similar use, whereby the patentee agrees for a money consideration not to place his article on the market, or license others so to do within the state wherein the manufacturer of the inferior article is situated, no question affecting the validity, ownership or scope of the patent is raised, and the patent law has no dominating influence such as would prevent the courts of the state holding the contract to be one in restraint of trade, and imposing penalties accordingly. (Blount Mfg. Co., *vs.* Yale-Towne Mfg. Co., 166 F. R., 555.)

[The Supreme Court of the United States handed down a decision March 11 which apparently will have far-reaching consequences in furthering monopolistic control of patented apparatus by the makers. By a decision of four to three it was held that the maker of the Dick patented rotary mimeograph machine has the right to restrict the use of the machine to the supplies furnished by the maker. Chief Justice White in the dissenting opinion pointed out how dangerous the decision may be:

"My reluctance to dissent, is overcome in this case: First, because the ruling now made has a much wider scope than the mere parties to this record, since, in my opinion, the effect of the ruling is to destroy in a very large measure the judicial authority of the states by unwarrantedly extending the Federal judicial power.

"Second, because the result just stated, by the inevitable development of the principle announced, may not be confined to sporadic or isolated cases, but will be as broad as society itself, affecting a multitude of people and capable of operation upon every conceivable subject of human contract, interest, or activity, however intensely local or exclusively within state authority they otherwise might be.

"Third, because the gravity of these consequences which would ordinarily arise from such a result would be greatly aggravated by the ruling now made, since the ruling not only vastly extends the Federal judicial power as above stated, but as to all the innumerable subjects to which the ruling may be made to apply, makes it the duty of the courts of the United States to test the rights and obligations of the parties not by the general law of the land, in accord with the conformity act, but by the provisions of the patent law, even although the subject considered may not be within the embrace of that law, thus disregarding the state law, overthrowing, it may be, the settled public policy of the state and injuriously affecting a multitude of persons."

In view of the gravity of the decision which was made by four out of seven judges, whereas a full court consists of nine judges, the effort probably will be made to have a rehearing of the case before a full bench. It is generally conceded that the decision may lead to the creation of monopolies of the most oppressive sort.—EDITOR.]

To furnish good lockers is the duty of the institution—to take good care of them is the duty of the men using them.

BRASS ENGRAVING BY MACHINERY

By CHESTER L. LUCAS*

Among the many operations now being done by machinery instead of by hand, the engraving of brass signs and plates is of more than passing interest. The old way of making brass signs was to chip out the letters by hand, the quality of the work depending wholly upon the skill of the workman. Naturally the progress was very slow. At the present time many brass signs are etched, and a considerable number are cut by machinery. Another large field for brass engraving by machinery is in the making of printing plates for printing wooden box-sides. Not only has the introduction of engraving machinery resulted in faster work, but it has made it possible to do this work without the employment of skilled engravers.

Fig. 2 shows a Wesel routing machine in use at the Schwerdtle Stamp Co., in Bridgeport, Conn. The machine is shown at work on a brass sign, the work being more clearly

Fig. 1. Brass Dies for Bookbinders' Use and Cutters used for Engraving

shown in Fig. 3. The most essential features of a machine of this kind are that straight cuts can be quickly made either vertically or horizontally; that the cutter spindle rotates at a high speed without vibration; and that the cutter can be easily moved to any part of the work, there still being no play between the connecting joints. In this machine, a pulley on the vertical driving shaft transmits motion to the two-step cone pulley *A*. This pulley is mounted upon the swinging arm *B*, and its position is adjustable to allow for slight variations in belt lengths. From the adjustable slide *C* a second arm extends at right angles to arm *B;* this second arm is free to swing in the same plane as the first arm, and at its extreme end the cutter spindle is mounted.

The cutter spindle and adjacent parts are shown on a larger scale in Fig. 3. The cutter spindle (*D* in Fig. 3) receives its motion from the belt that passes over pulley *E*. This pulley is located at the center of the cutter spindle, thus equalizing the pull on the bearings. As the spindle revolves at the rate of 16,000 R. P. M., it is essential that the bearings should be good. The cutter *F*, or "bit," as it is called, is held in the end of the spindle. Just above it is a small aluminum fan *G* that blows the chips away from the cutter, leaving the lines to be followed in plain sight.

It will be noticed that the cutter spindle is mounted in a slide *H* that may be raised or lowered to accommodate thick or thin plates, or long or short cutters. This slide is operated by means of screw *I*. To supply artificial light, when needed, the two incandescent lights are provided; the use of two lights, on opposite sides of the cutter, eliminates

* Associate Editor of MACHINERY.

the shadows. The cutter-head is supported by means of a bar *K*, resting upon a small grooved roll on rail *L*, Fig. 2. By means of hand-rod *M*, the cutter is moved to and from the operator to make the perpendicular lines of the letters, and by moving bar *K* along the rail, the horizontal cuts are made. A bracket that is hidden by pulley *A* guides the horizontal movements of the cutter. Handwheel *N* is tight-

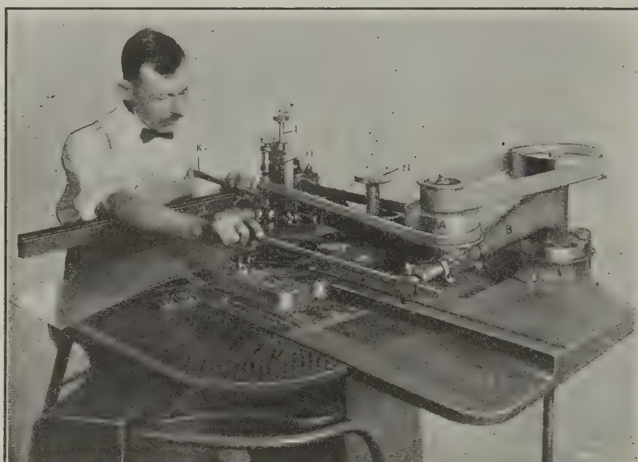

Fig. 2. Wesel Routing Machine at Work on a Brass Sign

ened only when the routing machine is used as a radial arm machine, in which case cuts may be made in any direction.

The cutter-head is raised by a foot treadle when necessary to jump from one letter to another, and the machine is started and stopped by another foot treadle. The work is held in place by clamping jaws, one of which is shown at *O*. This jaw is movable, and is tightened against the edge of the plate by handwheel *P*.

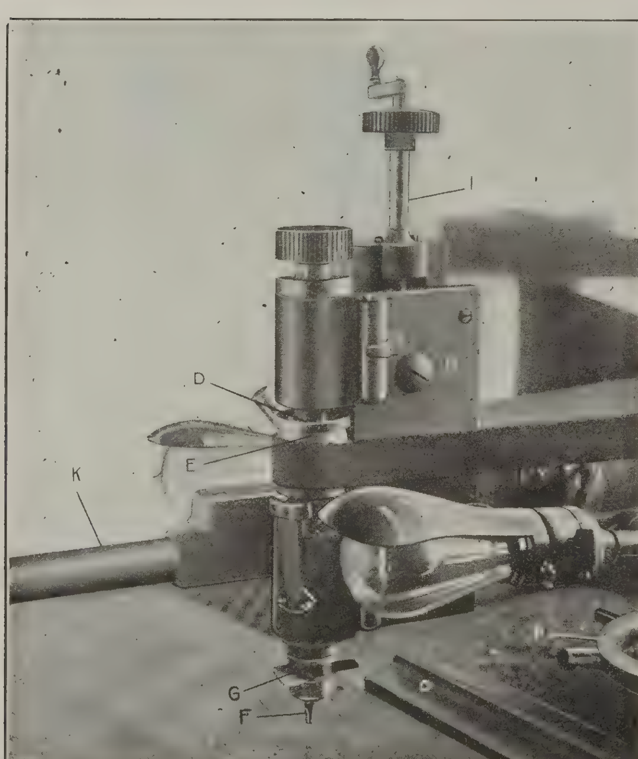

Fig. 3. Cutter-head at Close Range

The work of an engraving machine is not confined to large signs and plates, but is also utilized in getting out brass dies for bookbinders' use, similar to those shown in Fig. 1. It is impossible to finish completely such work as these dies on the machine, but the bulk of the metal in and around the design may be removed to good advantage. Some of the cutters used on this class of work are also shown in this illustration, most of them being of the one-lip variety, as this style of cutter is strong and has plenty of chip-room.

On work of this nature, the skilled engraver is still required to finish up the work, truing up the lines and cutting the parts that it is impossible to finish on the machine. Engravers' tools of various shapes are used for this part of the work. Fig. 4 shows an engraver, Mr. Louis F. Schwerdtle, finishing up brass dies. The work is held in a ball vise, made especially for engravers' use. Two jaws *B*, which swivel, are mounted upon the secondary jaws *C*. The jaws *B* contain numerous small holes in which pins may be placed to grip the work. These pins are usually shaped so as to grip the work without marring it. The secondary jaws *C* are located and held in place by large dowel pins upon the primary jaws *D*, which latter are operated by the right- and left-hand screw *E*, working in base *F*. It will be seen that this

Fig. 4. Finish-engraving Small Dies*

vise is doubly useful, for when not in use on small work, as shown, the vise may be utilized on large die work, by simply pulling off the secondary jaws *C*, which allows the primary jaws *D* to be used independently.

BOILING POINT OF METALS

In a paper presented at a meeting of the Faraday Society, London, England, Mr. H. Greenwood gave the boiling point of various metals at atmospheric pressure, as follows:

	Degrees F.
Antimony	2625
Bismuth	2550
Copper	4200
Lead	2775
Magnesium	2050
Silver	3500
Tin	4125
Aluminum	3250
Chromium	4000
Iron	4450
Manganese	3450

* * *

ARMOR PLATE VS. PROJECTILES

The competition between increased thickness and quality of armor plate versus big guns has come to a point where it is very evident that the big gun is victorious. The armor carried by battleships of the Dreadnaught type cannot prevail against the latest guns carried by the same ships. The latest guns made by the British navy and used on the *Orion* and the *Lion* fire a 1250-pound projectile. When it is remembered that an 850-pound projectile will pierce 17 inches of the best Krupp steel, it is evident that only an excessively thick armor would insure a vessel against the attacks of these new heavy guns. It, therefore, seems likely that the man-of-war of the future will carry less heavy armor, protection being obtained instead by high speed. This idea, in fact, has been carried out in the British navy in the battle-cruiser *Lion*, in which high speed, heavy guns and light armament has been consistently adhered to throughout the design.

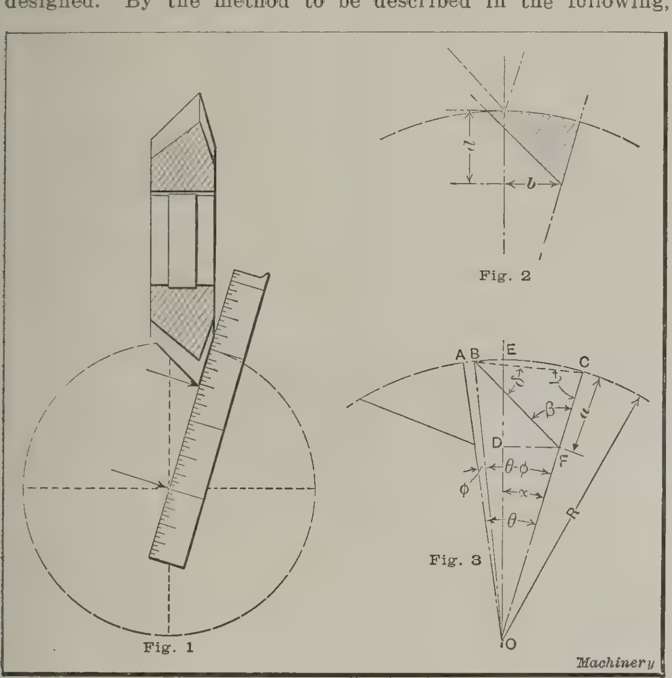
* For a complete description of the engraver's vise see MACHINERY, June, 1909, "Making an Engraving Block."

SETTING DOUBLE-ANGLE FLUTING CUTTERS*†

By GEORGE W. BURLEY‡

The ordinary method of setting double-angle milling cutters when fluting spiral mills and reamers is only an approximate one, and depends entirely upon the skill of the milling machine operator for its success. This method is indicated in Fig. 1. As will be seen from this illustration, two operations have to be performed simultaneously: the cutter has to be so arranged with respect to the center or axis of the blank that the edge of the scale or rule laid alongside the cutter, as shown, passes through the blank-axis, and that the distance from the center to the point of the cutter is a definite amount. This definite amount is a predetermined quantity, and is equal to the difference between the radius of the cutter or reamer to be fluted and the depth of the flute, which, of course, are elements in the design of the cutter or reamer.

It is fairly obvious that errors can readily be made; and it is not inconceivable that angular errors up to 1 degree and linear measurement errors up to 1-64 inch, or even greater, are being continually made. When this is the case, the finished cutters or reamers are not the same as those originally designed. By the method to be described in the following,



Figs. 1 to 3. Finding Formulas for Determining Setting of Double-angle Fluting Cutters

however, it is possible to set the fluting mill with respect to the cutter blank without recourse to the use of a rule, either for the purpose of making linear measurements or obtaining correct angularity. The method involves the setting of the cutter central (that is, with the angular point of the cutter exactly over the axis of the blank) and at a distance from the axis equal to the radius of the blank, as is indicated by the dotted lines in Fig. 2. This is done in the usual way. To get the off-set, the table is moved transversely an amount equal to b (Fig. 2), and raised an amount equal to d. These distances vary considerably, the exact values depending upon the radius of the blank, the number of flutes to be cut in it, the width of land, and the angles of the fluting cutter; but, whatever these distances are, they can be obtained on the machine directly from the micrometer dials on the feed-screws. The values of d and b for any particular case can be calculated in the manner indicated below, or taken directly from the accompanying Data Sheet Supplement.

Let R = the radius of the cutter to be fluted.
N = the number of teeth to be cut in it.
W = the width of the land of the tooth.
θ = the angle subtended at the center of the cutter by any one tooth.
a = the depth of each tooth measured radially.
α = the small side-angle.
β = the included or total angle of the angular fluting cutter.

R is the radius of the finished cutter, and as the blank is invariably left a little large, corrections, as will be indicated later, may have to be made for d, but not for b; usually, it will be found that the correction is a very slight one.

$$\theta = \frac{360}{N} = A\,O\,C \text{ (Fig. 3)};\ E\,O\,C = \alpha, \text{ and } B\,F\,C = \beta.$$

The width of the tooth-land, as usually defined, is measured on the face formed at the back of the cutting edge by the grinding wheel, and it is, therefore, a straight-line quantity, whether the land is formed by a cup-wheel (forming a flat land) or a disk wheel (forming a concave land). This is, therefore, not exactly the quantity $A\,B$ (Fig. 3), measured as an arc of the circle, but the difference between the two is usually so slight as not to be worth consideration from a practical point of view. As a matter of fact, the writer has found that the difference in the most extreme cases amounts to only three or four thousandths inch, an amount which, under the circumstances, is negligible. Hence, in what follows, we shall assume that the actual width of the land and the arc AB are equal. Let the width of the land and, therefore, the length of the arc $A\,B$ be equal to W. Then angle ϕ is the angle subtended by arc W at the center of the circle, and can, therefore, be determined by first calculating the angle in radians or fractions of a radian, and then consulting a table of angles for the equivalent angle in degrees. If no such table is handy or immediately procurable, the angle in degrees can be obtained as follows:

$$\phi \text{ (in degrees)} = \frac{W}{R} \times 57.296 \qquad (1)$$

From this angle and the angle θ, the angle $(\theta - \phi)$ can be obtained. This angle is the one which is subtended at the center of the circle by the chord $B\,C$; therefore,

$$\text{Angle } B\,C\,O = \gamma = \left(90 - \frac{\theta - \phi}{2}\right).$$ The angle $C\,B\,O$ is also equal to this. Hence,

$$\text{Angle } CBF = \delta = 180 - (\beta + \gamma) = 180 - \left(\beta + 90 - \frac{\theta - \phi}{2}\right)$$
$$= 90 - \left(\beta - \frac{\theta - \phi}{2}\right).$$

Let the length of the chord $B\,C = c\,R$, c being the length of the chord of a unit-radius circle which subtends the angle $(\theta - \phi)$ at the center. Then,

$$\frac{c\,R}{\sin\beta} = \frac{a}{\sin\delta}; \text{ therefore,}$$

$$a = \frac{c\,R\sin\delta}{\sin\beta} = \frac{c\,R\sin\left(90 - \beta + \frac{\theta - \phi}{2}\right)}{\sin\beta}$$
$$= \frac{c\,R\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta} \qquad (2)$$

From this expression, assuming any given data, the actual depth a of the flutes to be milled in the cutter blank can be calculated.

$$O\,F = (R - a)$$
$$= R - \frac{c\,R\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta} = R\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}$$

Now, d (Fig. 2) $= E\,D$ (Fig. 3) $= R - O\,D = R - O\,F\cos\alpha$

$$= R - R\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}\cos\alpha \qquad (3)$$

Usually the radius of the cutter or reamer blank is made a

* With Data Sheet Supplement.
† For information on allied subjects, see "Milling Axial Teeth in Cutter and Reamer Blanks," March, 1912, and articles there referred to.
‡ Address: University of Sheffield, Sheffield, England.

little larger (a few thousandths inch) than the finished cutter. Therefore, in actual practice,

$$d = R_1 - R\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}\cos\alpha \qquad (4)$$

where R_1 = the radius of the blank.

For any given values of $\frac{W}{R}$, N, α and β, the expression:

$$\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}\cos\alpha \text{ is a constant.}$$

Let this constant be represented by x; then,

$$d = R_1 - x R. \qquad (5)$$

This is the "elevation" formula, the values of x for a large number of combinations of $\frac{W}{R}$, N, α, and β, occurring in practice being given in the tables in the accompanying Data Sheet. The values of x for any combination not included in the tables can be determined as indicated above, or obtained by interpolation.

Further, b (Fig. 2) $= DF$ (Fig. 3) = the cross-movement required $= OF\sin\alpha = (R - a)\sin\alpha =$

$$R\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}\sin\alpha \qquad (6)$$

Again, for any given combination of $\frac{W}{R}$, N, α, and β, the expression:

$$\left\{1 - \frac{c\cos\left(\beta - \frac{\theta - \phi}{2}\right)}{\sin\beta}\right\}\sin\alpha \text{ is a constant.}$$

Let it be called y. Then $b = yR$. (7)

This is the "cross-movement" formula, the values of y for a large number of combinations being given in the accompanying Data Sheet beside those of x for the same combinations.

In regard to the values of $\frac{W}{R}$ which have been selected, the lower values are those usually chosen for milling cutters of medium and large sizes, the higher values being usually chosen for small cutters and reamers. If the value adopted in any particular design is not found in the tables, a simple calculation is all that is necessary for the determination of the corresponding values of x and y. By way of an illustration, let us suppose that 0.030 has been adopted as the value of $\frac{W}{R}$, and that $N = 20$ teeth, $\alpha = 12$ degrees, and $\beta = 60$ degrees. Then, upon consulting the accompanying tables, we find that when $W \div R = 0.020$, $x = 0.7750$, and $y = 0.1643$, and that when $W \div R = 0.040$, $x = 0.7908$, and $y = 0.1677$. By simple proportion, which in this case is sufficiently accurate, when $W \div R = 0.030$, $x = 0.7829$, and $y = 0.1660$. Therefore for the combination chosen,

$$d = R_1 - 0.7829\,R \text{ and } b = 0.1660\,R.$$

Dealing further with this case, let us assume that $R = 2.5$ inches, and that $R_1 = 2.503$ inches. Then,

$d = 2.503 - (0.7829 \times 2.5) = 2.503 - 1.9572 = 0.5458$ inch, and $b = 2.5 \times 0.1660 = 0.4150$ inch.

If this method of interpolating is not deemed sufficiently accurate, then the values of θ, ϕ, α, β and c can be determined for any particular case and introduced into Formulas (4) and (6). This method is, however, sufficiently accurate for all the ordinary cases that occur in everyday practice.

* * *

Solder which has been exposed to damp air for some time and has become more or less oxidized on the surface will not give as good results as fresh solder.

ROLL PRESSURE AND POWER REQUIRED FOR ROLLING MILLS

In a recent issue of *Stahl und Eisen*, Prof. M. Hermann gives some formulas for obtaining the roll pressure and power required for rolling mills. The *Engineering Digest* gives a summary of these formulas, which apply to the rolling of rectangular sections.

Let A = reduction of sectional areas per pass, in square inches,
k = limiting stress of lateral extension of metal, in pounds per square inch,
t = reduction of thickness of billet per pass, in inches,
D = roll diameter, in inches,
v = velocity of bar leaving rolls, in feet per second,
a = arc of contact of billet with the roll, in degrees.

Then $\cos a = 1 - (t \div D)$, from which $\sin a$ may be found.

Force required to draw billet through the rolls: $F = 2kA$.

Roll pressure in pounds: $P = \dfrac{kA\left(1 + \frac{1 - \cos a}{2}\right)}{\sin a}$

H.P. (exclusive of power required to run rolls empty)

$$= \frac{Fv\left(1.1 + 0.12\frac{P}{F}\right)}{550}$$

The value of k is difficult to determine; it increases with the number of passes, and decreases with increasing temperatures. Prof. Hermann gives a table taken from Puppe's experiments in which k (average) for the fifth to eighth passes ranges from 6940 pounds per square inch at 2237 degrees F., to 10,042 pounds per square inch at 2091 degrees F.; and for the ninth to seventeenth passes from 7965 pounds at 2237 degrees F., to 11,547 pounds at 2091 degrees F.; or the mean value of k for the 12 passes ranges from 7609 pounds at 2237 degrees to 11,265 pounds at 2091 degrees.

Example.—Let $A = 4$ square inches; $k = 8000$ pounds per square inch; $t = 0.75$ inch; $D = 20$ inches; $v = 6$ feet per second.

Then, $\cos a = 1 - (0.75 \div 20) = 0.9625$. Hence $\sin a = 0.2712$. $F = 2 \times 8000 \times 4 = 64{,}000$ pounds.

$$P = \frac{4 \times 8000\left(1 + \frac{1 - 0.9625}{2}\right)}{0.2712} = 120{,}000 \text{ pounds, approximately.}$$

$$\frac{P}{F} = 1.88$$

$$\text{H.P.} = \frac{64{,}000 \times 6\,(1.1 + 0.12 \times 1.88)}{550} = 925, \text{ approximately.}$$

* * *

It has been said of great scientists and engineers that they take nothing for granted and accept nothing as final simply because it has been done in a certain way since time immemorial. The really great engineer sees things as they ought to be rather than as they are, and that is the keynote of his preeminence in his chosen field. John Ericsson was one of those mechanical seers who are constantly at war with the mechanical superstition of their day. No better example could be cited to illustrate the fact that he would take nothing for granted, than a humorous incident from the days of his early childhood. When he was learning his alphabet, the shape of the letters did not suit his fancy and he had very decided opinions of his own about how they ought to be formed. He quickly perceived that the letters were symbols of sounds, and hence of arbitrary origin, and he forthwith proceeded to construct letters of his own design that to his mind possessed certain advantages of simplicity that were lacking in those of the time-honored Latin alphabet.

* * *

The estimate of Portland cement production in 1911, made by the United States Geological Survey, is 77,877,236 barrels. The production in 1910 was 76,549,951 barrels. The average factory price per barrel in 1910 was $0.891, and $0.867 in 1911.

THE TESTING OF SPIRIT LEVELS

By EQUA

In order to be able to produce accurate work on machine tools, it is necessary that they be set up level. Frequently there are complaints of the working of lathes and planers and the manufacturer is blamed for sending out a poor machine, when the real trouble is that certain parts of the machine are under a strain because of not having been set up level. Hence the spirit level is an important part of the equipment used by the machinist when erecting machinery.

The spirit level consists of a glass tube or cylinder, the inside of which is ground to a barrel shape. This tube is nearly filled with spirits of wine, ether, or some similar fluid, and hermetically sealed at each end. It is ordinarily spoken of in the shop as the "bubble," and is mounted in a brass tube having an opening at the top so as to make it possible to see the air space in the bubble or level. The brass tube is fixed to a block of brass or iron with suitable screws, so that it can be adjusted to be parallel to the base surface of this block.

It is readily understood that the chief part of the complete level is the glass tube, and the accuracy of the instrument depends entirely upon the curvature to which the inside of the tube has been ground. The makers of spirit levels use a device called a "level tester" for determining the accuracy of the bubble. A device of this kind is shown in the accompanying engraving, Fig. 1, the principle of the device being simply that upon turning the adjusting screw at one end of the bar or plate, this end is raised or lowered, so that the air space in the level will run from end to end. By means of this testing device it is possible to ascertain the curvature of the interior of the glass tube. The accuracy of a level is defined by saying that so many seconds of arc are equal to one-tenth or one-twentieth inch, etc. It will be seen in Fig. 1 that by turning the screw carrying the graduated disk we raise or lower the bar about the points A as pivots. The action of the screw is not the same as if the bar had worm teeth cut in it and the screw were a worm, but as the screw only has to move the bar through an arc of about two or three degrees, the error resulting from considering the action as that of a true worm and worm-wheel, is negligible. The adjusting screw on the testing device has 100 threads per inch and the graduated disk has 120 divisions. Each division should be equal to an angular movement of the bar about points A of one second. From this the distance from A to B can be determined. As the disk has 120 divisions and each division is equivalent to one second, one revolution of the screw will equal a movement of two minutes of the bar. The movement of the bar, however, is also equal to 0.01 inch for one revolution of the screw, and as there are 21,600 minutes in a complete circle, the total circumference of the circle having point A for a center and the distance AB for radius must be $10,800 \times 0.01 = 108$ inches. This circumference corresponds to a diameter of 34.377 inches and a radius of 17.188 inches, which is then the distance between A and B. It will be seen that for the accuracy of the device it is highly important that this distance be exact.

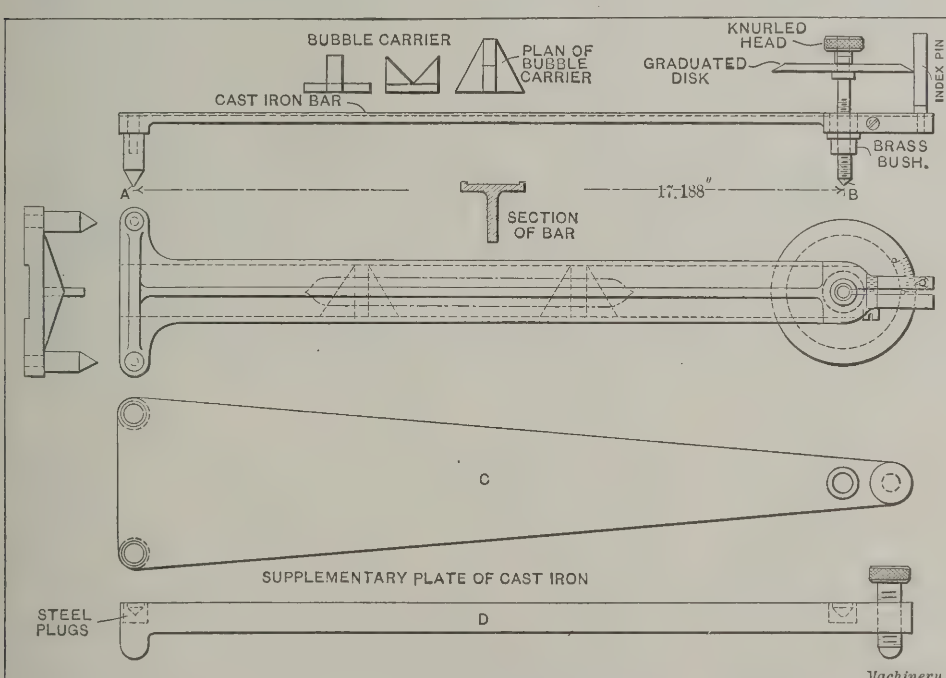


Fig. 1. Device for Testing Spirit Levels

With a first-class testing device a supplementary plate having a screw of coarser pitch than that already mentioned is also provided. This supplementary plate is shown at C and D in Fig. 1. One of the purposes of this plate is to enable the testing device to be quickly adjusted, and another object in view is to test the accuracy of the fine pitch screw. Suppose, for example, that we wish to test the screw. We place a level on the test-bar, set the graduated disk at zero, place the testing device on the supplementary plate, and by means of the coarse screw we bring the air space near the center, carefully noting its location. Then we turn the fine screw half a revolution or 60 divisions and find that the air space has moved, say, 12 divisions. Then by means of the coarse screw we bring the air space carefully back to its first place, and then turn the fine screw another half a revolution or 60 divisions in the same direction and note how much the air space has moved. Should it have moved only 11½ divisions, for example, we know that the lead of the screw or its point is slightly out of true. This test should be carried out over various parts of the screw, and if it is found that one half of a revolution is slightly finer than the other half, there is nothing to do but to take the average of the error and proceed with the calculations on this basis. Of course it is still better to get a new screw, if one that is perfectly correct can be obtained.

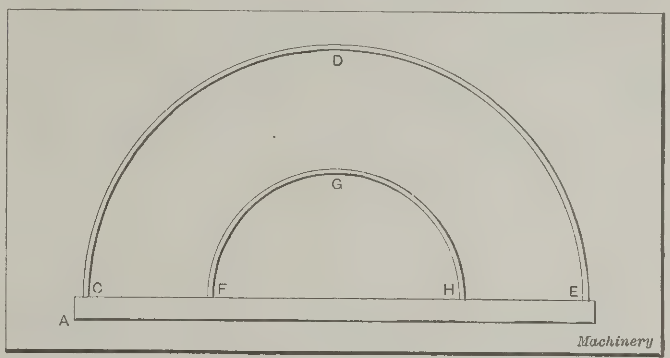

Fig. 2. Diagram illustrating Effect of Curvature on Sensitiveness of Level

When using the testing device it must be placed on a very firm foundation, free from vibration. The level to be tested is placed on the bubble carriers and allowed to come to rest. Should the bubble have been held in the hands just before putting it on the testing device, a few minutes must be allowed for the cooling of the tube and its contents.

The method of testing will be best understood by referring to an actual example. Suppose that the level to be tested is 6 inches long, and that it is divided into tenths of an inch. The three or four last divisions at each end may be ignored, as the level is rarely sealed up without disturbing these divisions. Of the sixty divisions on the level in question, however, fifty-four will be assumed to be serviceable. Assume further that the air space takes up twenty divisions.

The method of testing varies somewhat. Some testers will test every division, while others take the average of four or

five divisions. In this example we will take the average of every five divisions. The air space, at the beginning, is nearly at one end, and we note the lines between which it is located. Now the knurled head of the adjusting screw is carefully turned and the number of divisions on the graduated disk that are required to move the air space five divisions is noted. We find that it takes 60 divisions on the disk for the first five divisions on the level, and 63, 65, 65, 63, 61, 60 and 59 divisions, respectively, for the remaining sets of five divisions each. The average of this is 62 divisions on the graduated disk; therefore each division on the level is equivalent to $62 \div 5 = 12.4$ seconds of arc.

A level that varies more than 5 per cent from the average is spoken of as fair, one that varies 2½ per cent is termed good, and one that varies only ½ per cent is known as first-class. Hence the level tested in this case would be classed as a fair specimen. In making these tests, the temperature plays a considerable part. Nevertheless, a good level should show very little variation in its sensitiveness with a difference in temperature not exceeding 40 to 50 degrees F., although, of course, the air space will vary in length with this difference.

In order to understand how the curvature of the level affects its sensitiveness, it is perhaps best to take an extreme example. In Fig. 2 are shown two glass tubes *CDE* and *FGH*, bent to a semi-circular shape. One has a diameter of 12 feet and the other a diameter of 6 feet. As these tubes represent exactly half a circle, we will have 648,000 seconds of arc. The linear length of the larger tube, in inches, will be $(12 \times 12 \times 3.1416) \div 2 = 226.1952$, and of the smaller, 113.0976. Suppose that we have a girder 13 feet long and capable of being turned about *A* through an angle of 90 degrees. Now place the tubes on the girder, taking care to keep them in an upright position. The air space will be at *D* and *G*. Turn the girder through an angle of 90 degrees and the air space will have run to *E* and *H*, respectively. Now the air spaces in both tubes have run through 90 degrees, but the one in the larger tube has moved 113.0976 inches and that in the smaller tube 56.5488 inches. Thus we would say that the larger tube is twice as sensitive as the smaller, for it will be seen that to move the air space one inch in the larger tube, we need only to turn the tube through one-half the number of degrees required for the smaller tube. Of course in actual practice we never have to deal with tubes of this shape, but the principle is the same.

In all modern work the levels are divided on the outer surface to tenths and twentieths of an inch, except when they are divided according to the metric system. The following table gives the curvature of levels of various sensitiveness, the divisions on the level being in tenths of an inch:

Division of Arc of Circle to Each Graduation	Corresponding Diameter of Curvature of Level in Feet
1 second	3437.73
2 seconds	1718.86
5 seconds	687.54
10 seconds	343.77
20 seconds	171.88
30 seconds	114.59
1 minute	57.29
1 degree	0.954

All levels should be ground, although it often happens in cheaper ones that the glass tube is just bent to the approximate curve. These latter levels are not to be recommended except for work which does not require any particular accuracy.

The value of a division of a level may be found roughly by using a piece of metal about 12½ inches long and wide enough to support the level. Take, for instance, a piece of brass 12½ inches long and file away the lower surface so that it bears on two points exactly 12 inches apart. Put the level to be tried on it, bringing the air space near the center by putting packing under one of the bearing points. Note carefully where the air space is, and then put a feeler gage of 0.002 inch thickness under one of the bearing points of the brass bar. If then the air space runs say 0.1 inch, what is the value in seconds of arc of one division of the level, and what is the curvature to which the level has been ground?

The distance from the bearing point to the feeler gage is 12 inches; this is the radius of a circle whose circumference is 75.3984; hence 75.3984 inch is equivalent to 1,296,000 seconds of arc, and from this we find that 0.002 inch equals 34.3 seconds of arc; or in other words, each 0.1 inch on the level equals 34.3 seconds of arc. To find the curvature, we know that 34.3 is to 1,296,000 as 0.1 is to the total circumference of the curvature circle. Hence:

$$\frac{0.1 \times 1{,}296{,}000}{34.3} = 3749.27 \text{ inches,}$$

which is the circumference of the curvature circle of the level, the diameter being 99.1 feet. This calculation indicates the simplicity of finding the sensitiveness of the level, and further if the user of a level does not know the value of a division on the level, he can by this means ascertain more easily how much out of level a piece of work is that he is setting up.

A good level is one of the most sensitive instruments made, and the utmost care should be exercised when using it. Levels are generally fixed in the brass tubes with plaster of paris. This method is satisfactory for all levels of an accuracy of about 5 seconds to 0.1 inch. For finer levels it will be found best to fix one end only with plaster of paris and the other end with cork, for if the level be fixed rigidly with plaster of paris at both ends, there will be a strain on the level at the extremes of temperatures at which it may be used, and as the coefficients of expansion of glass and brass are different, an inaccuracy is liable to occur. For fine levels it is also best to have an extra glass tube around them in order to prevent the heat of the hand from affecting them. In general practice, the length of the air space is from one-quarter to one-third of the length of the level. A level of 1 minute to 0.1 inch is most serviceable for general use. One having an accuracy of 30 seconds to 0.1 inch must be used on a floor free from vibration, and still finer levels are used mostly on surveying and astronomical instruments.

POSTAGE FOR FOREIGN COUNTRIES

By FINK

As an employe of a European firm which has an extensive correspondence with American manufacturers, the writer has observed that a great many letters from the United States are prepaid with only two cents instead of five cents, which is the regular foreign postage. It is true that letters from the United States to England or Germany need but two cents postage, but for every other European country the postage is five cents. Of course everyone who receives American letters insufficiently prepaid knows that the trouble is due to errors on the part of the clerks having charge of the mailing, but nevertheless, it is not exactly pleasing for the European business man to have to pay for the carelessness of the employes of an American firm, especially as this extra expense in a large house may amount to quite a considerable sum during the year, and this expense, with some attention, could be easily avoided.

The postage required to be paid on the European side is double that which is lacking, so that six cents has to be paid for every letter which is provided with a two-cent instead of a five-cent stamp. The writer feels sure that American manufacturers would regret the condition even more than the receivers of the letters, if they knew that their European customers sometimes pay six cents extra postage for practically every letter sent them. On the other hand, it is true that some firms always prepay the full postage on their letters.

Now I do not doubt that American manufacturers may have had this called to their attention in the past, but it is a matter that is easily overlooked. As a rather amusing incident in this connection, I might mention that I sent a letter similar to this to another highly esteemed mechanical journal in the United States, but my contribution was returned with an explanation that my remarks would not be of interest to the readers of that periodical. However, in spite of the fact that this journal considered my remarks too trivial to be worthy of publication, and that they contained nothing of interest to American manufacturers, the very letter in which my manuscript was returned was prepaid with only two cents instead of five cents, so that I had to pay the extra postage of six cents. I believe that this clearly shows that the matter to which I have called attention is one which American firms in general would do well to give some attention.

FEATURES OF APPRENTICESHIP SYSTEM AT THE G. E. CO.'S LYNN WORKS

By CHESTER L. LUCAS*

The apprenticeship system in vogue at the Lynn Works of the General Electric Co. was described in MACHINERY, in the April and September, 1906, numbers. As the apprentice department has recently moved into a large new building, and as some of the work being done at the present time is especially interesting from a mechanical standpoint, a description of the new quarters, and an outline of some of the work of the apprentices, may, perhaps, prove of interest.

The apprenticeship system, which is under the general supervision of Mr. Magnus W. Alexander, was started in February, 1902, with twelve boys. At the present time there are enrolled over three hundred boys, who have come from all parts of the United States, and even from Canada, to learn to be machinists and toolmakers, patternmakers, iron or brass molders, steam-fitters, etc. Although applicants for this course must be well qualified, educationally as well as physically, and come well recommended, and although the requirements as to home study and class standing are rigorous, there is always a long waiting list of young men who are looking for opportunities to take the course. This condition is due to the fact that it has become well known in mechanical circles that graduates of these courses are qualified to take responsible positions as skilled mechanics or as assistant foremen, and later as foremen and superintendents.

During the past year the apprentice department has moved into a large new building, designated as building No. 40 of the Lynn Works, where a well-lighted and ventilated training room for machinist and toolmaker apprentices is located. This room has over one hundred machine tools. The building also has large and well appointed class-rooms in which instruction is given in arithmetic, algebra, geometry, plane trigonometry, physics, mechanical drawing and tool-design, as well as in English and industrial history. This department occupies a space of 80 by 450 feet. A smaller, but equally well equipped training room for patternmakers is located in the wood-working building. A view of the machine shop is shown in Fig. 1, from which it will be seen that the shop is well appointed, of modern construction, and equipped with the best of machine tools. The General Electric Co. does not believe that "anything is good enough" for an apprentice, and the lathes, shapers and other machine tools are modern in every respect. It is also interesting to note that all machines are motor driven, so that no overhead belts are required.

A trial period of two months must be served by all applicants for positions on the course, after which time, if the applicant is found to be satisfactory and adapted for learning the chosen trade, he is permitted to sign the apprentice agreement. Compensation is paid, even during the trial period, at the rate of eight cents per hour for the first half-year, ten cents for the second half-year, twelve cents for the second year, fourteen cents for the third year, and sixteen and one-half cents for the fourth year. If the four years' work has been satisfactorily completed in every respect, a cash bonus of one hundred dollars is given to the graduate. The courses for molders and steam-fitters, however, are completed at the end of two years, and the rate of compensation is ten cents per hour for the first half-year, twelve cents for the second half-year, and fourteen cents for the second year, and graduates receive a bonus of fifty dollars at the completion of the course.

The company also maintains apprenticeship courses for high-school graduates who, during a three-year period, desire to fit themselves for efficient service as draftsmen, designers, engineers, electrical testers, erection and installation men, or salesmen. Their initial training consists of well supervised machine work in the apprentice training-room. These apprentices receive ten cents per hour for the first half-year, twelve cents for the second half-year, fifteen cents for the second year, and twenty cents for the third year. A bonus of seventy-five dollars is also paid upon completion of the course. The class-room work is of a high order, and a high standard of work is maintained in the shops and testing departments.

Mr. Charles K. Tripp is the superintendent of apprentices and is in charge of all work. The educational feature of the course is a strong attraction to all, and a great deal of attention is given to this side of the work. The educational work is under the direction of Major A. W. Lowe, and a corps of instructors instructs the boys in those subjects that are closely allied to their work. Fig. 2 shows the interior of a class-room. Mr. Tripp is here instructing a class of apprentices in the proper methods of sharpening lathe tools, illustrating on the black-board methods which are right as contrasted with those which are wrong. As will be noticed, the apprentices are provided with pencils and paper in order that they

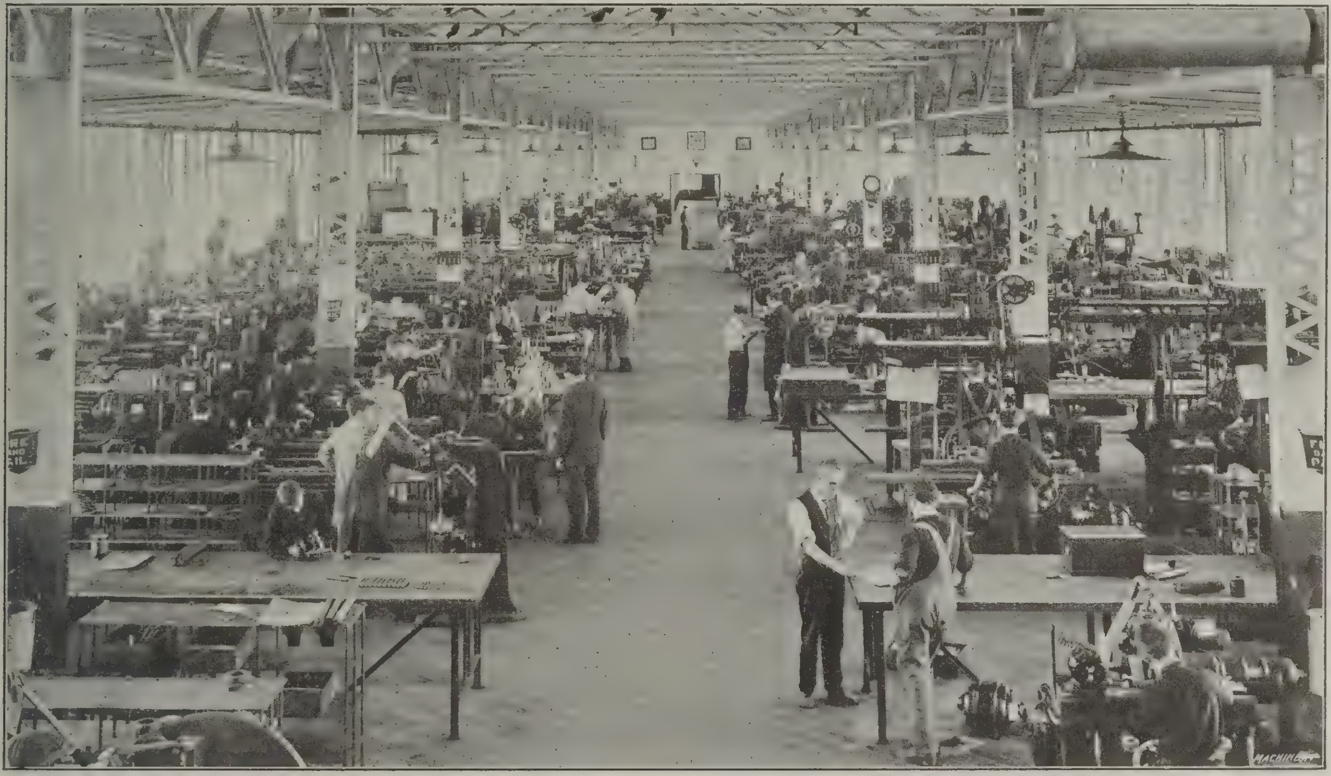

Fig. 1. A View in the New Training-room of the Apprentice Department

* Associate Editor of MACHINERY.

may take notes, for they are expected to remember the points brought out in these lectures when the time comes for their practical application in the shop.

The chief aim of the educational side of this course is to develop proper thinking on the part of the boys, and to familiarize the apprentices with such problems as are apt to come up in their everyday work. Practical examples are always selected to impress upon their mind the value of the information they get. Many boys are dropped from the course on account of their inability to keep up with the class work, this inability being due either to natural dullness or to indifference.

Fig. 2. Another of the Class-rooms with the General Foreman showing Methods of Tool-sharpening

Work done by Apprentices

The following examples are given to convey an idea of the class of work that the apprentices perform in the training-room, before being placed in the various departments of the plant. All of the work described, as well as many of the tools used for doing the work, has been done by apprentices more or less advanced in the course.

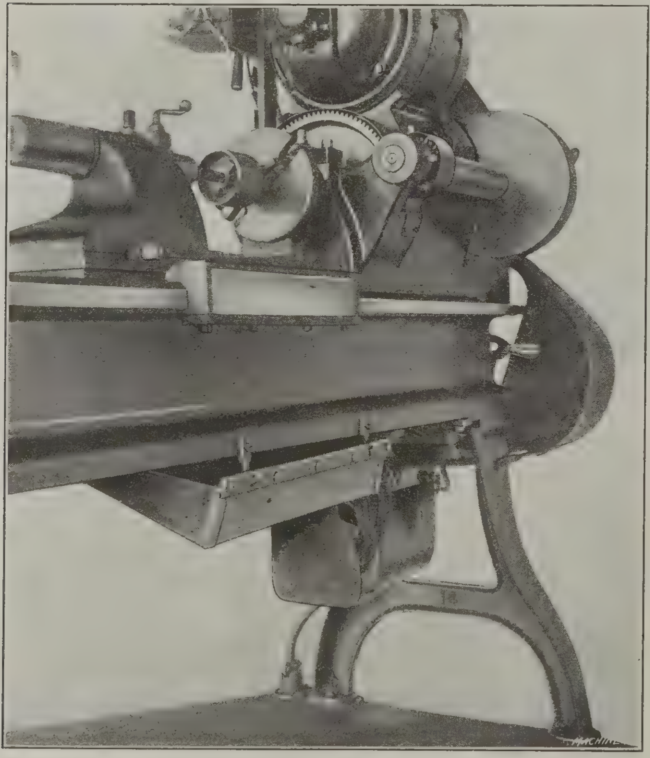

Fig. 4. Chip-pan and Method of attaching to Lathe

T-slotting in the lathe, as shown in Fig. 3, is an unusual operation, but in the apprentice department it is employed to good advantage on turbine work. The piece of work—a turbine valve shown at *A*—is held in a block *B*, bolted directly to the carriage of an old lathe. The cutter *C* is then held in the universal chuck, and a straight slot milled by feeding the cross-slide on to the cutter to the required distance. This operation is followed by inserting T-slotting cutter *D* in the chuck. This cutter mills the bottom of the slot to the proper size and shape. This method has the advantage of cheapness, as it requires only an old lathe instead of a first-class milling machine, and it certainly produces a very good job.

The simple little contrivance shown in Figs. 4 and 5 helps to keep the floors beneath the lathes clear of oil and chips. Fig. 4 shows the pan in position. In cleaning out the pan, it is simply unlatched at the front and allowed to drop, and the chips and oil are caught in a regular dirt pan, as shown in Fig. 5.

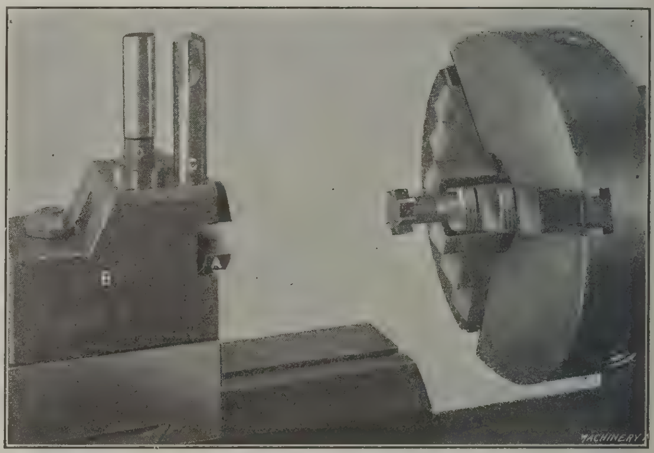

Fig. 3. Using a Lathe for T slotting

A little kink that often proves useful in shops where comparatively little cutting-off is done, is the method of cutting-off short duplicate lengths of round stock on the lathe, as shown in Fig. 6. The solid chuck grips the work, while the other end is supported by the tail-center. The cutting-off, of course, is done with the usual cutting-off tool, and the distance the bar enters the chuck governs the length of the pieces.

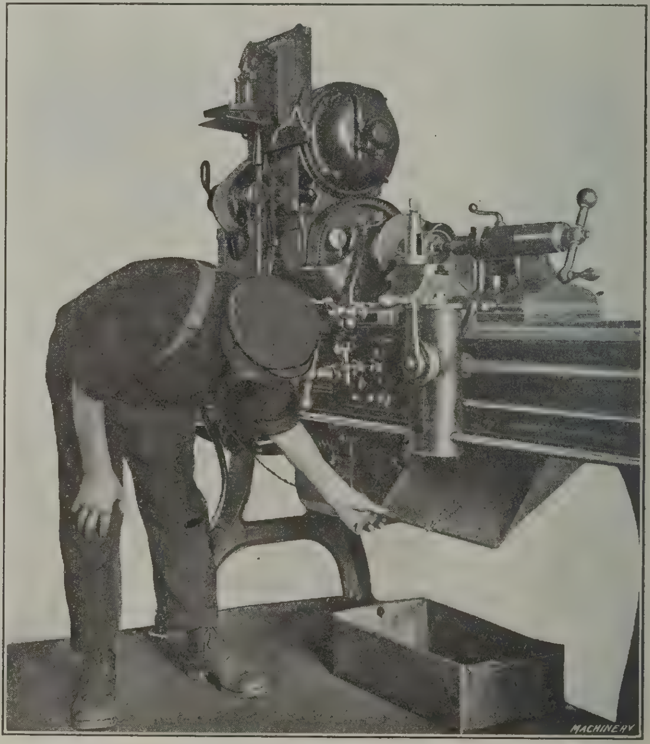

Fig. 5. Removing the Chips and Oil

Valve-seats, a group of which is shown finished in Fig. 7, present some unusually interesting machining methods. At *A*, Fig 7, is shown a rough casting from which the valve-seats are turned, and in Fig. 8, is shown a line-engraving of the valve-seat. It is important that these castings be internally gripped and held central on the arbor by the three points *M*, shown in Fig. 8. For this purpose the special arbor

shown at *B*, Fig. 7, is employed. This special arbor consists of a steel core *C*, on which is slidably mounted a sleeve *D*, one end of which terminates in a tapered flange. At the opposite end of this core is permanently located a collar *E* in which three pins are equidistantly placed about the flange. These pins are so supported that when the sleeve *D* is moved toward the collar *E*. the pins are forced outward due to the action of a taper bearing under the pins.

In operation, the casting is slipped over the arbor, care being taken to locate the three internal spots *M* over the pins that extend from the arbor. Sleeve *D* is then inserted and

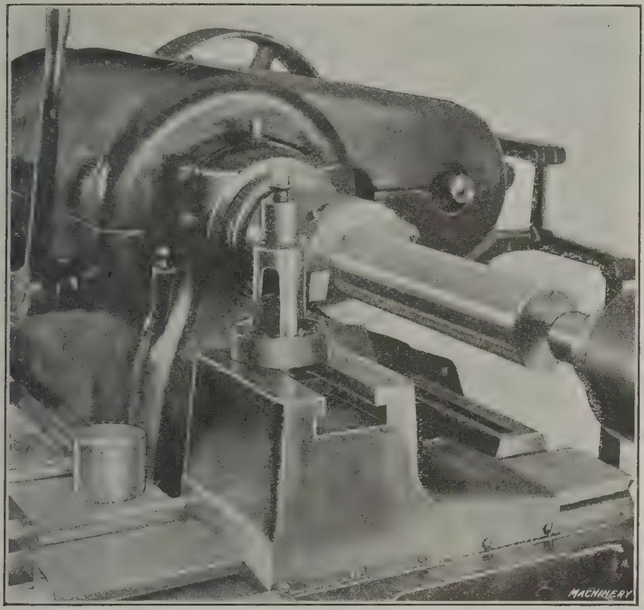

Fig. 6. Cutting-off Short Pieces of Stock

nut *G* tightened. This operation forces the three pins to grip the casting internally, while the tapered flange on the sleeve centers the other end of the casting. In this position the outside of the casting is turned. Next, the casting is removed from this arbor, and one end is held in a chuck while the body of the valve-seat is supported by a steady-rest, thus leaving the interior clear for machining. After being rough-bored, reamer *H* is run through, after which the succeeding counterboring tools, *I*, *J*, and *K* are used. Each of these tools is held in the tail-center of the lathe and each counterbores some particular part of the valve-seat. The interior of the valve-seat being thus finished, it is finally slipped on the arbor *L* and the exterior of the work polished with emery cloth.

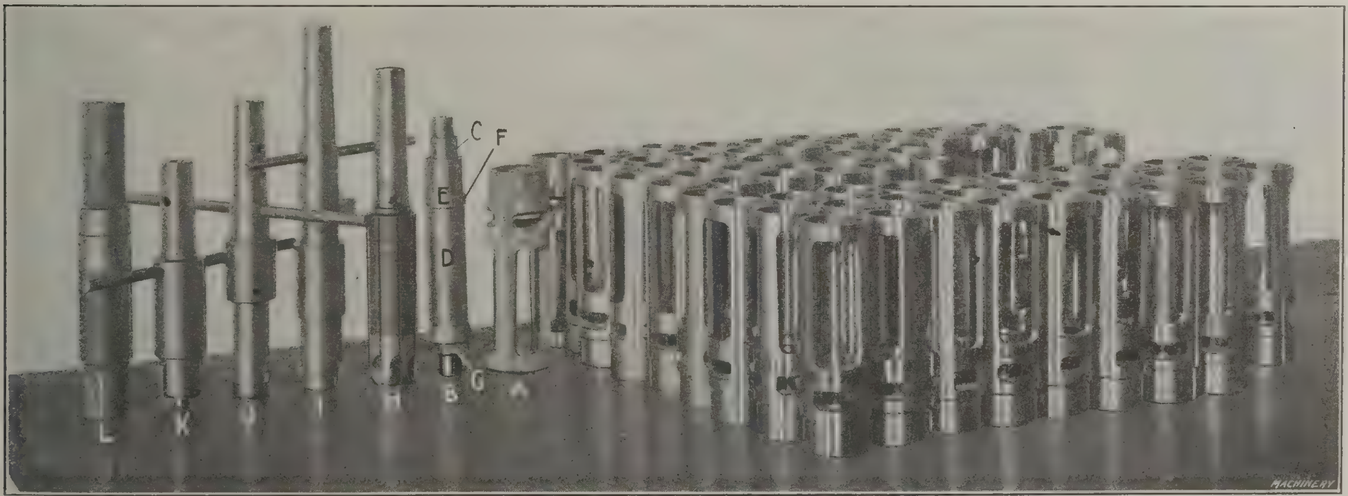

Fig. 7. Turbine Valve-seats and Tools for Machining. A Specimen of Apprentices' Work

Large numbers of cast-iron pulleys are turned in this department, this work being one of the first jobs that the prospective machinist receives. In finishing these pulleys considerable filing must be done, and with the ordinary face-plate and dog, there are plenty of chances for a novice to have his jumper-sleeve caught, with possible injury to himself. To overcome this danger, the lathes in the apprentice department are fitted with faceplate guards, consisting of a piece of sheet metal bent into circular form and fastened to the edge of the faceplate with small screws. The guard (see Fig. 9) extends over the dog, and there is no possible chance

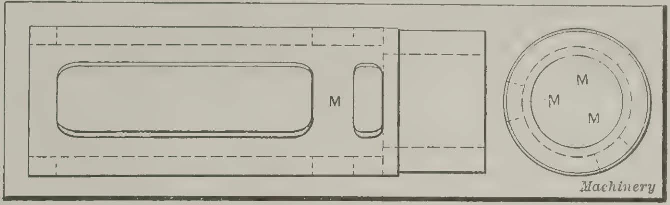

Fig. 8. Turbine Valve-seat Casting before Machining

for any part of the workman's sleeve or arm coming in contact with the dog.

In connection with the pulley work there is a splining operation, which is interesting on account of the method by which the splining bars are made. The bar is mounted on

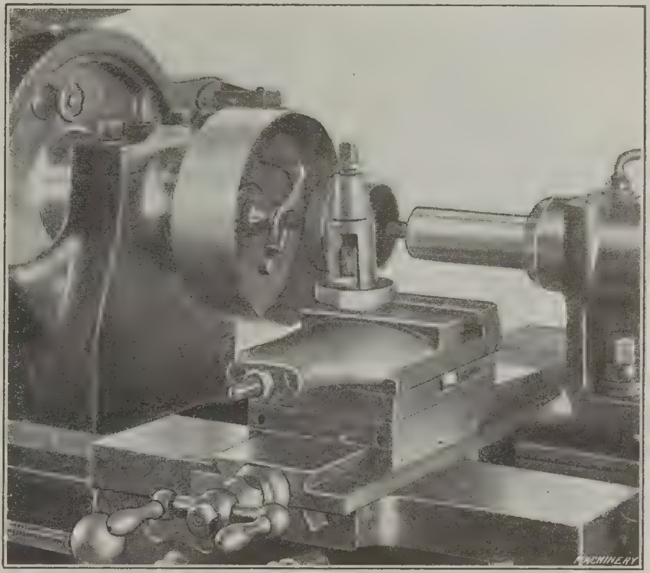

Fig. 9. Guard for Faceplate and Dog when filing in the Lathe

the table of a vertical milling machine, with one end slightly raised. The holes for the teeth are then milled to the same depth, measured from the surface of the table. This, of course, results in each hole being slightly shallower than the preceding hole. As the teeth are made the same length, it will be readily seen that when soldered in place, they will project from the bar with regularly increasing amounts.

Fig. 10 illustrates the way in which the apprentices are taught to run the various machines, the example illustrated being a grinding machine. The apprentice who is to learn to run the machine is instructed by an older apprentice who has already performed work on this machine in a satisfactory

manner. The younger apprentice operates the machine under the guidance of the more experienced boy, and the two work together until the younger apprentice is proficient in handling the work alone. This illustration shows the operation of grinding shafts, of which a great many are used by the General Electric Co., in building small motors. As soon as the younger boy becomes experienced in handling this machine, the older apprentice is taken off and started at work on some other job, and, in due time, the younger boy proceeds to instruct a new recruit. All of this work, of course, is under the supervision of the foreman and his assistants.

In Fig. 11, one apprentice is shown running the machine

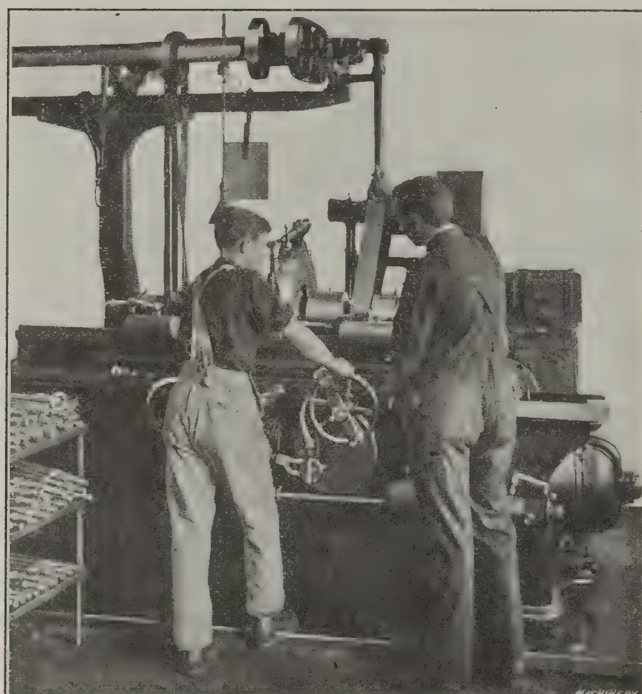

Fig. 10. How One Apprentice instructs Another to operate a Grinding Machine

while the other, who is more experienced in the work, is measuring the finished motor shafts with micrometers. This work, being regular production work, is extremely good practice for apprentices to work upon, as the limits of accuracy are held to within 0.0005 inch. The grinding machine here shown was built by apprentices. The illustration also shows

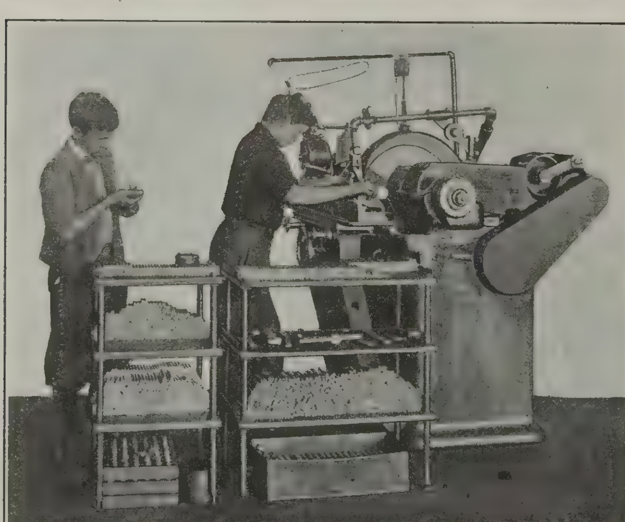

Fig. 11. Grinding Small Motor Shafts. Grinding Machine made by Apprentices

a simple type of homemade shop-stand, built up of iron plates and short lengths of pipe, the whole being held together by long bolts with nuts at the top.

Fig. 13 shows an extremely convenient type of dog used for driving work on the grinding machine. The tail of the dog, which comes in contact with the driving pin, is hinged in the frame of the dog. The hinged end is made cam-shaped so that the slightest pressure upon the tail causes the cam to grip the work, and as the pressure increases, the cam grips the work still harder. The eccentric is kept normally on the work by a spring *A*. This dog is the design of Mr. Tripp and is used exclusively for small grinding work in the apprentice department.

In Fig. 12 is shown an interesting example of turning. The piece of work is a bronze oil deflector, approximately six

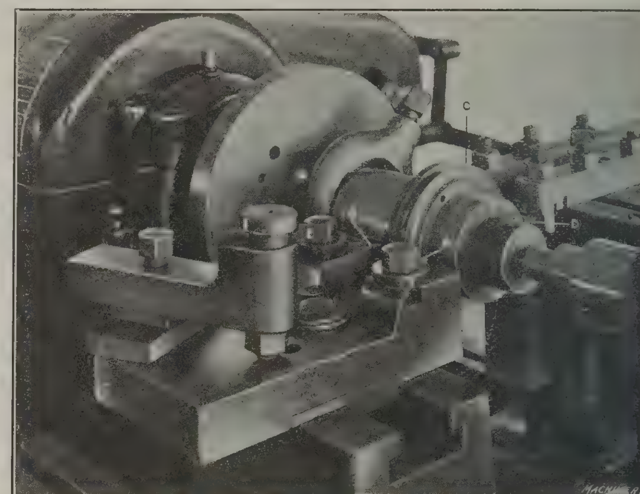

Fig. 12. Multiple-turning an Oil Deflector

inches in diameter, made from large bronze tubing cut to lengths slightly longer than the finished pieces. It is necessary that the inside of this piece be perfectly smooth and accurately sized within 0.0005 inch. This sizing is done by forcing a perfectly smooth arbor through the hole after it has been brought approximately to the required internal diameter. This operation is practically a planishing operation, in that it leaves the metal with a fine finish—far better than could be produced by reaming. Another important reason for using this method in preference to reaming, is the fact that reamers dull very quickly in cutting this hard bronze.

The method of doing the lathe work on this piece is interesting, because it involves multiple-turning. After the interior of the piece has been finished, it is held upon an

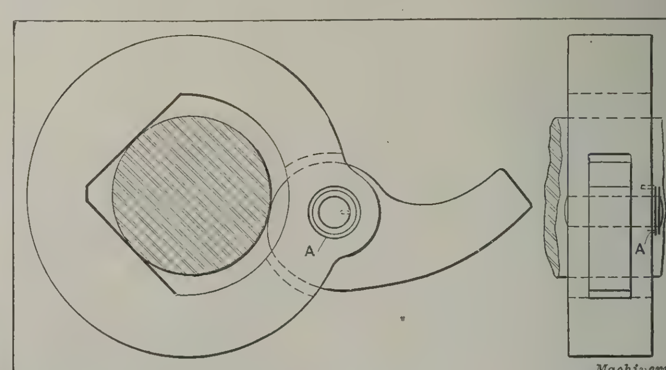

Fig. 13. Dog with Cam-grip; used in Driving Work for Grinding

arbor and placed between the centers of the lathe. Tools *A* and *B* are used for facing the sides of the work, at the same time sizing the piece. These tools are, of course, operated by running in the cross-feed of the carriage-slide. As soon as this operation has been completed, the cross-slide is withdrawn, bringing tools *C* and *D* into contact with the surface of the work. These tools each cut away certain parts of the metal, after which tool *E* is set to cut the grooved section near the center of the oil deflector. In this manner the pieces are finished very quickly and accurately.

In Fig. 14 is shown an example that aptly illustrates the work of the apprentices in fixture making. The operation being done is that of milling a turbine detail, and not only is the work done by apprentices, but the fixture used has also been made by them. The method of doing this milling, in common with many of the other jobs that have been previously described in this article, originated with Mr.

Tripp, who is constantly working out new ideas to be carried out by the apprentices. Referring to the illustration, the work A is clamped on the faceplate B, of a fixture C. It is located at the bottom by set-screw D, and at the top by latch E, which engages in the longitudinal slot in the work. The seats for the work are V-blocks F. The faceplate B is removable from the body of the fixture; it is located accurately by two removable dowel pins G, and held in place by four swing-bolts H.

It will be noticed that one section of the cut is slightly deeper than the other part, a condition that is met by using cutters of different diameters. As soon as one cut has been made in the work, the top half of the fixture is loosened and reversed, and the second cut is made at the other end of the turbine part. While this cut is being taken, the apprentice clamps a new part in a duplicate faceplate, and at the completion of the cut, he simply removes the top half or faceplate of the

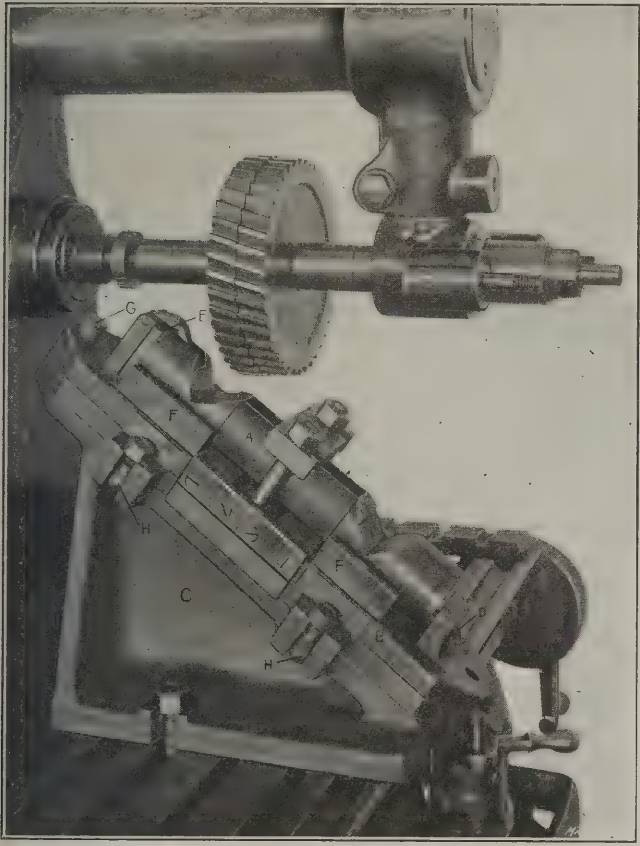

Fig. 14. Fixture employed in milling Turbine Parts

fixture, replacing it with the duplicate faceplate that has a new piece in it, and is ready for milling. In this manner the machine is kept at work all the time.

There are many other jobs done by the General Electric apprentices that are worthy of description. Screw-cutting bench lathes and other machines have been built complete in this department, and some unusually good punch and die work and general toolmaking has been done, but enough has been said to make it plain that the apprentices on this course get "real work" to do.

* * *

During the last thirty-six years the fire losses in the United States, according to an article by Mr. S. G. Koon in the *Engineering Record*, have amounted to more than $5,000,000,000. This is more than seven per cent of the average estimated national wealth during this period. The fire loss per capita is considerably over two dollars a year, which is about six times the fire loss per capita in some of the leading European countries. When it is known that over ninety-five per cent of all fires in buildings equipped with automatic sprinklers are either completely extinguished by the sprinklers or held in check so as to be easily handled by the firemen, it is evident that these enormous fire losses are not necessary. A department store with a sprinkler system stopped the progress of the Baltimore fire. Had the building in which this fire started been properly protected in this manner, there would have been no conflagration to stop.

DAD'S BOY

By A. P. PRESS

We had a new man come in lately. This is not, in itself, an unusual thing, for new men come in every day. In fact this one came in with a "bunch" of five; but he "stuck out" from the rest, although he did not put himself forward—he just stuck out, anyway. He had on a blue woolen shirt, but it was clean; and he had blue eyes—and they were clean too. He did not have much of a kit—none of the boys do nowadays. A kit is in the way on the bench if kept in a chest, and on the set-up job it is not needed anyhow; but what tools this new man had were first-class.

He started in just the same as the rest of the men, and no favors were shown him, but one thing we noticed was that he "peeled off" before he started, the same as the molders do, and put on some rough clothes.

The floor boss came along past the desk, that noon, just as we were eating lunch, and said:

"Say, but that new man is all right." (He didn't say which new man, but we all knew who he meant.) "He showed me how to get the angle on that big brace without a protractor and it came out right, just as the drawing called for. You can't get a protractor on it very well anyhow—there is no planed surface to work from."

"A good man, is he?"

"He sure is," was the reply, and the matter was dropped.

About a week after that we wanted a nice lathe job done. It was a kind of a government job. It happened this way. We broke down one of the big cranes, and it was due to carelessness, so we hated to ask the office for an order to fix it, as that would mean a lot of explanations as to how it was done. It only needed a new bushing with a taper hole in it to make it as good as new, so we asked the floor boss if he had a good lathe hand in the gang.

"Sure and I do not think of one, sir; but wait a minute and I'll ask that new man and see what he knows."

Back he came in five minutes. "Yes, sir, the new man says he can do anything in the way of a lathe job; and that is not all—he has a pair of 'mikes' and a pair of vernier calipers in his coat pocket, both in little cases."

We got the use of a good lathe in the experimental room and sent the new man in there with a sketch showing what was wanted, and a solid casting to cut it from. Along in the afternoon he came out with the job and fitted it into the crane—it *was* a fit, too—and went back to his floor work, and said nothing.

A week after this the man on the big planer was taken sick, and word came from the planing job to ask if we had a man who could take his place for a week, as the planer had all it could do every hour of the day. We called in Mike, the floor boss, and put it up to him.

"Sure, and that new man does have a machinery paper, and he is reading most every noon; I will ask him." Back he came and said, "Yes, he says he has run big planers and is not afraid to take hold of this one—in fact, he is very willing to do it." So on the planer he went and he made good, and stayed there until the regular man got back again; and then he went back to the floor.

A month went by, and one morning we got a telephone message from Mike. "Sure," said he, "and I was going upstairs with a hod of coal, and I fell and hurted my ankle. The doctor says that it will be a week before I can get in." Well, we were stuck, for that meant that we either had to find a piece of stock on the floor that we could hammer a floor boss out of, or be boss ourselves. The new man was the first one that came into our mind, so we went gunning for him at once.

"Did you ever handle any men?"

"Yes, sir, on several jobs, sir," was the reply.

"How many?"

"Oh, anywhere from five to fifty," was the quiet reply.

"Can you take hold of this gang and run it until Mike gets back?"

"I can try," he answered.

"Go ahead."

And "go ahead" he did; and although Mike's one week with his injured leg, stretched out into three, things ran so smoothly that we should never have known he was out—as far as the work was concerned. Mike came back at last, and then our curiosity got the best of us, and we called the new man into the office.

"See here, now, what are you doing here? You have been here four months and you have shown that you are an expert lathe hand, a good planer hand, and also a good floor boss—and still you are working for a journeyman's pay. We know drinking is not the trouble."

"Well, boss, you see it is like this: Dad is superintendent of the Smith Co. (naming one of the largest concerns in the country) and it has always been his brag that he was a self-made man and came up from the ranks. He said that any boy of his had got to do the same—and that is just what I am doing now. I started in three years ago in the lumber mills of Vancouver, worked my way along to Seattle, put in a year in 'Frisco, and then worked my way through the gulf shops to New York. I put in nine months in a big garage there before I came here—and I would like to respectfully give you notice that I wish to leave next Saturday night. I am going across to the old country for a year in France and on the Continent. Then I am going home to Dad."

Now, we have not the pleasure of the acquaintance of "Dad," but we certainly have the highest respect for him and his method of bringing up the boy—and we should like to be in Dad's shoes when the kid gets home.

* * *

TABLE OF ALLOWANCES AND LIMITS

FOR DRIVING, PULLEY, RUNNING, SHRINK AND SLIDING FITS

By H. M. NICHOLS*

In manufacturing machinery where the parts must be interchangeable, it is necessary to have some standard of allowances and limits in order that parts made at different times will go together without fitting. The accompanying table gives the allowances and limits for sizes from zero up to 8 inches for driving, pulley, running, shrink and sliding fits. The allowances are in all cases added to the even dimensions to determine the dimension that is put on the drawing for the mechanic to work to. The limits are given after the important dimensions on the drawing, and all pieces must be made to the degree of accuracy called for by these limits; that is to say, if the limits for a particular piece are +0.001 and —0.000, it must at least caliper to the size and must not be more than 0.001 inch over to pass the inspector.

As an example, suppose we have a 3-inch shaft and a collar to be shrunk onto it. Referring to the accompanying table we find that there is no allowance for the bore, and consequently the dimensions for the bore of the collar would be written $3.000 \frac{+0.000}{-0.0005}$. The allowance for the shaft is 0.003 inch, so that the dimensions for the shaft would be written $3.003 \frac{+0.0005}{-0.000}$.

It is customary to write dimensions that have to be accurate to the thousandth part of an inch in the form of a decimal, annexing ciphers in case a particular dimension happens to come out an even figure. All other dimensions are written in sixteenths or multiples of sixteenths. This enables the workman to pick out all dimensions requiring accurate work. The limits are usually given in small figures immediately following the main dimensions and a little above the main dimensions. Some concerns have letters to represent their standard limits which they add to the general dimensions requiring limits.

[While the values given in the table for shrinkage and force fits are all right for average conditions, they cannot be used in all cases, the allowance to be made depending on the length of the work, diameter of the hub, character of the bore, and numerous other conditions. For a more extended treatment of the subject, reference should be made to the article on "Shrinkage and Force Fits in the Bradford Shops," which appeared in the August, 1911, number of MACHINERY, engineering edition, and also to the two articles by William Ledyard Cathcart, entitled "Shrinkage and Force Fits," in the April and May numbers of MACHINERY, engineering edition.—EDITOR.]

TABLE OF ALLOWANCES AND LIMITS

Diameter in Inches	Driving Fit			Pulley Fit		Running Fit			Shrink Fit			Sliding Fit		
	Bore, No Allowance	Shaft		Bore, No Allowance	Shaft, No Allowance	Bore		Shaft, No Allowance	Bore, No Allowance	Shaft		Bore		Shaft, No Allowance
	Limits, Inches	Allowance, Inches	Limits, Inches	Limits, Inches	Limits, Inches	Allowance, Inches	Limits, Inches	Limits, Inches	Limits, Inches	Allowance, Inches	Limits, Inches	Allowance, Inches	Limits, Inches	Limits, Inches

MAKING PISTON RINGS*

By C. A. ROGERS†

The subject of making piston rings has been discussed before, but as this is an interesting problem in machine shop practice, the writer feels that there is still more to be said. A great many mechanics insist that piston rings must be ground, yet I have seen very few ground rings that were parallel sideways, and consequently they would not have a perfect bearing when placed in the cylinder. The piston ring, the manufacture of which is to be described in the following, is for a 4-inch cylinder and is shown in Fig. 1. Fig. 2 shows the casting from which the piston rings are made, while Fig. 3

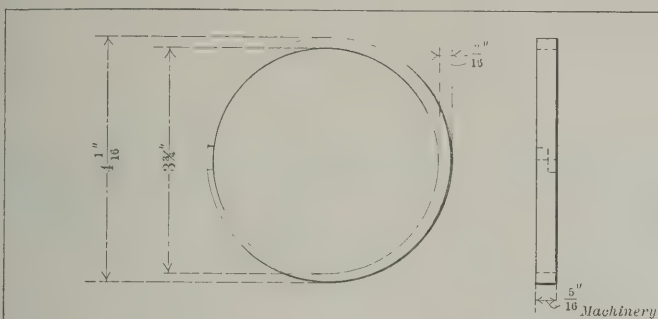

Fig. 1. Piston Ring for a 4-inch Cylinder

is a fixture fitted to the lathe spindle for holding the casting shown in Fig. 2.

The fixture shown in Fig. 3 consists of a casting *A*, fitted to the nose of the spindle and which is machined out on the front end to receive a block *B*. This block is counterbored to fit the external diameter of the casting shown in Fig. 2, the latter being reduced on one end to 4⅛ inches. The casting is held in the block *B* by a binding screw which securely holds

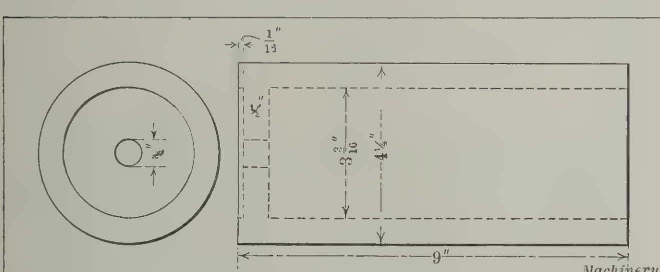

Fig. 2. Casting from which the Piston Rings are cut

the casting while it is being turned, bored, faced, and the rings cut off. The block *B* is provided with a pin *C*, which locates it in two positions so that the castings for the rings can be turned eccentric. The block when located in the desired position, is held by cap-screws as shown.

The casting is turned, faced and cut up into rings by means

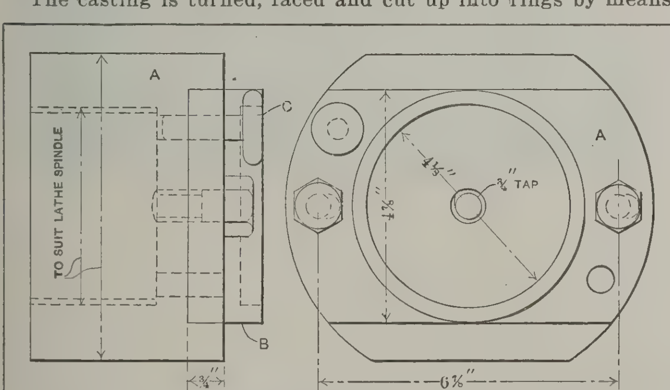

Fig. 3. Fixture for Holding Casting when turning, facing and cutting-off Piston Rings

of tools held in the turret toolpost, shown in Fig. 4, which comprises three blocks of machine steel. The turning tool *A* is used for rough turning; tool *B* for finishing; *C* for cutting off; and *E* and *F* for side facing. The first operation after placing the casting in the fixture, Fig. 3, is to rough down the external diameter with the tool *A*, Fig. 4, at a feed of 1/16 inch per revolution, and a surface speed of 80 feet per minute, leaving 1/32 inch for the finishing tool *B* to remove. Finishing tool *B* is operated at the same speed as tool *A*, and finishes the casting to the required diameter.

Cut-off tool *C* is then brought into position, and is used to face off the outer end of the casting. The carriage is then

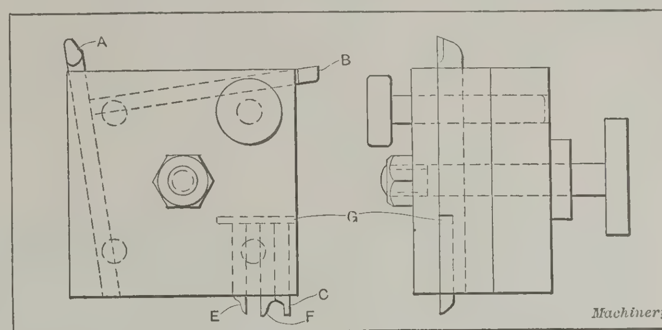

Fig. 4. Turret Tool-post for Holding Turning and Cutting-off Tools

moved 5/16 + 0.020 inch, and the cut-off tool put in to within 1/64 inch of cutting the ring off. The carriage is again moved 5/16 + 0.020 inch, and while the groove is being cut to form the second ring, the two side facing tools *E* and *F* face the first ring and cut it off. This order of operation is repeated until the casting is cut up into rings.

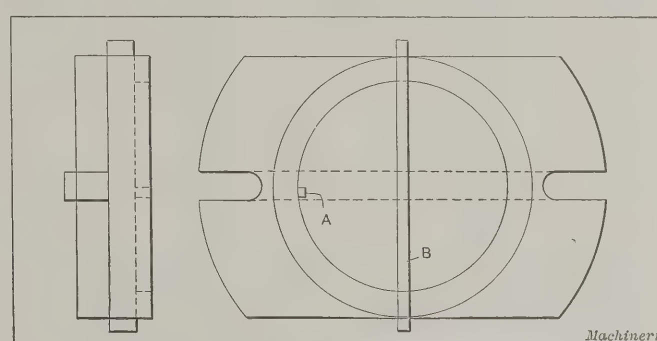

Fig. 5. Fixture used in Splitting Piston Rings

After the rings are turned externally and cut off, they are taken to the milling machine and placed in the fixture shown in Fig. 5. This is a fixture for holding the rings while the slot is milled, a cutter 0.197 inch wide being used. The fixture is set off center, an amount equal to half the thickness of the cutter—0.0985—and all the rings are milled on one side. Then

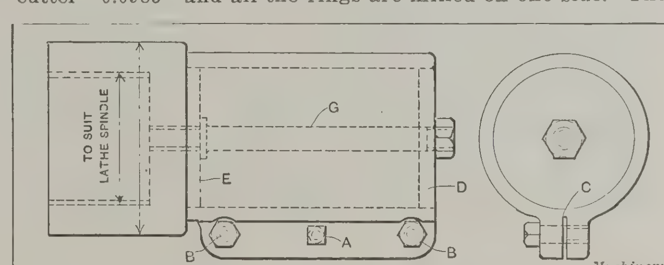

Fig. 6. Fixture for Holding and Clamping Piston Rings when taking the Finishing Cut

the piece *A* is slipped into position to fit the slot already cut, when the rings are milled on the other side.

Following the milling of the rings they are taken back to the lathe and placed in the fixture shown in Fig. 6. This consists of a clamping sleeve which will hold as many rings as are cut off from the casting. To make the sleeve ready for holding the rings, the set-screw *A* is backed out and the binding screws *B* tightened, so that the sleeve is cracked open at *C*; then the fixture is filled up with rings, leaving sufficient room for the washers *D* and the projection *E* on the fixture. The retaining sleeve holding the rings is now slipped over the stud *G*, the washer *D* put on and the nut tightened. The binding screws *B* are now loosened, and the set-screw *A* tightened slightly, when the sleeve can be easily removed. A center is provided in the end of stud *G* so that it can be supported with

* For additional information on this and kindred subjects, see "Automatic Piston Ring Peening Machine," August, 1911; "Fixtures for Machining Eccentric Piston Rings," April, 1910, and articles there referred to; "Turning Gas Engine Pistons in a Turret Lathe," April, 1910; "Making Accurate Automobile Engine Pistons," January, 1910; "Automobile Factory Practice," January, 1910, engineering edition; "Automobile Factory Practice," October, 1909, and other articles there referred to.

† Address: 33d and Eastern Blv'd., Des Moines, Iowa.

the tailstock center when taking the finishing cut. The finishing tool *B* shown in Fig. 4 is used for this last operation.

As the sleeve is bored the same size as the cylinder (plus 1/32 inch to allow for turning), and as the rings are closed together when they are placed in it, they are thus turned when in their compressed condition so that they fit the cylinder of the engine snugly. The total time required to make these rings is five minutes each, and when made on a good engine lathe equipped with fixtures as illustrated, a very good job will be the result.

Referring to Fig. 5, the strip *B* is used for pulling the rings from the fixture. They require no holding in this fixture, as the cutter should be fed down from the inside, and any tendency for the rings to fly up on the opposite side is easily overcome by holding them down by the fingers. If the rings were clamped down, the time required for clamping would be nearly as long as that required for milling. The strip *G*, Fig. 4, is set in a milled slot to prevent the cut-off and side facing tools from slipping back. The two side facing tools should be packed apart with tin foil so that they can be adjusted for wear, as the rings should be a very close fit in the grooves of the piston.

SPECIAL ACME-THREAD MACHINE TAPS

By FRANK LANG*

Having had considerable trouble in making machine taps with Acme threads due to the change of the lead in hardening, the writer designed the type of tap shown in Fig. 1. This tap has proved practical and has given very good results. An accurate thread is produced, there is less heating in tapping, and a greater number of pieces can be tapped in the same time, with less chance of breakage. One tap, 1 15/16 inch in diameter with two threads per inch, left-hand, was used for tapping seventy-five pairs of Le Blond heavy-duty lathe half-

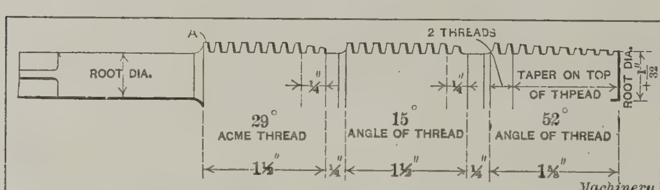

Fig. 1. Method of making Acme-thread Taps

nuts, and not a scratch could be seen on the thread when the last pair was removed from the jig; the tap was ground twice.

When making this tap a tool is first ground to a 52-degree angle, as indicated by the gage shown in Fig. 2. This tool is used for threading the first third or roughing part of the tap. The thickness of the tooth at the bottom of the thread in the tap is made 0.010 inch less than the figures given in a table of the standard Acme thread dimensions. The next third of the tap is made with a tool having a 15-degree angle, the

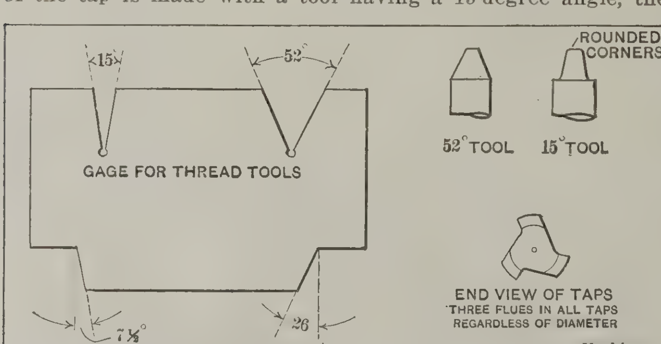

Fig. 2. Gage for Special Thread Tools, Shape of Tools, and End View of Fluted Taps

flat at the top of the thread being made 0.010 inch smaller than the Acme standard. A small round on each corner of the tool is made as shown in Fig. 2. This is a good feature as it makes the tap less liable to break when straightened after hardening. The last third of the tap is made with a regular Acme thread, except that the thickness at the bottom of the tooth is 0.005 inch less than standard, in order to allow this amount to be removed by a hand tap.

The diameter of the shank is made equal to the root diameter, and its length depends on the length of the piece to be tapped. The square in this case is hardened and tempered, as this tap is driven by a tap socket having its square at the outer end, so that the shank has no bearing in the socket and the square does all the driving. A small round corner should be left between the sides of the square, as this strengthens the square. The tap shown in Fig. 1 is ¾ inch in diameter with six left-hand Acme threads. The one-half of a thread shown at *A* should be ground off from each tap, as otherwise it may become distorted in hardening and mar the tapped pieces, and the trouble may never be located. In chasing the threads in the tap, a ⅜-inch square piece of high-speed steel is used in an Armstrong toolholder when the space of the thread does not exceed the width of the tool.

It may be of interest to some of the readers of MACHINERY to know that the hand taps made in our shop are not made exactly to the standard formula, but the outside diameter is made with the following allowances:

Outside diameter, up to 1 inch diameter = nominal diameter + 0.005 inch.

Outside diameter, from 1 to 1½ inch diameter = nominal diameter + 0.007 inch.

Outside diameter, from 1½ inch diameter and over = nominal diameter + 0.010 inch.

The length of the flute is 2½ inches in all cases. This applies to hand taps only.

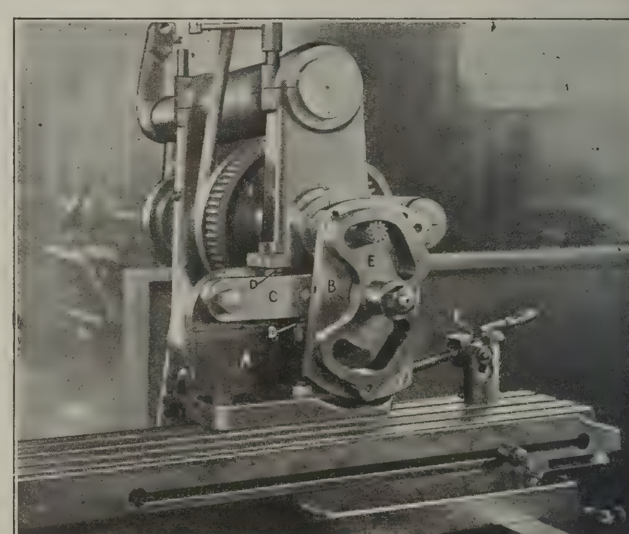
SHIFTER CAM MILLING ATTACHMENT

The cams used on metal planers for shifting the belts require to be accurately formed and smoothly finished. The accompanying illustration shows a simple milling attachment used by the Cleveland Planer Works, Cleveland, Ohio, for milling out the slots.

The attachment consists of an angle-plate *A* on which is mounted a master cam *B* pivoted in the center. The master cam is not mounted directly on the angle-plate, but on a horizontal piece *C* which has a limited up-and-down motion. This



Belt Shifter Cam Milling Attachment

piece is held in a horizontal position by two short coil springs, *D* and D_1, oppositely placed.

The cam to be milled is mounted on the master cam-plate, as shown at *E* in the illustration, and an end milling cutter having a shank that closely fits the slot in the cam-plate is placed in the spindle. The slot is milled with a horizontal feed of the machine until the curve is reached, when its feed is thrown out. The cam-plate is then rotated by hand by means of the screw and handle *F*, shown at the right. When the curve has been traversed, the horizontal feed is again thrown in and the cutter traversed to the end of the slot.

This simple attachment is found valuable. It insures accuracy of the slots, interchangeability, and saves the time of a first-class mechanic filing out the slots by hand. A boy runs the machine carrying the attachment successfully, and produces work superior to that turned out by a mechanic at the vise.

NOVEL USE OF RETOUCHED MACHINERY PHOTOGRAPHS

Manufacturers that issue illustrated catalogues and circulars accumulate retouched photographs and wash drawings that represent many dollars' investment. They are usually kept carefully stored away where no one sees them except when they are resurrected for use in making new illustrations. That machinery photographs and drawings can be put to other good use is shown in the illustration which shows how the Kearney & Trecker Co., Milwaukee, Wis., utilizes the retouched photographs of its "Milwaukee" milling machines and details of the same. The photographs, large and small, are mounted under mats and glass in oak panels on the four walls of the the president's and secretary's office. In this form the photographs make an effective and pleasing ornament to the office. The large photographs show details of the machines advantageously, and can be studied more easily than if they were loose or in an ordinary portfolio, and the color effects make them more attractive than ordinary catalogue illustrations.

Novel Use of Retouched Machinery Photographs in Kearney & Trecker Co.'s Office

The frames of the panels are of oak, the same as the desks and furniture. Each top and bottom strip of the sections is in one piece and is screwed to the wall, as are the vertical division strips between them. The panes of glass are independently mounted so that changes can be made in any section without disturbing the others. Ordinary picture mats are used with holes cut through of the size of the photograph that is to be shown. Back of the mats and photographs is placed a layer of ordinary corrugated backing which holds the glass against the molding.

The arrangement of the panels and pictures extends all the way around the office with breaks for doors and windows only, and the whole makes a most effective feature, which in this case partially solves the problem of properly taking care of retouched photographs and using them to good advantage.

TAPS AND TAPPING*†

The average user of machine screws and bolts may hear little about the theories and other details relating to tap- and die-making, but he must be interested, nevertheless, in being able to buy or make screws and bolts which can be depended upon to fit the tapped holes in the product he is making. There must always be a difference in dimensions of the screws and the tapped holes in order to make up for unavoidable imperfections in manufacture and for wear of the taps, and also to allow sufficient freedom of fit. The difference, however, should be confined to such limits that the smallest permissible diameter for the tap should be but slightly larger than the largest permissible diameter of the screw. If the limits are too large, a screw which happens to be used in a hole tapped by a maximum size tap would be too loose; again, if the limits are too small, interchangeability when assembling would be impossible, and the taps would not allow a reasonable amount of wear.

The two most vital factors are the size and the lead. In order to talk intelligently about the size, we must understand how a tap is measured. The fit of any screw should be on the sides of the angle of the thread, as the outside and root diameter have comparatively little to do with the actual fit. Unless the angle and the lead of the threads are the same in both screw and tapped hole, and the diameters measured across the angle of the threads are relatively right, a proper fit cannot be obtained.

In Fig. 1 is shown the effect of having nuts and screws of

* Abstract of a paper by Mr. F. O. Wells, read before the American Society of Mechanical Engineers, March 12, 1912.

† See also the following articles on this and kindred subjects previously published in MACHINERY. "Hook-fluted Taps," October, 1911; "Taps and Tapping," June, 1911, and the articles there referred to; "Rules for Threading Square Thread Taps," and "Making Hand Taps in Sets," May 1911, engineering edition; "Rapid Nut Tapping," April, 1911; "Dimensions of Bit-brace Taps," March, 1909; "Power Required for Tapping," June, 1909; "Power Tapping," February, 1909.

different angles of threads fitted together. In this case the screw is shown with a more obtuse angle than the nut, and the bearing between them will be on the sharp, fragile apexes of the teeth. The necessity of measuring correctly in the angle of the thread has led to the adoption of the term "pitch diameter" for screw threads, the same as for gears. In Fig. 2 is shown a micrometer for measuring the pitch or angle diameter. The merit of this tool is that it is not rendered inaccurate by the helix angle of the thread. It will, therefore, measure the finest lead as well as the coarsest within its range.

Fig. 3 shows how variation in the lead will affect the fit between the screw and the nut. The angle in this case is assumed to be correct, but the nut has been tapped with a tap having a long or stretched lead, with the result that at the base there will be a bearing on two threads only, as indicated at *A*, *B*, *C* and *D*. This is not an unusual condition, and explains why a nut tapped with a large enough tap will often start freely on a screw, turn a few turns and then bind. This also places all the strain on one tooth at a time, making it possible, with a sufficient longitudinal strain, to strip one tooth after another with a shearing action.

The difficulties due to variations in the sizes of screws and taps are well known to those who have to use them. For this reason many are using limit gages which are made especially to measure the screw diameters across the angle, and thus insure uniformity, within working limits, of the screws to be

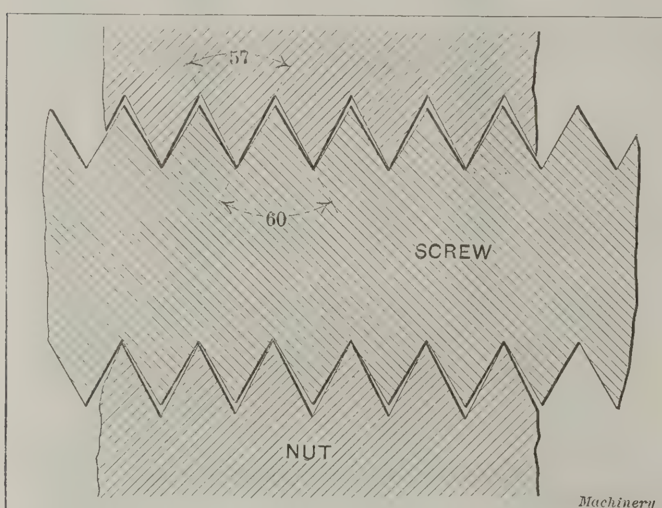


Fig. 1. Effect of Difference in Thread Angle of Nuts and Screws

used. Figs. 4 and 5 show one of these gages in use. The screw being measured has just passed the "go" or maximum limit in Fig. 4 and with the same movement of the hand is carried down to the "not go" or minimum limit, as indicated in Fig. 5. The rapidity and accuracy of this method of gaging is apparent. An inspector can pass on seven hundred and fifty ¼-inch taps per hour, both as regards angle and outside diameter, using, of course, two limit gages of this style. For ordinary screw work requiring less accuracy, he could pass on even a greater number.

As regards the lead of taps, it must be remembered that all steel will change somewhat in length in hardening; hence the lead of taps will vary somewhat from the standard. If in addition to this the hardened tap is warped on the threaded end, the condition of the tapped hole will be as indicated in Fig. 6.

We have now seen the effects that errors in lead, angle, angle diameter and warping in hardening will have on the taps. Add to this the effect of usage, reducing the size of the tap by wear, and then add the commercial variation in the lead, angle and diameter in screws and bolts, and it will be readily seen that under the best possible conditions, there will be a multiplicity of minute errors that must be taken care of by an allowance between the minimum limit of the tap and the maximum limit of the screw. There must also be a maximum limit for the tap and minimum limit for the screw in order to prevent too much looseness in the fit of the threads. There is at the present time a great diversity of opinion among tap and die makers, as well as among screw makers in general, as to what these allowances should be for the regular U. S. standard sizes, and hence the buyer of taps and screws is working under a serious difficulty in his efforts to obtain proper fits and interchangeable work. The standard adopted by the American Society of Mechanical Engineers for machine screws has been of great value, but the question of limits for the larger sizes of screw threads is still unsettled.

When a tap breaks or anything goes wrong in connection

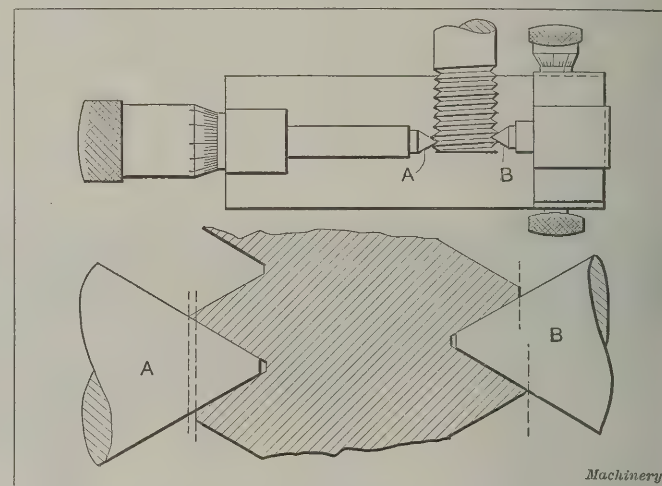

Fig. 2. Device for Measuring Angle Diameter, and Enlarged View showing its Application

with its work, it is probably the most natural thing in the world to blame the tap maker. In many cases, however, the trouble is due entirely to the condition under which the tap is working. In order to determine some of the practical questions in this connection, such as the proper sizes of tap drills, the best lubricants, the correct cutting angles and shapes of the flutes, the right number of threads among which the cutting should be distributed, the best method of hardening to increase the life and strength of the taps and to prevent undue distortion and shrinkage, the proper way to grind cutting edges, etc., the Wells Bros. Co., of Greenfield, Mass., built special testing machines showing the power required to drive any tap. A record of the cutting action was taken on indicator cards or charts.

Tap manufacturers often find that users of taps actually punch or drill the holes to be tapped of a smaller diameter than the root diameter of the thread, so that the end of the

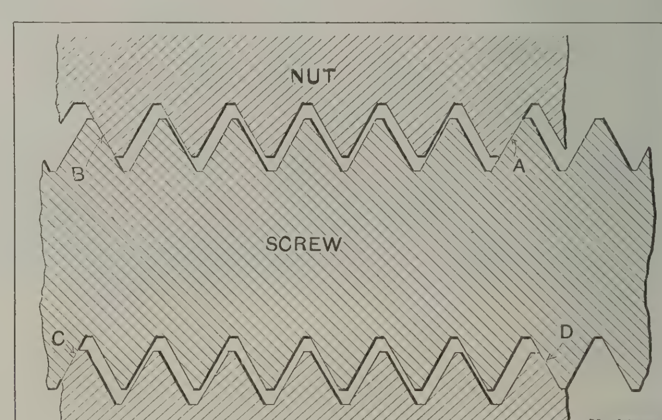

Fig. 3. Effect of Difference in Lead of Screw and Nut

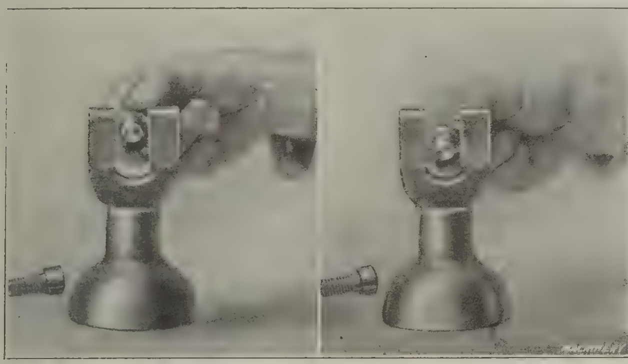
tap must act as a reamer before the thread can be cut. In Fig. 7 are shown sections of such nuts through which taps have passed. In this case the tap becomes a taper reamer, reaming a tapering entrance to the hole, as shown in the nuts at the top. Frequently the tap will refuse to "catch the thread" at all and will ream clear through the nut. Should the thread happen to "catch" after reaming part way, however, a short, weak thread results, as indicated by the two nuts at the right in the lower part of the illustration. This condition evidently requires considerable power, and explains why taps frequently break as soon as they begin to cut. When it is remembered that generally not more than 80 per cent of the

standard thread depth is necessary in ordinary manufacturing work, and that in many cases not more than 50 per cent is required, it is apparent how useless it is to have the holes too small, and, in most cases, to even attempt to secure a full thread.

Tap drill sizes for machine screws, in particular, should be varied according to the material to be tapped and the depth of the tapped hole. In general, for holes where the screws enter more than one and one-half times the diameter, one-half of the full thread is usually sufficient. Soft, tough materials, such as copper, Norway iron, drawn aluminum, etc., should have a larger hole for the tap than the hard, crystalline materials, such as cast metals. The reason for this is that otherwise the taps of the threads of the softer materials will



Figs. 4 and 5. Limit Gage for Screw-thread Diameters, and its Use

be torn off, thus actually decreasing the effective depth of the thread of the tapped hole as compared to what it would be had the hole originally been drilled larger. On the other hand, if the hole is originally drilled large, the tap will, when cutting tenacious materials, especially after the keen edge has been slightly dulled by use, reduce the size of the hole by drawing the metal at the top of the thread, thereby increasing

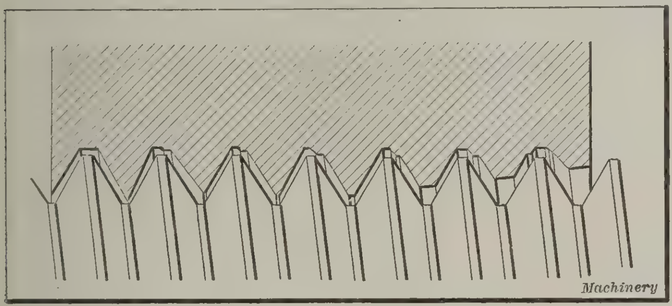


Fig. 6. Thread resulting from Tapping with a Warped Tap

the depth of the threads. It should also be remembered that it is impracticable to tap a hole with the basic root diameter size, unless serial taps or taps with long steps are used, so as to divide the work into a series of successive operations.

The size of the hole also affects very materially the power required for tapping. This is particularly important in machine tapping. The power is also affected by the kind of lubricant

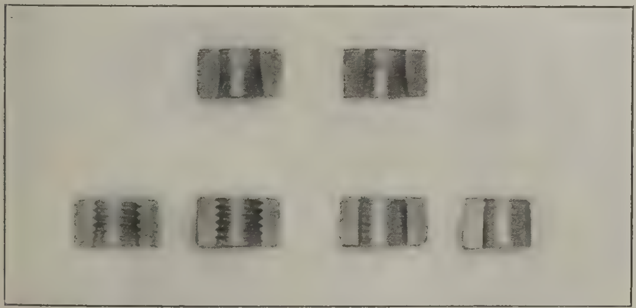

Fig. 7. Nuts, having too Small Tap Holes, reamed by End of Tap

used, by the condition of the tap as regards being sharp or dull, by the shape of the cutting edges and their effect on the shape of the chip, and by the shape of the flutes. In Fig. 8 are shown three taps with different kinds of flutes. The tap in the middle (having what is called a "hook" flute) produces a long, curling chip which in a deep hole will have sufficient length to curl up tightly, jam the tap and cause it to break off if there is sufficient driving power. The chips from this tap are shown in Fig. 9. In Fig. 10 are shown two nuts in which these long curled chips have rolled up and broken the tap. The end of the broken tap is also shown.

The tap shown to the right in Fig. 8 does not cut properly, but pushes the metal ahead of it, often accumulating so much compressed metal as to resist further compression, which

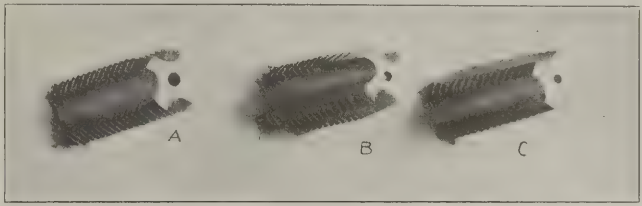

Fig. 8. Taps with Different Flutes having Different Cutting Action

causes the tap to break. This tap broke while tapping cold punched nuts, twisting off near the shank at a strain of 1100 inch-pounds. The work was divided between 48 cutting teeth. The chips made by this tap are shown in Fig. 12. They are compressed in character and show by their appearance the relatively large amount of power required for tapping. In Fig. 13 are shown sections of four nuts tapped with the type of taps mentioned, and which broke while being tapped.

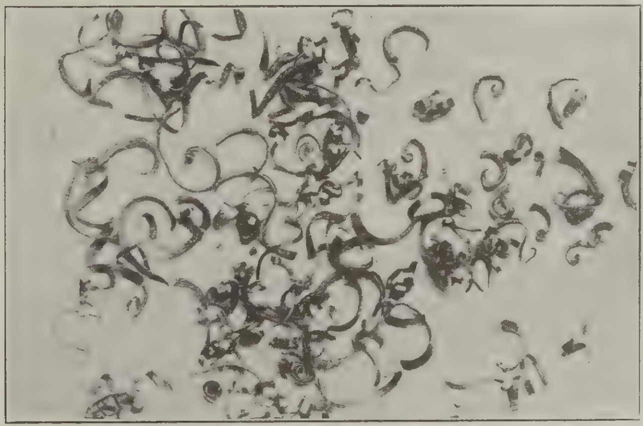

Fig. 9. Chips produced by Tap B, Fig. 8

The compressed mass of metal still adhering to the thread should be noted.

The tap shown to the left in Fig. 8 is properly made. It produces a slightly curling chip, which breaks up into short lengths and easily slides out through the flutes. This tap requires only about one-third of the power of the tap to the right. The chips cut by this tap are shown in Fig. 14. Fig. 11 shows a section of a nut in which this last style of tap was

Fig. 10. Nut tapped by Tap B, Fig. 8, and Part of Broken Tap

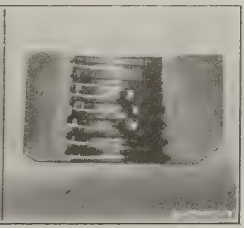

Fig. 11. Nut tapped by Tap A, Fig. 8

started, and the nut was then cut open to show the action of the chip. The smooth thread and the clean, short chips just at the point of breaking should be noted.

As almost all machine tapping is in through-holes, and bottoming taps are seldom used, experiments have been made to determine the effects of sharpening or grinding the taps back from the end for a varying number of threads, so as to ascertain the effect of dividing the work between a greater or smaller number of cutting teeth. By repeated tests and careful records it has been found that it requires approximately 25 per cent more power to drive a tap which has been ground back only four threads (which in a four-fluted tap divides the work between 16 teeth) than for one which has been ground back six threads (thus having 24 cutting teeth); the latter

tap produced a much smoother thread and cut more closely to size.

Chattering in tapping is often due to burrs thrown up on the cutting edges of the tap during its manufacture, and it is very necessary that the taps be free from burrs. Considerable attention should be paid to this point in order to produce good taps.

TABLE II. EFFECT OF VARIOUS LUBRICANTS AND DIFFERENT DIAMETERS OF TAP DRILL HOLE

By multiplying the percentages given by 10, the actual average power required for tapping in inch-pounds, may be obtained.

	Lubricant	Animal Lard Oil	Sperm Oil	Graphite, 10 per cent; Tallow, 90 per cent	Cataract Soap Compound	Mineral Lard Oil	None (Tapping Dry)	Machine Oil
0.425 Diam. Tap Hole (75 % Thread)	Power required*	15.9	16.5	16.9	18.9	19.9	29.9	34.2
	Breakages in tests†	None	None	None	None	None	14	15
	Quality of thread	Smooth	Smooth	Smooth	Smooth	Smooth	Rough	Torn
0.410 Diam. Tap Hole (90 % Thread)	Power required*	....	23	....	25.1	36.5	60.2	62.5
	Breakages in tests†	....	None	....	None	None	50	71.5
	Quality of thread	....	Smooth	....	Smooth	Smooth	Rough	Badly torn
0.400 Diam. Tap Hole (Full Thread)	Power required*	....	35.5	....	41	57.5	71.8	100
	Breakages in tests†	....	None	....	None	None	66	100
	Quality of thread	....	Smooth, Taps torn	....	Slightly Rough, Taps torn	Smooth, Taps torn	Torn, partly stripped	Torn, Chips wedged

* In per cent of breaking strength of tap. † In per cent.

The power required for tapping different materials is shown in Table I. This table gives the results found from tapping five different materials with fourteen different taps. The maximum and minimum power required by each tap when tapping consecutive test pieces is given in inch-pounds. The taps Nos. 6 and 8 had a slightly poorer form of flute than the rest and did not cut as smoothly nor as easily. Table II shows the effects of variations in the tap drill sizes as well as the effect of different lubricants. In this chart, which is the final result of a long series of tests, it is assumed, for comparative purposes, that the breaking strength is 100, and the strain produced by tapping holes under different conditions is given as a percentage of this. The power required to break a properly made ½-inch, 13 threads per inch, U. S. S. tap, is approximately 1000 inch-pounds; hence by multiplying the percentage given in the table by 10, the actual average power required, in inch-pounds, may be obtained. The test pieces were common hexagon cold punched nuts, accurately reamed to the respective sizes of holes, the taps being regular taps taken from the stock-room.

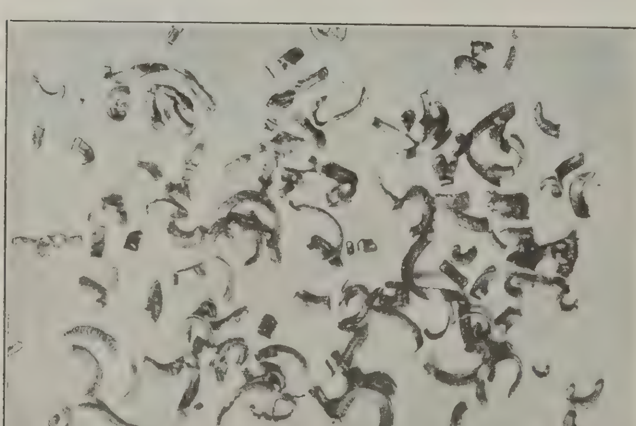

Fig. 12. Chips produced by Tap C, Fig. 8

The points brought out by this series of tests were:

1.—The lubricants used, up to a certain point, have the same effect on the power required for cutting as if more or less metal were to be removed; for instance, to tap a one-half inch nut having a hole of 0.425 inch diameter, using machine oil instead of sperm oil, would have practically the same effect on the power required as if the diameter of the hole to be tapped were reduced 25 per cent of the total depth of the thread. It will be seen in the table that the power is approximately doubled in both cases. When changing from sperm oil, the increase is from 16.5 per cent to 34.2 per cent while when changing from 0.425 inch to 0.400 inch tap drill the increase is from 16.5 per cent to 35.5 per cent.

2.—Animal lard oil, sperm oil, and graphite and tallow mixture are the best lubricants of those tested.

3.—A good soap compound is better than mineral lard oil for tapping.

4.—Machine oil is a detriment instead of an advantage. Taps cut better dry than with this lubricant.

5.—The breakage of taps is greatly reduced by the using of a proper lubricant. Taps should never be used without a lubricant when tapping steel.

6.—The diameter of the tap drill hole should not be smaller than is absolutely necessary to give the required strength. If for any particular purpose the full depth of the thread is required, it would be advisable from a tapping standpoint to gain strength by using a larger size thread instead.

7.—If for any reason it is necessary to produce a thread of full depth, serial taps should be used, with the best lubricant obtainable.

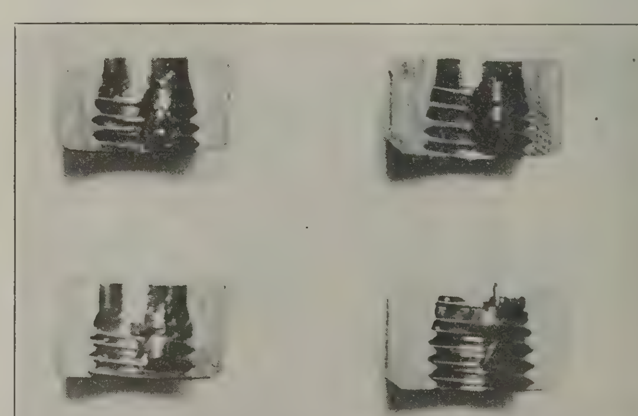

Fig. 13. Nuts tapped by Tap C, Fig. 8

8.—Every decrease of even one-thousandth inch in the diameter of the tap drill hole materially increases the power required for tapping and also the percentage of broken taps.

Referring to the sperm oil column in Table II, it will be

seen that the decrease of 0.015 inch in diameter from 0.425 to 0.410 inch, required only 6.5 per cent additional power, or 65 additional inch-pounds. This is an average of a little over 4 inch-pounds per 0.001 inch. A decrease in the tap-hole size of 0.010 inch, from 0.410 to 0.400 inch, required 125 additional inch-pounds of power, or an average of 12.5 inch-pounds per each thousandth inch.

Discussion of the Paper

In the discussion that followed the reading of the paper abstracted in the foregoing, several interesting points relating to the inspection and use of taps were brought out. Mr. A. A. Fuller spoke of the relation between errors in lead and angle diameter, and presented diagrams showing how limits can be established that take into account the combined effect of these errors. The principle involved was the same as that explained in MACHINERY, July, 1907, in an article entitled "Remarks on the Making of Hand Taps," but Mr. Fuller's method was a refinement of this, and the definite limits established were indicated. It was pointed out that the shorter the hole, the greater could be the allowable error in the lead; but as it is more difficult to tap a long hole with a minimum error than a short hole, it is best, in practice, to adhere to an allowable error per inch in the lead and to compensate for that error by varying the angle diameter. The increase in diameter, for one inch depth of hole and 60-degree thread, should equal the error in lead divided by 0.58. If the depth of the hole is less or more than one inch, it is only necessary to correct the

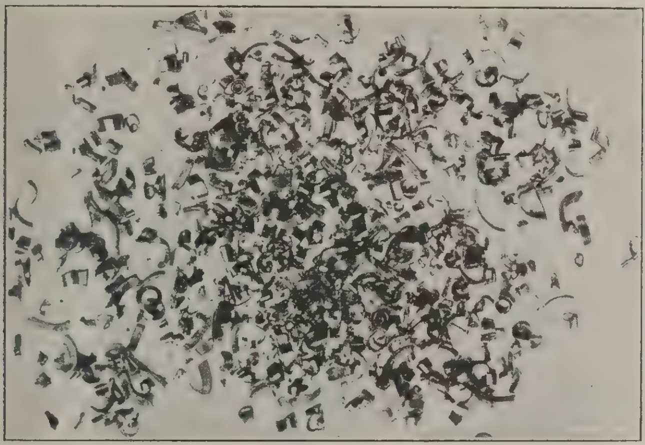

Fig. 14. Chips Produced by Tap A, Fig. 8

diameter in proportion. The error in lead, however, is more objectionable than the error in angle diameter, on account of the lack of bearing which the former produces.

Mr. L. D. Burlingame presented a paper the object of which was to arouse the engineering societies and the manufacturers to the needs for a fine screw thread standard with U. S. S. threads, similar to that adopted by the Engineering Standards Committee of Great Britain, for Whitworth screw threads. (See MACHINERY, October, 1906, "British Standard Fine Screw Thread.") A comparative table of different screw thread standards was also presented. Mr. George W. Adams called attention to the need of education among foremen and machinists relative to the measuring of screw and tap threads. He thought that the tap manufacturers could do a great deal in this respect by giving a greater amount of useful information in their catalogues, and he said that he believed that they would find it to their own advantage to do so, as it would lessen the number of complaints of their products, many of which are due simply to ignorance on the part of the user.

Mr. C. B. Russell stated that in order to determine the progress of the adoption of the U. S. standard thread as compared with the sharp V-thread, he had looked up the sales of the Wiley & Russell Mfg. Co., Greenfield, Mass., and had found that 93 per cent of all tapper taps sold were of U. S. standard, as compared with 7 per cent of the V-form. Of hand taps, however, 50 per cent are still of the V-form.

With respect to lubrication, Mr. J. E. Winter mentioned that in threading steel pipe, cottonseed oil gives even better results than lard oil. The only objection to this oil is that it tends to "gum up" the machines, but it can easily be cleaned off by kerosene oil. Cottonseed oil is much cheaper than lard oil. Mr. G. Pickop mentioned that grape-seed oil has about the same efficiency as lard oil, and is extensively used as a threading lubricant.

Mr. F. O. Wells stated that when new an ordinary commercial tap has an average factor of safety of 2. He also called attention to the influence of lubrication on the size of the hole tapped or screw cut. If a screw is cut with a die using lard oil as a lubricant, the size sometimes will be from 0.007 to 0.008 inch smaller than when a soap compound is used as the lubricant.

DON'TS FOR GEAR-HOBBERS

By A. E. BOWYER-LOWE*

Don't forget to keep your hobs sharp.

Don't forget to put the key in the hob.

Don't forget to put the covers on the gears.

Don't start the cut before the pump is working.

Don't expect a fine finish if you crowd the feed.

Don't mesh the dividing or feed gears in too tightly.

Don't forget to give the table-driving worm plenty of oil.

Don't forget to pack up the blank on as large a diameter as possible.

Don't bush a large gear to fit a small mandrel; make a large mandrel.

Don't forget to see that the blank runs true before you start cutting.

Don't try to cut a spiral gear without first keying the job to the mandrel.

Don't forget to pull the machine around by hand before starting a new job.

Don't take the numbers stamped on the change gears for granted; count the teeth.

Don't try to hob a wormwheel, without first clamping the hob carriage to the column.

Don't forget to look now and again at the wire rope holding the hob carriage balance weight.

Don't omit to center a tooth of the hob; it doesn't take long, and if it does no good it certainly does no harm.

Don't try to hob steep angle spirals without knocking off the partial teeth at the leading end of the hob.

Don't forget to use both ends of the hob, in addition to the center; it saves a lot of grinding, and the hobs last longer.

Don't set the feed knock-off when hobbing spiral gears, without being at hand to stop the machine as soon as it operates.

* * *

As an example of the effect upon production, and the consequent financial results, of the use of automatic machinery, under efficient management, I cannot refrain from mentioning the Singer Sewing Machine Co., where I have reason to believe that the application of automatic machinery has reached one of the highest marks in this country. It is a recognized fact that automatic machinery, under efficient management, has been the chief cause of the tremendous financial success of this company. The original investment of this company was only $600,000. It has declared a stock dividend of $75,000,000. It has paid $440,000,000 in dividends to its stockholders, and is now paying 12 per cent dividends on a capitalization of $100,000,000. The figures are those of Mr. Robert Hearne in a statement before the Senate finance committee on the Underwood steel bill at a hearing in Washington a couple of weeks ago. Mr. Hearne also claimed in this connection that in spite of the fact that labor is about 40 per cent cheaper in Europe than in the United States, sewing machines can be and are manufactured cheaper in the United States than abroad, a fact which can be attributed largely to the use of automatic machinery, superiority of American workmanship and that American labor is more experienced and better equipped. As a proof of his statement, he pointed to the fact that the United States exports annually $9,000,000 worth of sewing machines, meeting foreign competition in its home markets.—*From an address by A. L. Valentine on "Comparison Between Industrial Conditions in the United States and Europe," before the American Society of Swedish Engineers.*

THE CARE AND REPAIR OF HYDRAULIC JACKS*

By ARTHUR J. HUMPHREY†

Many mechanics who use hydraulic jacks are unfamiliar with their construction and the methods employed in the repairing of them. Hydraulic jacks are manufactured in a variety of types and sizes, but they are all fundamentally of the same construction. For the purpose of illustration in this article, I have selected a vertical single inside pumping type of jack. More recent types of jacks are on the market, some having double pumps for light or heavy duty, but there are probably in use to-day more jacks of the type chosen than of any

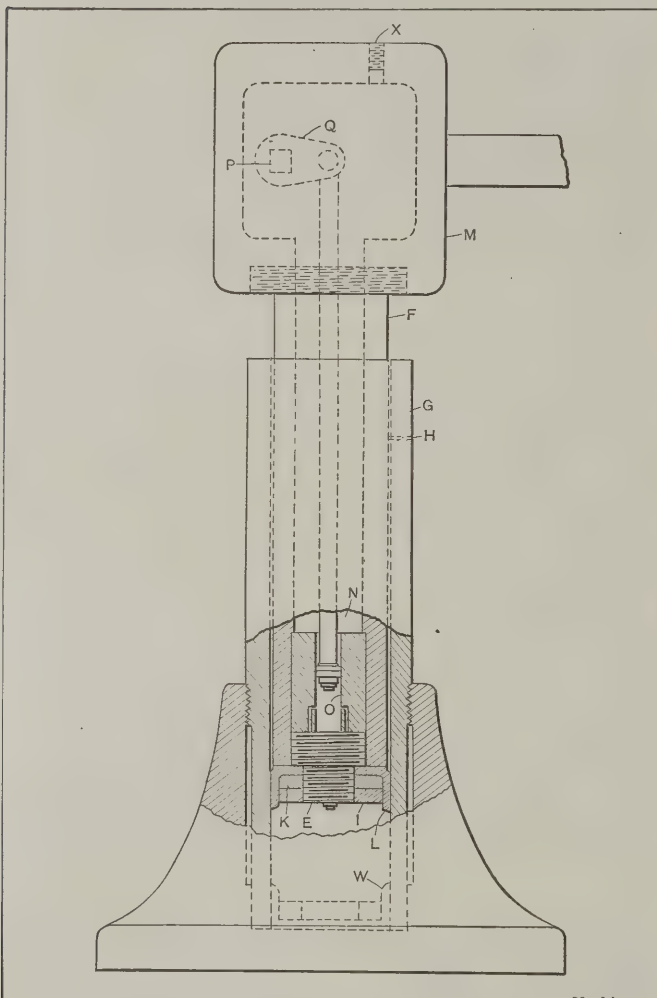

Fig. 1. Elevation of a Vertical Single Inside Pumping Type of Jack

other, and as the principle upon which all types of jacks work is the same, the following description will apply generally.

In the type of hydraulic jack illustrated in Fig. 1, the head and interior tube or ram form a reservoir in which the liquid flows to the pump. From the pump the liquid is forced by the downward stroke of the piston past the lower valve into the cylinder, and as the latter is closed at the bottom, the ram rises to allow space for the liquid. When lowering, the lower valve *A*, Fig. 2, is pressed from its seat by the end of the piston rod, and the liquid returns to the upper part of the jack by passing around the piston through small port-holes *B*.

To illustrate the proper procedure to follow in repairing a hydraulic jack, suppose that a jack has been reported as failing to work. Now the jack may fail in a number of ways and from various reasons, and the nature of the failure may indicate the location of the trouble and how to remedy it. For instance, there may not be any liquid in the jack, in which case the jack will certainly not work. To remedy this, it is only necessary to fill the jack with liquid, provided it has not been emptied long enough to dry out the leather packing on piston and ram. If the jack raises the load, but will not lower it, the bottom valve *A* is probably too short, so that the piston when clear down will not force the valve from its seat. To remedy this a longer valve is inserted, or if there is no valve available and it is necessary to use the jack before one can be secured, a small amount of solder may be dropped on the end of the valve to lengthen it. However, this is not recommended, and should only be used as a makeshift.

If the jack lifts, but will not hold a load, it is evident that the liquid, after being forced into the cylinder, must be leaking out again. By observing the jack while under pressure, and noting whether the liquid leaks around the bottom or over the top of cylinder *G*, we can determine which particular packing leather needs renewing. If no leak appears at these points, the liquid must be slowly leaking to the top of the jack through the ram valve *A*, piston valve *C* or around the piston packing *D*.

The valve seats and piston packing if only slightly cut will allow a light load to be raised quickly, but as the liquid leaks out the ram will slowly drop down again. Of course, if the seats are cut considerably, the jacks will not raise or lower at all. It is sometimes found that pieces of grit or dirt lodge on the valve seats, or the valves stick to their seats and prevent the jack from working. By giving the jack lever a firm quick jerk up and down, the dirt may be dislodged and the valve released. If when pumping or under pressure the lever rises

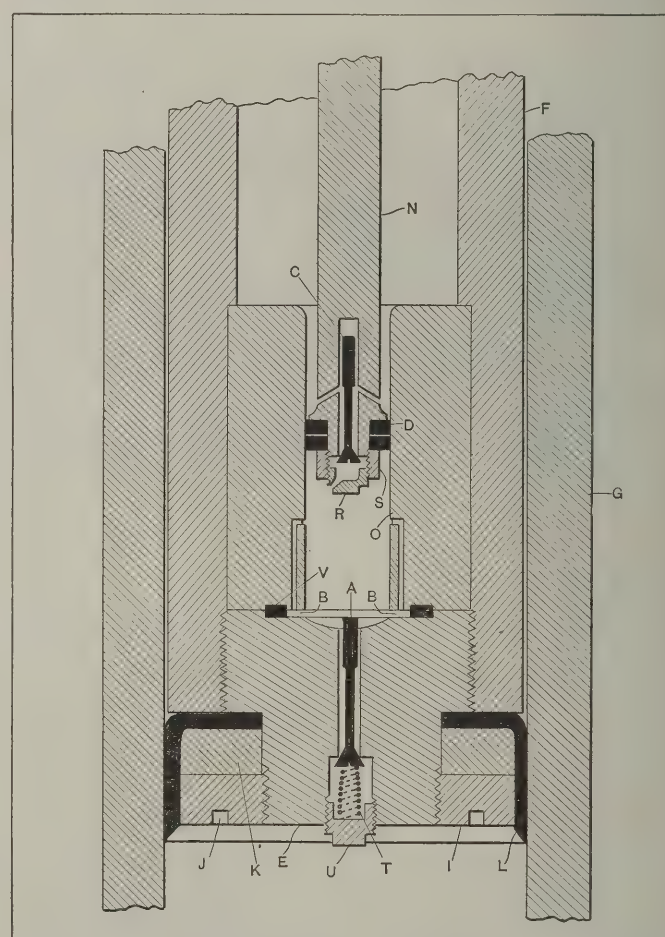

Fig. 2. View of the Principal Working Parts of the Jack shown in Fig. 1

when the hand is removed, there is something under the ram valve *A*, or the seat is cut so that the liquid returning through the pump plug *E* communicates pressure to the piston, raising it to the top of its stroke. Probably the most common jack failure is that of not raising the load due to leakage in the valves or looseness in the pump packing. Assuming that such is the case and that it is necessary to overhaul the jack, proceed as follows:

Referring to Fig. 1, remove the ram *F* from the cylinder *G* by pumping it up as far as possible and lifting it out of the cylinder. If the ram is too heavy, or the packing too tight to permit this, the ram may be entirely removed by driving a wooden plug into the small vent hole *H* in the side of the

* For additional information on hydraulic jacks and kindred subjects, see the following articles previously published in MACHINERY: "Dudgeon 'Universal' Hydraulic Jack," March, 1910; "Notes on the Manufacture of Hydraulic Machinery Gathered in the Shops of the Watson-Stillman Co.," October, 1899.

† Address: 144 Teller Ave., Grand Junction, Colo.

cylinder. This vent hole limits the travel of the ram, so that when it is plugged and sufficient water is poured into the reservoir to entirely fill the cylinder, the ram can be removed. If it should so happen that the ram cannot be pumped out, it may be necessary to pull it out with a crane, or force it out with a long lever. The jack lever should be pressed down before attempting to do this.

Let the liquid stay in the jack cylinder for the present, and grip the ram in a vise, taking care not to mar it. Unscrew the nut I (see Fig. 2) with a spanner fitting in the holes J and remove the ring K and the ram packing L. Now unscrew from the ram the pump plug E, and the head M, Fig. 1. The pump piston N may now be withdrawn from the pump cylinder O. If it is desired to inspect the socket packing, this may be done by loosening the set-screw and withdrawing the socket P from the arm Q. To renew the packing, cut a washer from sole leather, making the inside of the diameter slightly smaller than the socket, and the outside diameter the same as the recess. After inserting the new packing washer, remove all small pieces of leather which have been cut off from the washer, then drive the socket in place again through the ram and tighten the set-screw.

To examine the pump cylinder O to see if it is cut, drive it out with a wooden plug. If the cylinder is badly worn it

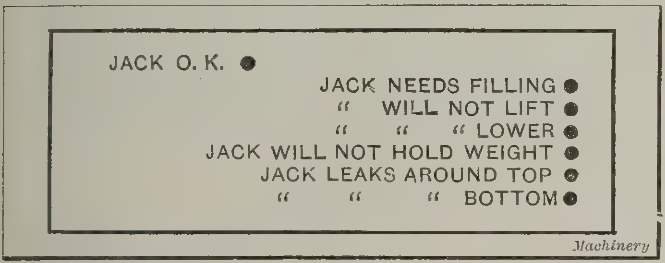

Fig. 3. Repair Report Nameplate fastened on Each Jack in Use

should be trued by reaming. Then force the cylinder over the piston and note if the piston packing is a tight fit in the cylinder. Sometimes it will be found that the piston packing is tight at the ends of the cylinder but quite loose in the middle, indicating that the cylinder has become worn where most of the travel is. If this is found to be the case, it is necessary to ream the cylinder and straighten it up, removing as little material as possible and using oil as a lubricant. After enlarging the cylinder, the piston packing must be renewed. To do this remove the brass valve bonnet R, piston packing ring S, piston packing D and valve C. Now insert a new packing leather washer on the piston, then a cup packing leather, with the cupped side facing bottom of jack; then screw up piston packing ring fairly tight, and fit the packing in the cylinder with a clean file.

Proceeding with the inspection, examine the valve C and its seat; the latter will usually be found to be all right, but if the seat is deeply cut, it should be "reset," with a set having an included angle the same as that on the valve. If the valve is much worn a new one should be put in. An old valve may be fitted, by carefully filing and then grinding it into the seat with oil and flour emery. If the ram packing L has become worn and the liquid has been leaking over the top of the cylinder or through the vent hole, place a strip of thin tin around ring K. After ascertaining that all the port holes, etc., are free from dirt and grit, assemble the ram by replacing the head, piston and then the cylinder. Before replacing the pump plug E, inspect the leather washer V to see that it makes a tight joint between the plug and cylinder. If it does not fit tightly, a new one should be inserted. Examine valve A and its seat and grind them if necessary. After the plug E is in place, the valve A should be inserted and tested, to see whether it will release the jack or not. To ascertain this, press the valve to the seat and force the piston down to the bottom of the cylinder, at the same time observing if the valve is pressed from its seat—a space of 1/8 inch is sufficient; then replace spring T, bonnet U, ram packing L, ring K and nut I, and empty the liquid from the cylinder G.

The bottom packing W, Fig. 1, seldom gives trouble, but if it should become necessary to renew it, remove the old packing and drive the new packing and ring in from the upper end of the cylinder by means of a wooden plug, which is slightly smaller than the cylinder bore. If the cylinder is badly cut and it is impossible to renew it, it can be repaired by reboring it and then forcing in a cold-drawn tube lining of the proper size.

After washing out the cylinder, wipe and oil it and then insert the ram. A handy appliance to assist in starting the packing into the cylinder, is a clamp made of thin sheet iron. This clamp encircles the packing and the ends are turned outward to receive a small bolt for tightening it. After pressing the jack lever down in order to open the valve so that the air may escape, push the ram down and strain the liquid into the jack through the filling and air plug X. The liquid recommended for use in hydraulic jacks is as follows: To one part of grain alcohol add two parts of water. This liquid is probably the best as it does not freeze in cold weather, corrode the pump, gum and clog the valve, and has not a deteriorating effect on the leather packing. Never fill a jack without straining the liquid.

After a jack has been overhauled, it is advisable to put it under pressure and let it remain so for a few hours. This will test the jack and set up the packing. If the jack has been fitted with new packing, it is well to let it remain over night before using it in order that the leather may be thoroughly soaked. If the repair has been handled in the proper manner the jack will give good service. It is essential, however, to keep it in good order, and without this precaution it is useless to expect satisfactory service from it. Most of the trouble met with in using hydraulic jacks is caused by neglect—allowing rust or foreign substances to collect, or broken and dried-up packing to remain; another precaution is not to overload the jack. The ram should be down when the jack is filled to prevent using more liquid than the reservoir will hold. If a jack is full when the ram is run out, and the cylinder under the ram is also full, it would be possible to burst the reservoir if the ram was lowered while under load and the air-hole in the reservoir had become plugged.

Always keep the ram quite down within the cylinder when not in use, otherwise the piston and ram packing may be out of the water and so become dry. For the same reason do not jack a load up to the full extent and let it remain so for several days, rather block under the load and remove the jack. Do not push the operating lever down too quickly, nor check the lowering of the load suddenly, especially under a heavy load. The sudden checking of a heavy load traveling at a high momentum, is likely to swell the cylinder to a permanent set, which will ruin it. To lower the weight, push the lever to the bottom of the stroke, then take it out and turn it with the projection upward, and with a slight pressure of the hand, the weight may be lowered as slowly as required and stopped at any point.

In large shops and round-houses where a number of hydraulic jacks are in constant use, the repairs may be made much more quickly by adopting the following system: A brass plate, Fig. 3, similar to a nameplate is attached to each jack, say on the outside of the cylinder, and a number of small holes drilled and tapped as shown, and provided with a thumb-screw to fit the hole. When the jack is sent in for immediate repair, whoever has condemned the jack, should remove the screw from the hole opposite "Jack O. K." and place it in the proper hole, designating why the jack has been sent in for repairs. Each jack is numbered and a record is kept by the man in charge of repairs; then by noting in which hole of the plate the thumb-screw has been placed, and by referring to the record book to see what repairs were made in the past, it is possible to determine very quickly just what must be done to make the jack fit for service as soon as possible. After the jack is repaired, the thumb-screw is placed in the "Jack O. K." hole again. Of course a printed report blank or card sent in with the jack would answer the same purpose as this plate, but it is difficult to get the mechanics using the jack to take the time and trouble to fill out the blank, and the thumb-screw is much handier. The plate may be cast or cut out of sheet brass and stenciled, or a printed card may be pasted on it and covered with white shellac.

NARROW VS. WIDE GUIDES FOR MACHINE TOOLS

In the January number of MACHINERY, Mr. J. S. Detrick, of the Detrick & Harvey Machine Co., explains why his firm has adopted the narrow guide for machine tools in preference to the wide, and gives the readers to understand that by reducing the ratio between the length of the guide and the width it was found that cross-winding was considerably reduced.

Theoretical considerations of the problem indicate, however, that the width of the guide has no vital influence upon the amount of cross-winding which can take place, but that the length of the guide has. This is explained in the following treatment of the case. Let $L =$ the length of the guide; $B =$ the width of the guide; and $db =$ the amount of play between the surfaces of the guide and those of the sliding part.

These conditions are indicated in the accompanying diagram in which the amount of slack or play is shown considerably exaggerated. The angle α is the angle of cross-winding of the sliding part on the guide, this angle being formed by the diagonal of the sliding part in two positions, namely, the intermediate or normal position and one of the extreme positions. Let

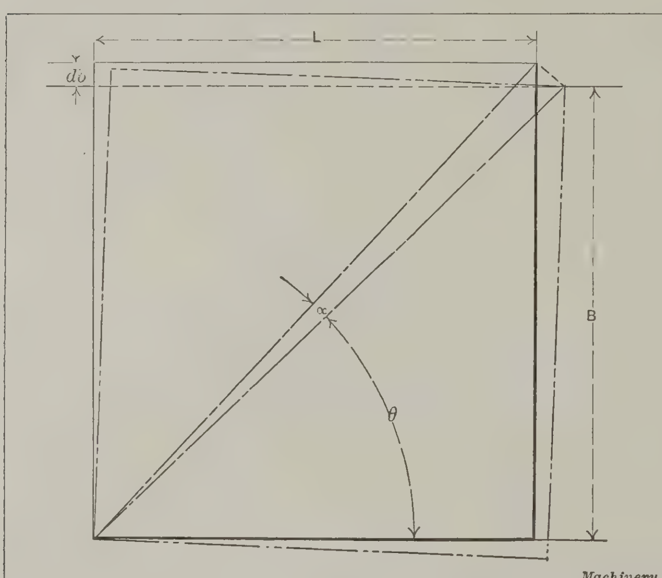

Fig. 1. Showing that the Angular Displacement for Given Clearance is nearly the Same on Wide and Narrow Guides

the length of this diagonal be denoted by x. Then, from an inspection of the diagram, it will be seen that

$$\frac{B + d\,b}{x} = \sin(\theta + \alpha) = \sin\alpha\cos\theta + \cos\alpha\sin\theta$$

Now, $\sin\theta = \dfrac{B}{x}$; $\cos\theta = \dfrac{L}{x}$ (practically); $\sin\alpha = \alpha$ (practically) because α is very small; and $\cos\alpha =$ unity for the same reason. Hence,

$$\frac{B}{x} + \frac{d\,b}{x} = \alpha \times \frac{L}{x} + 1 \times \frac{B}{x};\ \text{therefore}$$

$$d\,b = \alpha \times L,\ \text{and}$$

$$\alpha = \frac{d\,b}{L} = \frac{\text{amount of slack}}{\text{length of guide}}$$

This shows that the amount of cross-winding is inversely proportional to the length of the guide or slide, always assuming, of course, that the amount of slack or play is a very small quantity, and that the width-dimension is not a factor in this connection.

This conclusion is opposed diametrically to the conclusion Mr. Detrick arrived at as the result of practical considerations, and it would be very difficult indeed to explain the difference between them. One explanation which has occurred to the present writer is that it is much easier to machine narrow guides which are reliable and parallel than it is to machine wide guides possessing the same qualities. This appears, however, to be a point which requires the results of a series of reliable experiments for its satisfactory elucidation.

Sheffield, England GEORGE W. BURLEY

[Although it is true that the angle of deflection due to cross-winding is the same with wide and narrow guides, other conditions being the same, the lateral pressure on the sides of the guide and slide is greater on a wide guide than on a narrow guide for any given eccentric load. Referring to the diagram,

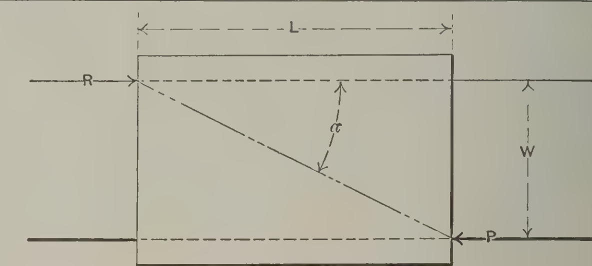

Fig. 2

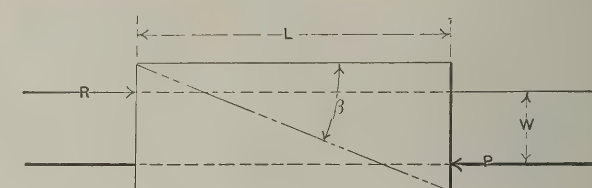

Fig. 3

Figs. 2 and 3. Showing that Lateral Friction and Wear are Greater on Wide Guides than on Narrow Ones

Fig. 2, suppose an extreme case in which the pressure required to move the slide is applied at one corner directly over the edge of the guide and the resistance to movement is all at the diagonally opposite corner, as shown at P and R. Then the turning moment is $\dfrac{P \times W}{L} = P \tan\alpha$. In the case of the narrow guide, Fig. 3, it is apparent that $P \tan\beta$ will be less than $P \tan\alpha$. Hence the greater angle α is, the greater will be the lateral pressure, approaching infinity as W becomes very wide or L very short. Therefore friction and wear are greater on wide guides than narrow ones.—EDITOR.]

POWER REQUIRED TO DRIVE REAMERS

Recently we wrote to three manufacturers of reamers and one of our prominent colleges asking if they had ever made tests to determine the difference in power consumed as between three-groove spiral chucking reamers and four- or six-lip parallel reamers. None of them had made tests or knew of any results to which they could refer us.

With so much being written on efficiency and economy in manufacturing, is it not rather curious that there should be no data on this subject?

The writer has used both kinds of reamers, and knows there is a great difference in the amount of power required to drive these reamers. The feed and speed that can be used with spiral reamers is much greater than with parallel reamers and much less care is required for the belts. In fact we can almost feel safe in saying that the saving is fifty per cent. We can get all the data necessary as to rake, clearance, etc., on lathe or planer tools, also on drills. We can get the horsepower consumed driving these tools with these various clearances and angles, but who can tell us the difference in horsepower consumed as between three-groove spiral chucking reamers and four- to six-lip parallel reamers?

Auburn, N. Y. A. A. BERTRAND

DEVICE FOR TESTING AND MEASURING GEARS

The device shown in Fig. 1 has been used for several years with very satisfactory results. Differences in diameter and eccentricity of 0.01 millimeter (0.00039 inch) can be measured by it, and the exact meshing of a couple of gears can be accurately tested. On the cast-iron base are fitted two slides, each being provided with a spindle to hold the gears to be tested. The slide to the right is moved by means of a long adjusting screw; the one to the left has only a very limited adjustment, but transfers its motion, greatly magnified, to an index placed on the front side of the base. Fig. 2 is a longitudinal section of the device; it clearly shows how the motion is transferred to the index, which measures the differences in eccentricity and the errors in mesh with great accuracy. To detect differences in eccentricity, it is most convenient to place the gear to be tested on one spindle, and to use a blank with a single tooth on the other. This tooth is meshed in succession with all the teeth of the gear under test, and by observing the different positions of the index while each tooth is measured, the eccentricity may be determined with great accuracy.

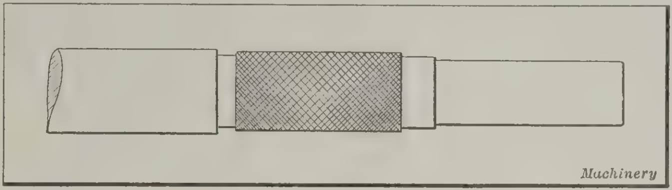
Torino, Italy. C. Boella

SAVING A SHAFT BY KNURLING

It has been common shop practice to condemn shafts, axles, etc., which have not met the allowance required for a press fit. This practice has made the manufacturer as well as the mechanic suffer for slight errors, and the junk dealer alone has profited. The manufacturers have lost thousands of dollars yearly due to small errors, such as shafts or axles being, for example, 0.0005 inch or 0.001 inch too small for the gears, pulleys, collars, flanges, etc., into which they are to go, or because commutator shells are from 0.0005 to 0.001 inch too large for a press fit.

Here is where the knurl plays a big role by rectifying even larger mistakes in a few minutes. Suppose that a commutator shell, pulley, or gear has accidentally been reamed or bored 0.001 or 0.005 inch too large. Instead of scrapping and duplicating these parts, put the shaft between the lathe centers, and knurl the seat for the press fit as shown.



Saving a Shaft by Knurling

The knurl should be coarse and can be straight, spiral or crosscut, and of any size or width, although for a small shaft a narrow knurl is required. After knurling, the shaft will be about 0.020 inch larger, depending upon the coarseness of the knurl. After this operation the shaft can be turned down again to the press fit allowance. This simple operation will prove very satisfactory in any line of work where press or shrinkage fits are used. J. E. U.

MULTIPLE-THREAD INDEXING IN THE LATHE

The following formula will be found useful to any machinist or toolmaker. The writer has had occasion to cut multiple-thread worms or spiral gears in the lathe, and in not one instance has the operator been able to do the proper indexing. It is quite simple to index for a double or triple thread, but few average workmen know what to do when the number of threads is greater than that. Therefore the writer has formulated the following rule which will cover every case:

Multiply the number of threads per inch of the lead-screw of the lathe by the lead of the spiral to be cut, and multiply this product by the number of teeth in the gear on the lead-screw; then divide that product by the number of starts or teeth in the worm or spiral. The quotient is the number of teeth the lead-screw gear will have to be turned to give the proper indexing.

For example, we want to cut a spiral gear having 8 starts or teeth, with a lead of 1½ inch in a lathe having a lead-screw with 6 threads per inch. We first figure our gearing for the lead, which gives a gear having 24 teeth for the lead-screw. According to the rule, we then have

$$\frac{6 \times 1\frac{1}{2} \times 24}{8} = 27$$

teeth, as the number of teeth the lead-screw gear must be turned. Cut the first thread, bring the lathe to a stop, mark the intermediate gear and the gear on the screw, disengage them, move the lead-screw one full turn and 3 teeth, engage the gears, and the next thread may be started. Repeat this until the gear is finished.

Of course if the product in the formula does not contain the divisor without a remainder, the gear on the lead-screw must be changed until one is obtained which will give the desired results. The ratio must, of course, be retained.

Detroit, Mich. John G. Paine

[The reason why this rule will give correct results may not immediately be apparent. It is evident that what we want to do is to move the carriage forward a distance equal to the distance from one thread to the next, that is, equal to the linear pitch of the worm; in the example given this distance is 1½ ÷ 8 inch. As the lead-screw has 6 threads per inch it makes 6 revolutions when moving the carriage one inch. Hence,

to move the carriage $1\frac{1}{2} \div 8$ inch, it will make $(1\frac{1}{2} \div 8) \times 6$ revolutions. For each revolution 24 teeth are engaged. Hence, the total movement from one thread or start to the next equals $(1\frac{1}{2} \div 8) \times 6 \times 24$, which may also be written in the form used by our correspondent.—EDITOR.]

THE PRINCIPLES OF PROJECTION

The writer believes that the general principles of projection—the reasons why the views are placed on a drawing the way they are—are not generally understood by mechanics and sometimes not even by draftsmen. In America, the method indicated in Fig. 2 appears to be universal, but in England there is really no universal way of projecting one view from another, as some use first-angle and some third-angle projection. In Fig. 2 is shown what is ordinarily termed third-angle projection, and which, undoubtedly, is the best way to show an object in a drawing. In this case the end views are placed nearest the end from which they are viewed. The plan is placed above the front elevation, and the bottom view or inverted plan is placed below the front elevation. An excellent way to demonstrate to students the reasons for showing the views in this manner, is as follows: Imagine a box having six glass sides as shown in Fig. 1. Place an object inside of the box and draw the view of each side on the face opposite it. Then open the box and the views will be presented in a plan as indicated in Fig. 2. The writer has found this to be the best way of demonstration, and the easiest way to remember.

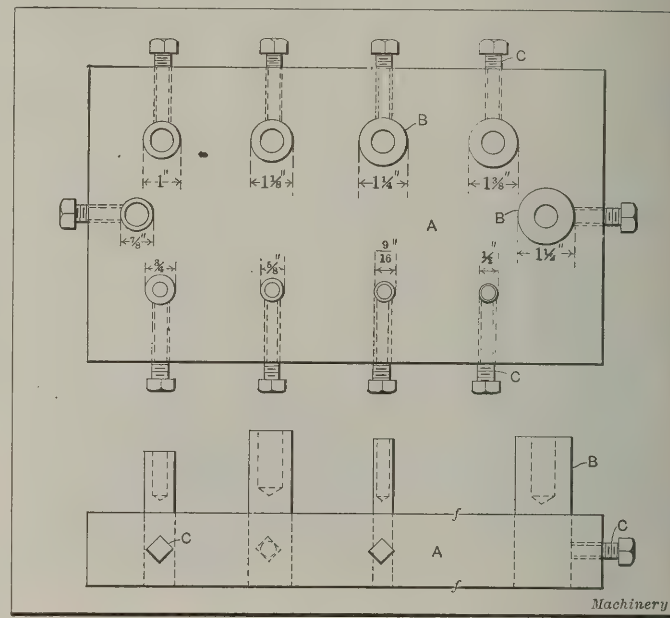
FIXTURE FOR HOLDING LEVERS, ETC., WHEN FACING THE BOSSES

Every mechanic knows how troublesome it is to face the bosses of levers and brackets and get the faces true or at right angles with the holes. When the lever or bracket is strapped onto the drill press table, it is liable to spring in clamping, which results in the faced surface of the boss not being true with the hole.

The fixture shown in the accompanying illustration consists of a cast-iron parallel block *A*, 14 inches long by 8 inches wide by 2 inches thick, finished on both sides. This block has ten holes drilled in it varying in diameter from ½ to 1½ inch. Of course any number of holes can be drilled and the block made of a suitable size to handle the work for which it is to be used. The holes drilled in the block *A* are made to receive the studs or pins *B* which should be made from cold-rolled steel and casehardened. These studs have a hole drilled in one end to receive the pilot of the counterbore, and are adjustable in the fixture, being held when set to the desired height by means of the set-screws *C*. In the fixture shown in the illustration, the holes in the small studs are made ⅜ inch in diameter, while the holes in the large studs are made ⅝ inch. The studs *B* should be made to fit the hole in the lever or bracket snugly so that the boss will be faced true with the hole.



A Fixture for Holding Levers or Brackets when facing the Bosses

In use, the block *A* is fastened by clamps to the drill press table and the hole in the stud *B* is set in line with the pilot of the counterbore. The lever or bracket, after the hole has been drilled, is slipped onto the stud *B* and swung around until it touches one of the other studs, which acts as a stop. Stud *B* may now be set to the desired height, so that the lever will be faced to the required distance when the counterbore touches the top face of the stud. DAVID MCINNES

Plainfield, N. J.

CHAIN CASES

In the February number of MACHINERY, Mr. J. F. Winchester defends the unprotected chain on motor trucks. It seems to be his contention that trucks operate under conditions and on roads that are worse than those under which pleasure cars operate; hence, chains should not be protected. The truth of relative road conditions alone might properly be questioned, because touring cars are usually to be found wherever there are trucks, and very often in places impossible of access by trucks; but, granting the necessity for operating trucks on poor roads, does it not make the need of a protected chain all the more urgent?

Bearings in machines that do not operate in dirty surroundings do not need protection, as, for example, in the high-speed stationary engine. We have seen them operate successfully without being enclosed, and it was only a few years ago that completely enclosed splash oil systems of lubrication were first made. Such engines are now found in the cleanest power houses built, where the enclosure can be of value for facilitating lubrication only. Where there is dust and dirt, the covering serves a double purpose; the dirtier the surroundings, the greater the value of the cover. Certainly, if trucks run on dirtier roads, they are in greater need of protection.

Chain cases do not require much space on a vehicle and need not lessen the clearance between road and sprocket more than an inch, at most. Any driver who is competent enough to negotiate a road that is full of ruts without chain cases on his car, but who would break the cases, were the same chains

covered, would be a refined driver indeed. Besides, can a sprocket and chain withstand more rough treatment than a solid braced cover?

Chain cases as ordinarily located are in a large measure protected by the wheels. Hence, they are in less danger than gear boxes, which are invariably located in the center of the rear axle and directly exposed to the point where obstructions on unpaved roads usually exist. Yet, geared drives are invariably enclosed! The writer has several times repaired gear cases broken by striking obstructions on country roads. In every case, however, the vehicle was not immediately rendered useless. The oil ran out of the gear case, to be sure, and for that reason the transmission efficiency may have been slightly impaired by the accident, but the vehicle was still operative. If the uncovered gears had struck the obstructions, would they have kept going merrily on?

It is not illogical to compare chains and gears because of the difference in construction. In the operation of each form there is sliding contact—more in the gears than in the chain, true enough—and wherever there is sliding contact, abrasion is augmented by grit and dust; everybody knows that. The figures reported in the November issue of MACHINERY show this nicely. Chain manufacturers cannot compel machine manufacturers to cover the chains they use, nor do they insist on it strongly. It might be of interest, however, to know that one of the largest manufacturers of chains is endeavoring to show the user the importance of using cases, and in many instances this chain manufacturer's suggestions have been advantageously heeded. More data such as contained in MACHINERY'S November editorial will be of much value to automobile and chain manufacturers.

New York City W. F. SCHAPHORST

MORE COMMENT ON AUTO-TRUCK TRANSMISSION CHAINS

The use of uncovered chains is certainly indefensible on motor cars—trucks or touring. Any car, to be sure, is liable to have its chain break; but when that chain becomes laden with foreign material, the chain- and sprocket-wear increases to a great extent. The life of both the chain and the sprocket is shortened, and the car is out of commission oftener while renewals are being made. It is a small matter to design a chain case that can be removed quickly; the cost is nominal, and compared to the cost, the results are phenomenal.

No doubt the makers of chains know more about them than anyone else, so let me quote from the catalogue of one of the largest manufacturers of chains: "Chains should be housed and run in oil, the same as are gears, to give best results; but as an alternative they should by all means be protected from heavy grit or mud, the deposit of which increases the base diameter of the sprocket, resulting in rapid wear and elongation of pitch of both chain and sprocket." While we all did not wear out chains and sprockets on our bicycles, it is a matter of easy recollection how much easier "she" ran after we had taken off the chain and cleaned and greased it.

C. P. W.

WHY THE SHOP DOES NOT RETAIN THE SKILLED MECHANIC

In the January number of MACHINERY I noticed an article entitled, "Why the Shop Does not Retain the Skilled Mechanic," and would like to make a few comments on the opinions there expressed. I believe that the expert machinist and toolmaker is not required to the same extent today as he has been heretofore. Different methods of management are gradually eliminating the all-around man and developing specialists in all lines of work—expert lathe hands, planer hands, etc. Young men do not wish to start in as apprentices and work for \$3.00 to \$5.00 per week for several years, when they can start in with small experience on some one machine and earn considerably more. The young man of today does not want to waste his time—he considers it waste —by acquiring knowledge that he thinks he will never need. It is to be regretted that this type of man is becoming more and more common, but this is the reason, principally, why many large firms have discontinued their apprentice systems.

In regard to placing machinists and toolmakers on the honor system, it may be said, in the first place, that in very few shops does one now find any employes, except stenographers and bookkeepers, employed on the honor system. It has been proved that this system does not "work out" with the average man. It is too easy for him to be late or absent when no record is kept of his coming or going. Time-clocks would not have been installed if it had not been found to be necessary. Consider for a moment a large manufacturing plant employing, say, one thousand men. If only a few men were making a practice of being absent all or part of each day, the routine of the work would suffer. The time-clock is necessary for the simple reason that the average man thinks of no one's convenience but his own. It is much easier to come in late than on time, and those who may mean well enough, soon become careless.

It was also mentioned that it takes more skill to become a machinist or toolmaker than to become a draftsman, and, therefore, the former man should have as much, if not more, consideration than the latter. Perhaps the writer of the article referred to, never worked as a draftsman, and in that case he is excused for the remark. Comparatively few machinists or toolmakers, when they have finished their day's work, give a thought to it until the morrow. On the other hand, most draftsmen, no matter in what line of work they may be, have to study or work out problems that have come up in their daily work, at least, say, three nights a week. A writer in a magazine recently said that "men employed in engineering work have a most confining life for that very reason." Besides this, a draftsman has to work hard many years with his books before he is able to fill his position.

I do not mean this to be direct criticism of the position taken by the former writer, for he may have found the facts as he stated them to be true in his case; but the opinion I have expressed is based on the facts as I have found them in a number of large manufacturing establishments.

Philadelphia, Pa. EDWARD R. GLENN

A SIMPLE TAPPING FIXTURE

Having occasion to tap several thousand swaged nuts of the form shown in Fig. 1, a fixture to be used on a horizontal tapping machine, as shown in Fig. 2, was designed. This fixture consists of a cast-iron angle-plate A, to the front face of

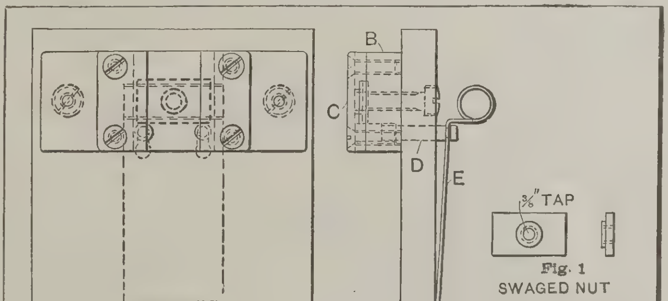


Fig. 1. The Swaged Nut. Fig. 2. The Fixture used for Holding the Nut while tapping

which is attached a soft-steel block B. Fastened to this block B are two guide strips C. Two hardened shoulder pins D which pass through the blocks A and B act as stops for the nut while being tapped. Attached to these stops and fitting over a groove turned on them, is a flat steel spring E. The holes in this spring are made keyhole-shaped, so that the spring can be inserted over the pins and then brought down into position, where it is held with the block F, a screw, and two dowel pins, as shown. The top of this spring is formed into a ring, so that it can be conveniently handled.

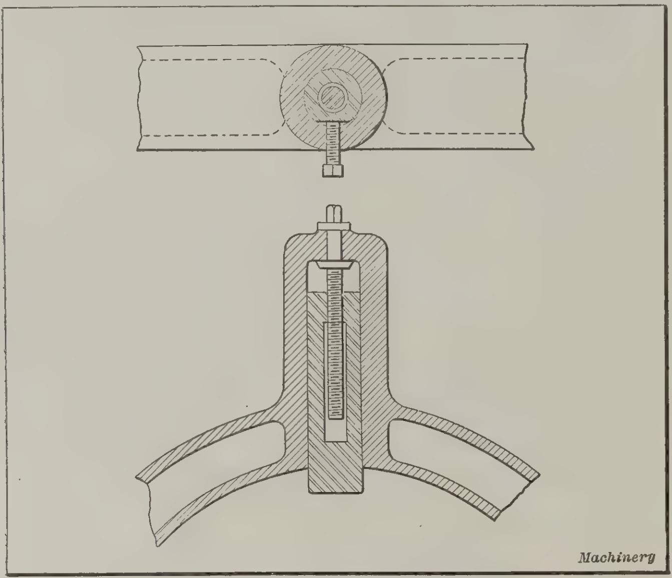
In operation, the nut shown in Fig. 1 is placed in the

guides, and rests on the pins *D*. The machine table is then moved forward, carrying the angle-plate, and the tap passed into the nut. The table is then withdrawn, and when the tap emerges, the spring *E* is pulled back, which withdraws the pins *D*, thus allowing the nut to drop into a pan placed on the table to receive it. This device can be cheaply made, but should be judged from its efficiency rather than its simplicity.

Detroit, Mich. ARON LAWRENCE

A LATHE STEADYREST OF UNCOMMON DESIGN

The accompanying illustration shows a lathe steadyrest which varies from that usually supplied by the lathe builders of today. The general outline and construction of the rest is the same, but the jaws are different. The ordinary rectangular jaw is replaced by a cylindrical piece fitting



A Lathe Steadyrest of Simple and Rigid Construction

snugly in a bored hole, as shown, which is adjusted by means of a screw. These jaws may be made of any material depending upon the work on which they are to be used. We use jaws made from steel on heavy lathes, when large cast-iron drums are turned. This construction is very rigid and is of simple design. H. TERHUNE

Plainfield, N. J.

THIS IS "ABSOLUTELY" TRUE

"Say, Bill, what was the matter with the boss and the young fellow that just left?"

"Well, you see, everybody, in the last few years, has been using the word 'absolute' in connection with the work turned out on their machines. That fellow came in and said to the boss, 'You ought to plane those plates on one of our machines; they plane absolutely true surfaces,' and I heard the old man tell him a little experience.

"'Young man,' he said, 'I want to give you a pointer. I had heard one fellow say that his machine grinds absolutely true, another that his turns absolutely true, another that his mills absolutely true, and another that his pulleys and shafting run absolutely true, for so long that I got the disease and agreed to build a machine for that old fellow down by the railroad track who hammers saws and does blacksmithing, that would grind saws absolutely true on their sides. Now I will tell you what happened to me because I did not know what the word 'absolute' meant. After I had built the machine and sent it down, and thought I had given him about enough time to pay for it, I decided to call around for the money. Now, I had seen some of the work turned out on it and had a letter from a man who had seen it wanting me to build one for him, so I felt sure everything was O. K.

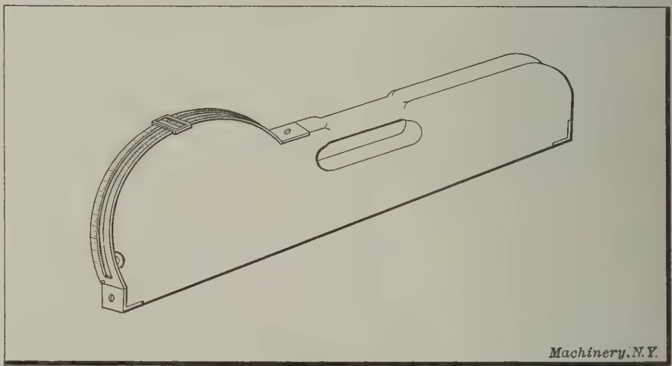
"'As I entered and stated my reason for calling, he asked me to look at some of the saws which were ground on this machine. He reached up on a shelf and got a nice new straightedge, and suspended a saw by a string hooked over the teeth and then held the straightedge against it. With the other hand he shoved the 0.004 inch blade of a feeler through, between the straightedge and the saw. Then without saying another word, he got my contract and pointed to the clause in which I agreed to produce a machine which would grind absolutely true. I requested him to put a saw in the machine and let me adjust it, and I proceeded to grind a saw. When I had it finished and the saw tallied with the straightedge, I called him over. He looked at it, and then got a surface plate about 10 inches square, and thinly covered it with lamp black and rubbed it over the surface just ground. Upon removing it, he informed me that the machine must grind absolutely true before he paid the bill.

"'Then it dawned upon me that I had used a word to convey one meaning that really meant another. I could not convince him of the injustice of his demands, and we went to law. My attorney could make no impression upon the court, which simply stated that if I agreed to build a machine to fly ten miles, the simple fact that it was impossible to do so did not entitle me to receive pay for a machine that would nearly fly. The above incident took place twenty years ago. We have since accomplished what was then considered an impossible thing, *viz.*, the flying machine, but are practically as far from producing machinery that does work absolutely true, as we were then. The only satisfaction which I got was that the machine was returned to me. I soon disposed of it, but it taught me a lesson.'" J. G. D.

GONIOMETER OR ANGLE-MEASURER

The goniometer, or angle-measurer, illustrated herewith is the invention of a German and is intended to measure the angle of an object on which it is placed without the use of any ways, screws, etc., it being merely necessary to lay the instrument on the object and read the angle off directly on the semi-circular scale at the left.

It consists essentially of a glass tube, bent into a circular form and filled with liquid; a bubble in this liquid, as in ordinary levels, tends to keep to the top. A sliding piece on a



The Goniometer, a German Instrument for Measuring Angles

circular scale is placed over the bubble and set in that position, thereby indicating the angle. This sliding piece also makes it possible to set the indicator and then remove the goniometer to a lighter place where the angle may be more easily read. In making this instrument, the one precaution necessary is to bend the glass tube containing the liquid to a perfectly circular form. ROBERT GRIMSHAW

Dresden, Germany.

A COUNTERBORING TOOL AND FIXTURE

While the automobile engineers are busy improving and perfecting their latest models, incidentally they are developing some very interesting machine and tool problems. The latest of these to come to the writer's attention was the facing and counterboring of a 5-inch diameter by 6-inch stroke cylinder. It appears that by the constant wearing of the piston rings upon the cylinder wall, a slight shoulder was formed near the extreme end of the piston ring travel in the cylinder. This shoulder however slight causes a piston knock when the piston ring reaches it. The resulting sound or knock could hardly be distinguished in the open, but as the knock occurs inside the cylinder which is closely connected with the crank case, the latter acts as a sounding box deceiving the ear to

such an extent that it is necessary to use a phonendoscope or vibracator to make sure of its location. To overcome this noise our engineer decided to relieve the cylinder bore at the upper end, so that the upper piston ring would travel about one-half its width above the counterbored recess. The tool shown in Fig. 1 was designed to perform this operation and was used in the fixture shown in Fig. 2, the fixture being held on a machine of the two-spindle vertical type which was formerly used for reaming cylinders.

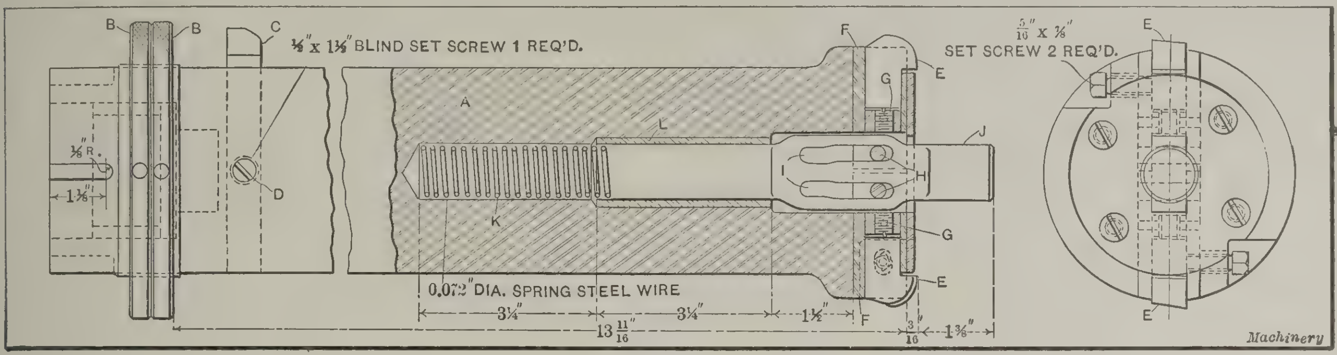


Fig. 1. Details of the Counterboring Tool

As shown in Fig. 2, the counterboring tool extends down into the cylinder to the required distance, and the tool-heads carrying the turning tools are operated by cam grooves in the central plug. The body of the tool *A* is made of machine steel, threaded in the upper end to closely fit the nose of the spindle of the machine. The total length of the body of the tool is 16 inches, and it is made of large diameter so as to afford sufficient support to the cutters to prevent chattering. The position of the counterbored recess is governed by stop collars *B*, which gage from the upper surface of the jig that holds the gas engine cylinder. Held in the body *A* by a screw *D* is a tool *C* which chamfers the open end of the cylinder to an angle of 45 degrees. The counterboring tools *E* are held in the tool-holders *F* and are adjusted by screws *G*. Driven into the tool-holders *F* are pins *H*, which operate in cam slots *I*, cut in the central plug *J*, the latter being operated upon by the spring *K*. The central plug *J* is fitted in a bronze bushing *L*, held in the body of the holder.

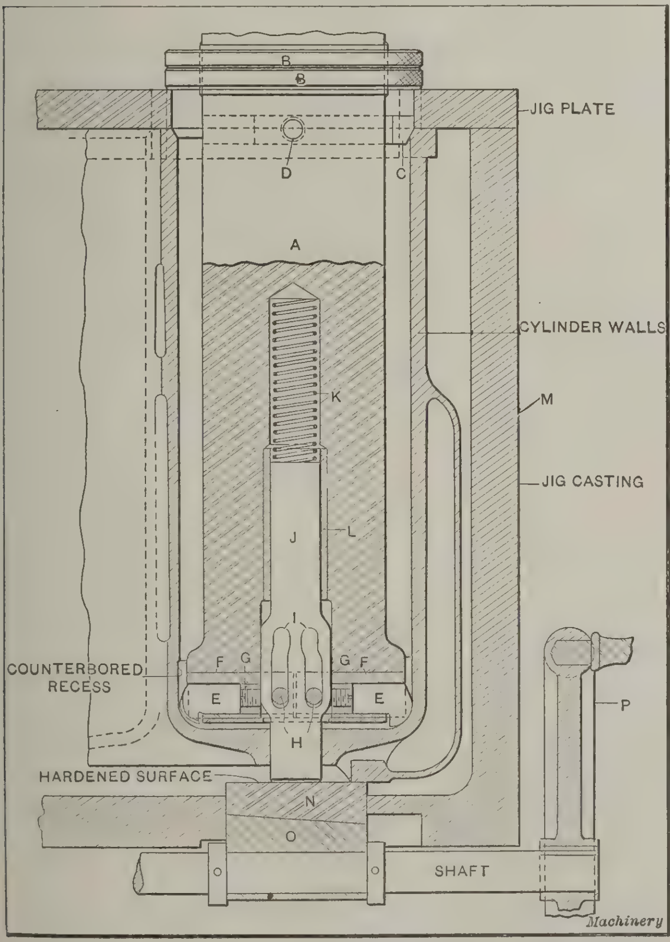

Fig. 2. Showing the Cylinder in the Fixture and the Counterbore at Work

In operation, the cylinder is clamped in the jig *M*, Fig. 2, and the body *A* inserted until the stop collars *B* come into contact with the top of the jig. At the same time the central plug *J* comes in contact with a hardened wedge *N*, which forces the former up into the body against the tension of the spring *K*—thus expanding the cutters. As the body *A* still continues in its downward movement, the cutters are kept to the same diameter by means of the straight portion of the cam slots, the extreme downward position of the cutters being governed by the washers *B* as previously mentioned. Adjustment for the central plug *J* is provided by a hardened wedge *N*, which is operated by the beveled plug *O* and handwheel *P*. The spring *K* has a very important function to fill, as the operation of the cutter depends entirely on its action. The tool-holders *F* are made from tool steel and are somewhat expensive to make, but as it is possible to hold short tools in them, a saving in steel is thus effected. The constant cutting in the hard scale and sand in the cylinder dome, requires frequent resharpening of the cutting tools, and when worn to the limit of the adjusting screws *G*, they must be replaced. The best high-speed steel obtainable is used for these cutters so that the smaller the cutter, the less the cost of maintenance will be.

Lansing, Mich. E. H. Pratt

SOME OBSERVATIONS ON GEARING

Speaking from practical observation and experience I believe that it is wrong to calculate the strength of steel gears as if they were able to continuously transmit two or more times the power transmitted by cast iron. I am not referring now to gears that run only intermittently, because with them it is more a question of strength than of wearing qualities, and I am referring only to ordinary steel forgings and castings, and not to alloy steels.

Ordinary cast iron on cast iron is a good combination so far as wear goes, while soft steel on soft steel, or on steel castings, is an exceedingly poor combination, as anybody can prove by using a steel shaft in a steel bearing. Why then should we expect steel teeth to wear as well as cast-iron teeth for the same load? And further, why should we expect them to endure under twice the load that cast iron is supposed to be able to carry? As a matter of fact, steel gears thus loaded are short-lived and uneconomical when run for eight or ten hours a day. I know of a great many instances that could be cited in support of this statement, and if any one of the readers of Machinery could name a case where steel gears will wear well when continuously transmitting anything like the loads allowed by the Lewis factors, I would be interested to know the details. I do not want it understood that I advocate cast-iron gears for I do not, but I advocate using the same factors when calculating steel gears as when calculating cast-iron gears, as far as the teeth are concerned. An ample margin for wear is just as important an economy for the purchaser of gears as it is in any other machine part. This is particularly true in the case of gears, where the labor cost is great in proportion to the cost of the material.

There is another thing that observation leads me to believe is more often done wrong than right, and that is the locating of the shaft centers for a pair of gears. I believe that they should be located enough closer than the theoretical distance,

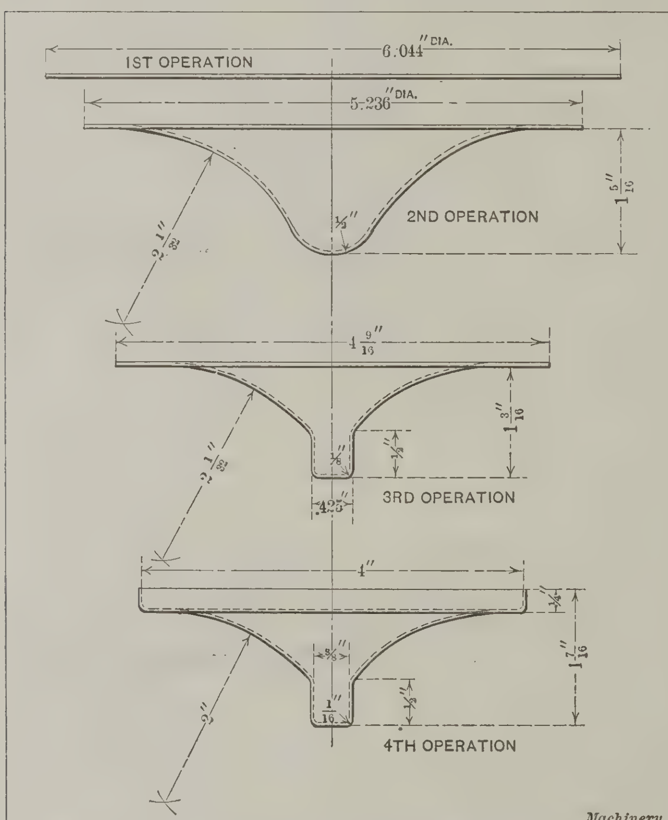
so that when the thrust of the teeth forces them apart by the amount of play there is in the bearings, they will be at the correct center distance. I believe that a great many breakdowns are due to the fact that the teeth do not mesh properly, because the centers of the gears are forced too far apart when loaded.

From a somewhat limited experience with worm-gear drives I have concluded that a well-designed worm and worm-wheel of high thread angle, made of the right materials and working well inside of the safe limits of pressure and speed, are much more satisfactory than two spur gears and two bevel gears to gain the same reduction and change of direction.

Scottdale, Pa. F. D. BUFFUM

THE DRAWING OF AN ODD-SHAPED CUP

In the February number, J. M. asks for advice relative to the drawing of an odd-shaped cup. In the writer's opinion this is a job in which considerable difficulty will be encountered. Owing to the small dimensions of the shank on this piece it does not seem feasible to do the work in less than four operations, as shown in the accompanying engraving.



Successive Operations in Drawing an Odd-shaped Cup

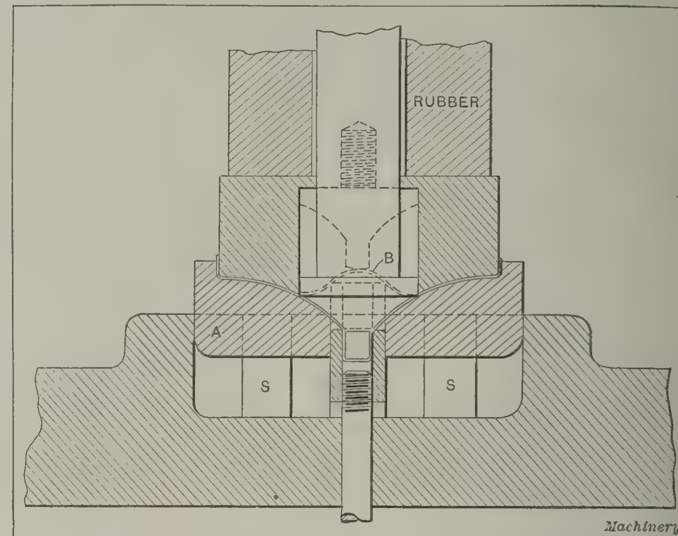
If it were attempted to do the work in a smaller number of operations, there would be considerable waste, in rejected pieces, as the metal would not flow fast enough to fill up, and the punch would break through.

As will be seen from the illustration, the metal is drawn out by easy stages until somewhat near the finished outline, before the sharp corners required are given to it. By the form of the question, the writer is led to think that J. M. is not equipped with good die-makers for making the dies. If that is the case it would be advisable to submit a sample of the piece required to some firm making a specialty of this class of work, so that this firm could bid on the dies, and decide exactly how they ought to be made and what would be the cost.

Fort Wayne, Ind. H. R. TALMAGE

DRAWING AN ODD-SHAPED CUP

In the February number of MACHINERY, J. M. asks for information regarding the tools necessary to make an odd-shaped cup. The accompanying illustration may serve as a suggestion as to the main features of the die equipment required. The dotted lines at *B* show the shape of the cup after the first operation, a combination cutting, drawing and embossing die being used for this. The dotted lines also indicate the location of the blank at the beginning of the working stroke of the second operation. With a two-inch stroke, provision must be made for the removal of the cup after forming. As a suggestion, the slots *S* are indicated, into which



Suggestion for Making Dies for Drawing an Odd-shaped Cup

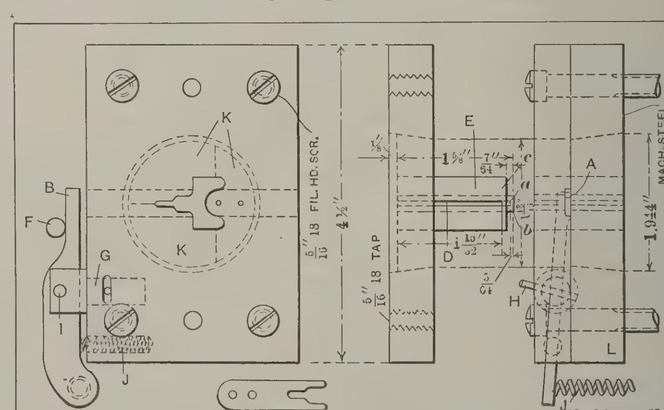
parallel wedge blocks are placed. These can be withdrawn after the stroke is completed, to allow the lower pressure ring *A* to fall and provide the required opening between the dies.

Columbus, Ohio. OTTO R. WINTER

A PIERCING AND CUTTING-OFF PUNCH AND DIE

An interesting punch and die for piercing and cutting off a typewriter part, is shown in the accompanying illustration. The stock which is a narrow strip, is fed through the channel *A* against the stop *B*, and is pierced and cut off by the punches *D* and *E*. The face of the punch *E* is made of varying heights, the forward part or face *a* and the following part or face *b* are both lower than the cutting-off face *c*, so that the slot will be cut in the blank before it is severed from the strip. The small holes in the forward end of the blank are pierced by the punches *D*, the faces of which are higher than the faces of the blanking and cutting-off punch *E*.

In operation, when the stop *B* is lifted, it swings in toward the die and rests on top of the finished blank, which is forced out of the channel when the strip is fed forward. When the blank drops out, the stop snaps down and engages the end of



Progressive Piercing and Cutting-off Punch and Die

the strip, and is forced by the latter against the pin *F*. The stop *B* rotates on the pin *G*, which is prevented from pulling out by the pin *H*. The stop *B* swings laterally on the pin *I*, and springs *J* are for actuating the stop.

The die proper is made up of three segments *K*, which are tapered and are driven into the die-block *L*. Two of these segments are symmetrical and can be milled out in one piece, then sawed apart before the taper for fitting them in the die-block is turned. To turn the taper on the die, the three pieces are soldered together and the punch is used as an arbor.

DESIGNER

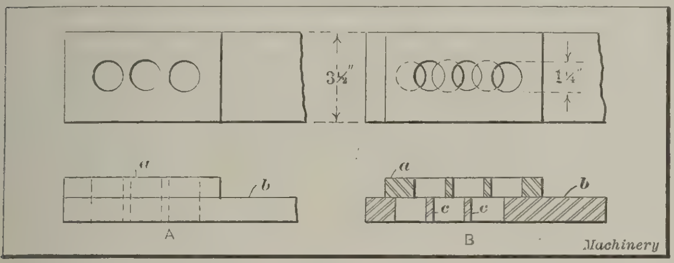
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this department. Write on one side of the paper only and draw sketches on separate sheets.

DRILLING ELONGATED HOLES

A simple method of drilling elongated holes is shown in the accompanying illustration. A plate *a*, which can either be made of machine steel and casehardened or furnished with hardened bushings, is clamped to the piece *b* to be drilled. The three holes, as shown at *A*, are then drilled

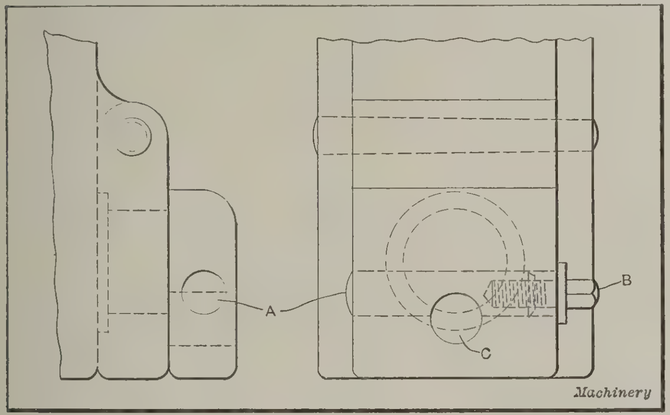


clear through, after which the block *a* is shifted to the position shown at *B*, and the remaining webs *c* are drilled out with an ordinary twist drill, ground square on the end. Preferably a high speed and light feed should be used; high-speed drills will be found to give better satisfaction than ordinary carbon drills.

SUBSCRIBER

EXTENSION TOOL-HOLDER FOR A SMALL SHAPER

In model and experimental work it frequently happens that the work to be handled in the shaper requires a tool projecting further than can be obtained with a regular tool. To meet such cases the clapper block shown in the accompanying illustration was made for the purpose of holding



an extension bar, in the end of which the cutting tool is held.

Referring to the illustration, *A* is a round rod into the end of which is tapped a hole for the screw *B*. A hole *C*, bored in the block at right angles to the rod *A*, provides an opening for the extension tool-holder. By tightening the screw *B*, after placing the tool-holder in position, the latter is held securely, the rod *A* acting as a clamp.

Hartford, Conn. F. CHARLES SCRIBNER

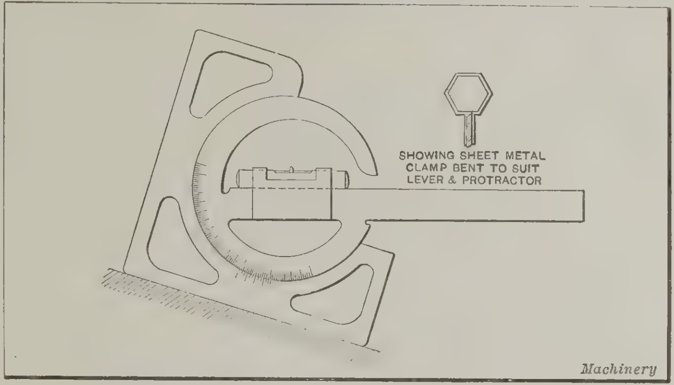
FACING WORK ON THE LATHE FACEPLATE

In facing on the lathe faceplate, it is common practice to pack up the work with tissue paper to prevent it from slipping around, and also to avoid the necessity of clamping it too tightly. Another method which is equally as good, if not better, is to deposit a thin coating of oil and fine emery between the work and the faceplate, spreading it evenly. This method allows a heavy chip to be taken when the work is clamped lightly. Still another method is to apply a thin coating of hot shellac to the faceplate, and also a thin coating to the side of the work that will be placed next to the faceplate. The faceplate is removed from the lathe and the work placed on quickly and moved around; then a weight is placed on it and left until the shellac is dry, after which the faceplate can be put on the lathe and the cut taken. This method requires no clamps at all, and was used with satisfactory results by the writer in taking a finish-facing cut from a cast-iron disk 6 inches in diameter and 1/32 inch thick.

Newark, N. J. H. E. WOOD

OBTAINING ANGULAR MEASUREMENTS WITH A B. & S. DRAFTSMAN'S PROTRACTOR

It frequently happens that a draftsman finds it necessary to measure an angular surface on a machine, but cannot do so because there is no finished surface to take the measurement from. The accompanying illustration shows how an angular measurement can be taken. This is accomplished by means of a Brown & Sharpe draftsman's protractor to which

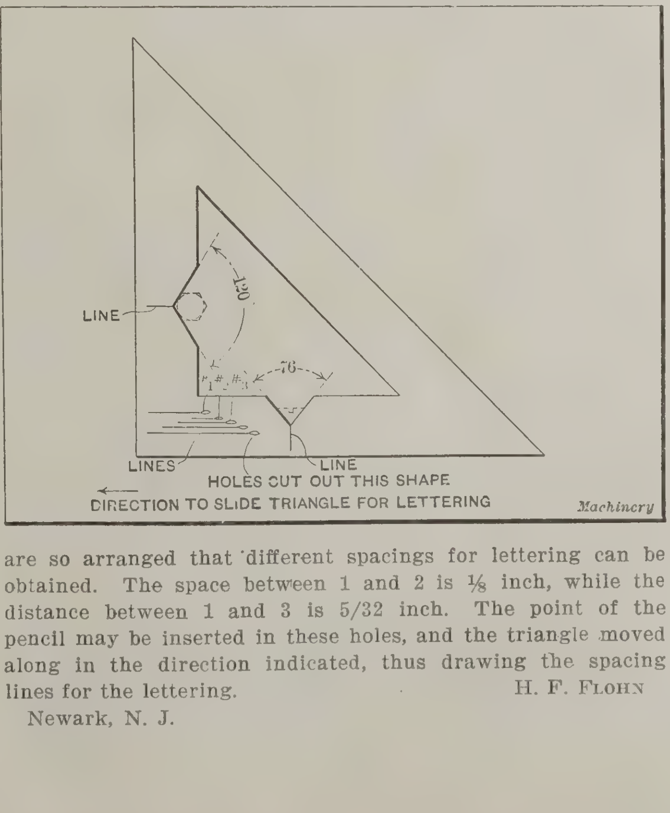


an L. S. Starrett level is attached by means of a piece of flexible material such as sheet tin, zinc or steel. The protractor can be placed on the angular face of the machine and the arm raised until the spirit level shows that the arm is in a horizontal plane, when the angle can easily be found.

F. D.

DRAFTSMAN'S TRIANGLE FOR DRAWING BOLT AND SCREW HEADS

The triangle shown in the accompanying illustration will be found convenient for drawing bolt heads, flat-head screws and laying out spacing lines for uniform lettering. Take a 45-degree triangle, preferably celluloid, and lay out the angles, as shown. The portion cut away at 120 degrees is for hexagon-head bolts, while that part cut away at 76 degrees is for flat-head screws. The small holes marked Nos. 1, 2, 3, etc.,



are so arranged that different spacings for lettering can be obtained. The space between 1 and 2 is ⅛ inch, while the distance between 1 and 3 is 5/32 inch. The point of the pencil may be inserted in these holes, and the triangle moved along in the direction indicated, thus drawing the spacing lines for the lettering.

Newark, N. J.

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer

METAL PAINT TO WITHSTAND ALCOHOL

S. J. B.—It is required to paint a brass vessel having a glass top with white paint which will successfully withstand the action of diluted alcohol in the proportion of 2 to 1 without the paint changing color. What mixture of paint should be used?

This question is submitted to the readers.

PROPORTIONS OF SHORT HYDRAULIC CYLINDERS

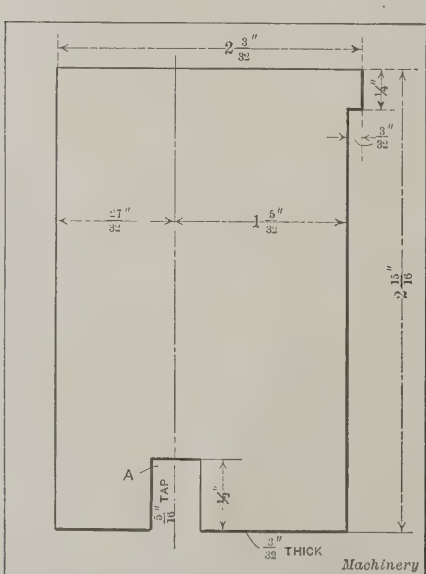
J. C. S.—The formula $\frac{R}{r} = \sqrt{\frac{S+P}{S-P}}$

in which R is the outer radius of the cylinder; r, the inner radius; S, allowable unit stress; and P, maximum pressure, gives the ratio between the outer and inner radii of thick hydraulic cylinders for given internal pressures. This formula does not apply to very short cylinders, however, because of the reinforcing effect of the thick head. The rule given by Kent for short cylinders is to make the thickness one-tenth the inner circumference for pressures of 3000 to 4000 pounds per square inch. I have to design a cylinder for 5000 pounds pressure, 8¾ inches internal diameter and 3 inches stroke. The material will be semi-steel, having a tensile strength of about 25,000 pounds per square inch of cross-section. Figured by the Kent rule an external diameter of 14¼ inches is safe for a pressure of 4000 pounds. Will a diameter of, say, 15¾ be safe for 5000 pounds? Figured by the first-mentioned formula the external diameter must be 22 inches, allowing a fiber stress of 7000 pounds per square inch.

The question is submitted to readers who are familiar with the modifications of theoretical design in such cases, enforced by commercial considerations.

BROACHING SCREW THREADS IN THIN PLATES

R. H. F.—I am building a machine in which there are 35 steel knives 3/32 inch thick which are held on a spider or knife plate with 5/16 inch—18 thread screws tapped into the slot *A*. The metal is cold-rolled steel, and the slot is 1/2 inch long. We punch the slot in a punch press and then put the knife in a small jig and tap the threads by hand. What I wish to know is, can the knives be tapped more rapidly in some other way, as our present method is slow and expensive?



A.—Inasmuch as the threads are tapped into the edge of the knife blade which is only 3/32 inch thick, the angle made by the thread is practically negligible. We suggest that the outline of the threads be broached with a suitable broach in a power press. The screw will have practically as good a hold of the knife when screwed into the broached thread shapes as though they were tapped. Of course, the bearing of the screw will not be theoretically correct, but by the time the screw is screwed home the bearing should be practically as good as is required for this class of work.

STATUS OF "PATENTED" ON MACHINES

S. J. R.—What is the law regarding the use of the word "patented" on manufactured articles; also with regard to blanket nameplates giving the dates and numbers of all patents owned by the concern making the products? I have noticed machine tools bearing nameplates on which legends similar to this appear: "Made by the Brown & Smithson Machine Tool Co., Brownsmithsonville, Ohio, operating under patents," followed by a list of all the patents owned by the company, giving the numbers and dates of issue. The machine carrying the nameplate may be a standard machine tool without a single patentable feature, yet it appears to be plastered with patents.

A.—Section 4900 of the United States Revised Statutes provides that when a patented article is not marked "patented" no damages shall be recovered by the plaintiff unless he proves that the defendant was duly notified of infringement. Section 4901 provides a penalty for marking "patented" on unpatented articles when done for the purpose of deceiving the public. So far as we can ascertain no decisions of the courts have been recorded regarding the use of blanket nameplates on machines, listing all the patents owned by the manufacturer. The practice has certain advantages for both the maker and user. It enables one style of nameplate to be used on all styles of machines produced, irrespective of their characteristics. The user is informed just what patents are owned by the company, but whether any of them apply to a particular machine is left in doubt.

JIGS AND FIXTURES—HOW DEFINED

D. T. H.—What are your definitions of "jig" and "fixture"?

A.—The answer is in the editorial under the above heading in the February, 1905, number, part of which follows: "Jig and fixture are words used interchangeably; a drilling-jig and a drilling-fixture may be one and the same thing—and they may be different, as we shall see later. Broadly, a jig is a device used in interchangeable manufacturing of machine parts for holding the work pieces and guiding cutting tools in any machining operation thereon; hence it may be used for drilling, boring, milling, planing, shaping, etc., but, we believe, it is preferably limited in general use to the first two operations, that is, drilling and boring. While fixture is a term generally used to mean the same thing, we believe that it is more comprehensive, and that it includes a lot of things which would not ordinarily be called jigs. If the device is of such a nature that it incloses and holds the work so that it can be lifted and transported as a whole, and, perhaps, has provision for a number of operations in different planes, we should surely call it a jig, but if it were the radius attachment to a planer for planing locomotive links, we should call it a fixture, although it is by no means a fixed or permanent part of the machine. A drilling vise is more of a fixture than a jig, but if it is provided with guide bushings we would term it a drill-jig or a jig-vise. Again a fixture may be one of the tools of a machine, as for example, the tools and fixtures of a turret lathe. A tool-post is an example of a fixture, but it is not a jig in the ordinary sense of the word. An "old man" for ratchet drilling is a fixture, as is also a former used on a planer as in planing relief for locomotive driving boxes, or as applied to the lathe for turning machine handles. A bending device which insures exact duplication is usually called a fixture, in preference to jig. A device for holding work pieces on the milling machine so as to insure duplication of parts is preferably called a fixture, although in many shops it would be called a jig. Hence the difficulty in assigning any definite and limiting meaning for either term. One difference that may be assumed to exist between jig and fixture is that a jig holds the work and guides the cutting tool independently of the machine supplying the driving power and feed, while the fixture is usually dependent upon the machine to guide the cutting tool or the work; one is self-contained and the other is not. We are fully aware that this distinction does not exist in actual practice, but it is one put forward as a suggestion for those shops which wish to define shop terms precisely."

STRESSES IN ELASTIC COUPLING

H. M. L.—The accompanying illustration, Fig. 1, shows a flexible coupling of the type in which a leather belt, looped around pins, transmits the power. How can the stress in the belt wound around the pins be calculated?

A.—In Fig. 2 a diagram is shown, indicating the necessary geometrical construction for finding the stress in the belt.

The radius of the outer pin circle is R and of the smaller, r. The radius of the pins is p, the number of pins is N in each pin circle, and α denotes the angle between the lines through the centers of adjoining pins. The requirement is to find the angle that line DE makes with a tangent to the outer pin circle, so that the tangential force to be transmitted can be translated into belt stress along line DE. Angle $\alpha = 360 \div 2N$. As we also know R and r, we can find the length of side BC in triangle ABC, by a simple trigonometric formula, and also the angle ABC. Then, in triangle CDF, $CF = \frac{1}{2} BC$,

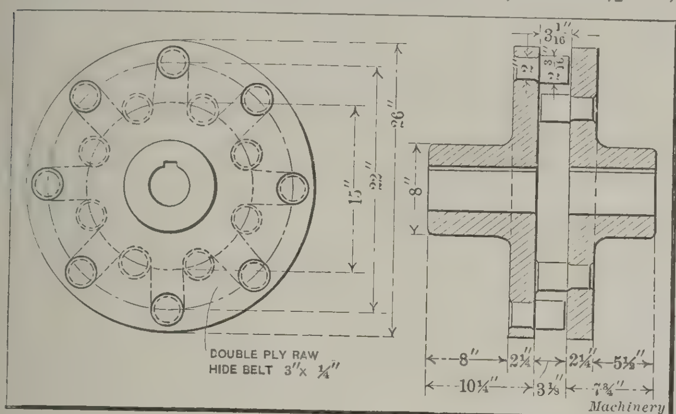


Fig. 1

$CD = p$, and angle CDF is a right angle. Hence angle CFD can be found, the sine of this angle being equal to $CD \div CF$. The angle that DE makes with AB, then, is equal to angle ABC — angle CFD, and the angle that line DE makes with a tangent through B equals 90 degrees minus this angle. The angle with the tangent will be denoted β. For the sake of simplicity, assume that the tangential force acts at the center of the pin, at B. In the force diagram, at the right, KL represents the tangential force at each pin, and KM the stress in the belt, the angle between the direction of these forces being β. Assume that P represents the total tangential force to be transmitted. If the horsepower to be transmitted is known, then $P = (33{,}000 \times \text{H. P.}) \div (2\,\pi\,R \times \text{R. P. M.})$, and the

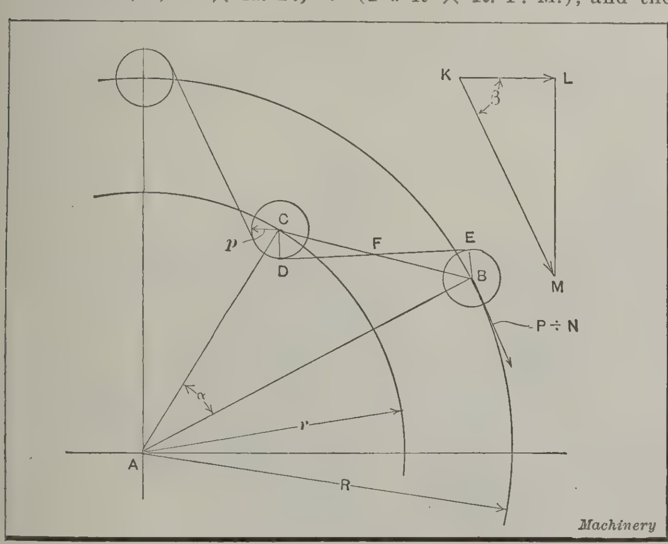

Fig. 2

force represented by $KL = P \div N$. From this we find KM, or the belt stress, is expressed as:

$$KM = \frac{P}{N} \div \cos\beta = \frac{P}{N\cos\beta}$$

Extreme refinement in this calculation is not necessary, as the relative positions of pins B and C do not remain constant, due to the elasticity of the belt, and hence the value of angle β will vary. The value found as shown, however, is the one which produces the maximum stress; with the coupling in torque, angle β will decrease, in which case the stress in the transmitting belt will decrease also. It is evident that the stress becomes very great if β is large, and as this angle depends upon the arrangement of the pins, it is advisable to make the difference in the radii of the pin circles as small as is consistent with the angular displacement required to absorb the shocks of transmission.

SPIRAL-FLUTED HOB ANGLES*

By G. H. GARDNER†

It is, of course, desirable that hobs should be fluted at right angles to the direction of the thread. Sometimes, however, it is necessary to modify this requirement to a slight degree, because the hobs cannot be relieved unless the number of teeth in one revolution, along the thread helix, is such that the relieving attachment can be properly geared to suit it. In the following it is proposed to show how an angle of flute can be selected that will make the flute come approximately at right angles to the thread, and at the same time the angle is so selected as to meet the requirements of the relieving attachment.

Let C = pitch circumference,
T = developed length of thread in one turn,
N = number of teeth in one turn along thread helix,
F = number of flutes,
α = angle of thread helix.

Then (see illustration):

$C \div F$ = length of each small division on pitch circum.

$(C \div F) \times \cos\alpha$ = length of division on developed thread.

$C \div \cos\alpha = T$.

$$\text{Hence } \frac{T}{(C \div F)\cos\alpha} = N = \frac{F}{\cos^2\alpha}$$

Now, if $\alpha = 30$ degrees, $N = 1\,1/3\,F$,
$\alpha = 45$ degrees, $N = 2\,F$,
$\alpha = 60$ degrees, $N = 4\,F$.

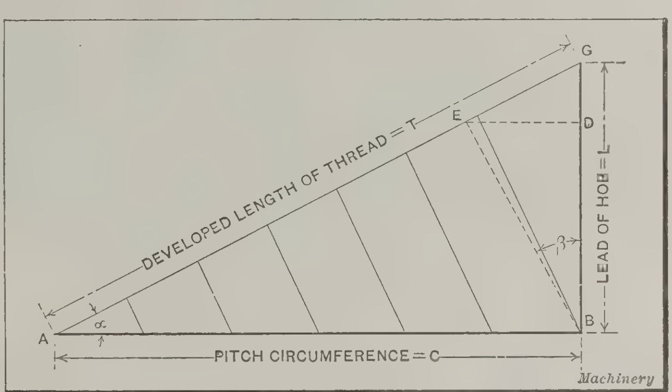

Diagram for Derivation of Formula for Spirally Fluted Hobs

In most cases, however, such simple relations are not obtained. Suppose for example that $F = 7$, and $\alpha = 35$ degrees. Then $N = 10.432$, and no gears could be selected that would relieve this hob. By a very slight change in the spiral angle of the flute, however, we can change N to 10 or 10½; in either case we can find suitable gears for the relieving attachment.

The rule for finding the modified spiral lead of the flute is: *Multiply the lead of the hob by F, and divide the product by the difference between the desired value of N and F.*

Hence, the lead of flute required to make $N = 10$ is:
Lead of hob $\times$ $(7 \div 3)$.

To make $N = 10\frac{1}{2}$, we have:
Lead of flute = lead of hob $\times$ $(7 \div 3.5)$.

From this the angle of the flute can easily be found.

That the rule given is correct will be understood from the following consideration. Change the angle of the flute helix β so that AG contains the required number of parts N desired. Then EG contains $N - F$ parts. But $\cot\beta = BD \div ED$, and by the law of similar triangles,

$$BD = \frac{F}{N} \times BG, \text{ and } ED = \frac{N-F}{N}\,C$$

The lead of the spiral of the flute, however, is $C \times \cot\beta$.

Hence, the required lead of spiral of the flute:

$$C \times \cot\beta = \frac{F}{N-F}\,L$$

This simple formula makes it possible always to flute hobs so that they can be conveniently relieved, and at the same time have the flutes at approximately right angles to the thread.

* See also MACHINERY, December, 1910, engineering edition, "Gashing Spiral Fluted Hobs."

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS
IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

BROWN & SHARPE INTERNAL GRINDING MACHINE

The Brown & Sharpe Mfg. Co., Providence, R. I., has recently placed on the market an internal grinder that is designed for general internal grinding operations. This machine has a capacity for grinding holes varying from 2½ to 12 inches in diameter and 8 inches deep, and the machine will swing 18 inches. By using a special spindle, holes less than 2 inches in diameter, but not exceeding 12 inches deep, can be ground. This machine is especially adapted for grinding holes in hardened steel gears, cutters, collets, bushings and similar work. Taper holes can also be ground as easily and accurately as those that are straight, and such work as facing recesses in automobile gears to obtain a bearing true with the hole can be done without removing the piece from the machine.

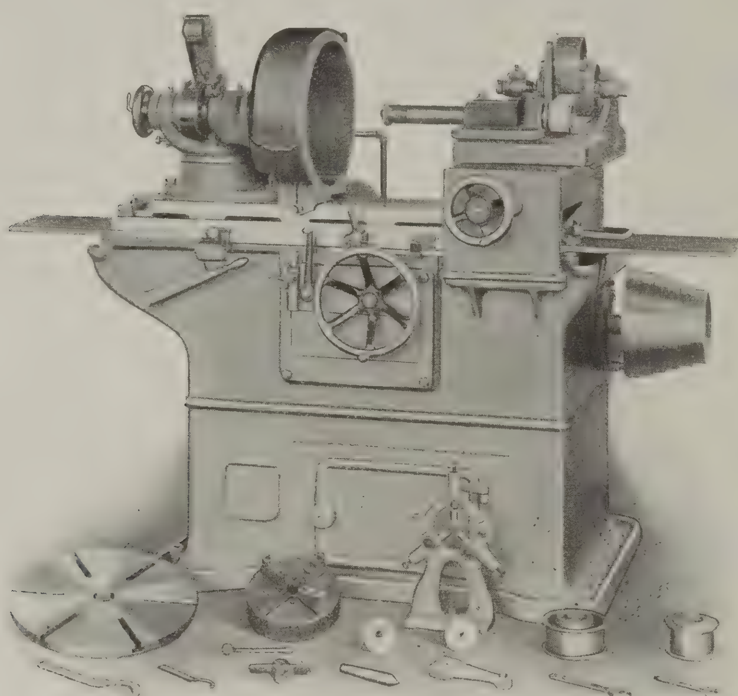

Fig. 1. Brown & Sharpe No. 22 Internal Grinding Machine

The design and construction of this machine, front and rear views of which are shown in Figs. 1 and 2, respectively, gives evidence of a careful study of the requirements for a grinder of this type. The general operation of the machine is as follows: The work to be ground is fastened either in a chuck or on a faceplate mounted upon the work spindle, which is driven from the overhead works. The headstock carrying the work spindle is fastened to the table of the machine, and the latter has an automatic, reversing, longitudinal movement similar to that of universal and plain grinding machines. The grinding-wheel stand and slide are mounted on a heavy bridge, which is bolted to the right-hand end of the machine bed and spans the work table. The grinding-wheel spindle is driven by a web belt from an intermediate shaft mounted at the back of the wheel-stand as shown, and this intermediate shaft, in turn, is belted to the over-head works.

The work speeds and table feeds of this machine are independent, the same as with the universal and plain grinders built by this firm. This arrangement makes it possible to obtain a correct table feed for any work speed. For example, when it is desired to remove stock rapidly, a slow speed and fast feed are available. Both work and table feeds are started and stopped by a single lever located on the front of the machine.

All wearing surfaces throughout are adequately protected from grit. The ways of the bed are always covered and the oil holes are protected from grit and dust. All screws, bolts and nuts requiring frequent adjustment are hardened. The handwheels and levers for controlling the various movements of the machine are all placed at the front.

Wheel Spindle, Stand and Slide

The wheel-spindle is of hardened tool steel and is enclosed in a heavy sleeve that extends practically its full length. The spindle and sleeve form a separate unit, which can be removed easily and quickly in case another spindle and sleeve of smaller size is to be used. At the front end of the spindle and close to the wheel there is a phosphor-bronze box in the sleeve, and at the pulley end an annular ball bearing is provided to take the pull of the belt and reduce friction to a minimum. The different grinding wheels used are mounted on a sleeve, which has a taper hole that fits the end of the spindle.

An ample range of independent spindle speeds is obtained by the use of interchangeable split pulleys on the intermediate shaft at the back of the wheel-stand. An idler pulley is provided to keep an even tension on the belt and take up the slack resulting from the use of pulleys of different diameters. Three split pulleys are furnished providing for speeds varying from 3990 to 7300 revolutions per minute.

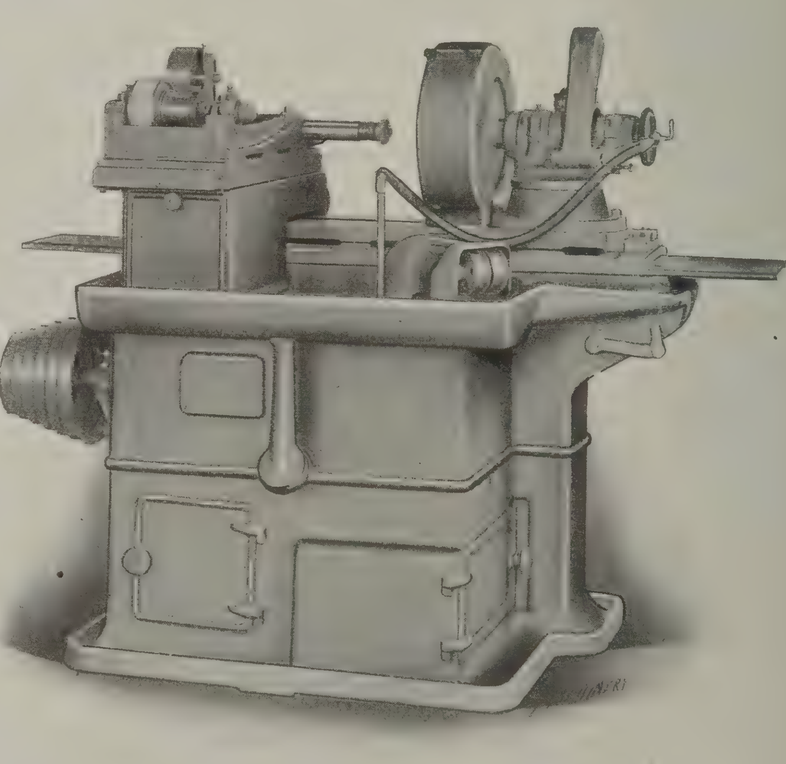

Fig. 2. Rear View of Brown & Sharpe Internal Grinder

The wheel-stand and slide are both of heavy, rigid construction, capable of resisting vibrations which would cause inac-

curacy in the work. The wheel-stand swivels, thus permitting the spindle to be set at an angle when grinding the faces of cutters or automobile gears. This feature is also convenient when a hole has been ground, and it is desired to grind the face of the work before removing it from the machine. The ways of the wheel-stand slide are long to insure alignment, and are amply proportioned to resist vibrations. A transverse movement of the slide is obtained through a worm and wheel, actuated by a handwheel at the front of the machine. When it is desired, an automatic cross-feeding mechanism, similar to that found on all Brown & Sharpe universal and plain grinding machines, can be furnished.

Headstock

The headstock is of a rigid design and is firmly fastened to the swivel table by means of bolts that slide in a T-slot. It swivels and can be set at any required angle, the amount of adjustment being indicated by graduations on the base. The spindle is hollow and runs in bronze boxes provided with means of compensation for wear. It can be locked in position when removing the faceplate, chuck, or an attachment. Over the spindle pulley there is a belt tightening device consisting of a small pulley mounted on a bracket that can be drawn forward or pushed back by means of the handle shown. The forward adjustment puts the driving belt in tension and causes the spindle to revolve and drive the work. When the idler is swung back, the spindle can be quickly brought to a stop for changing the work, or it can be revolved easily by hand when centering a piece. A range of twelve work speeds, varying from 40 to 340 revolutions per minute are provided.

Sliding Table

The sliding table is of rigid construction and its bearing surfaces are scraped to fit the ways on the bed which are aligned with master straightedges. The travel of the table is automatic and entirely independent of the speeds of the work and wheel. It is controlled by adjustable dogs on the front of the table that operate against a reversing lever in the usual manner. The dogs can be raised and the table run beyond the reversing points without disturbing the adjustment, which is a valuable feature when withdrawing the work from the wheel. When the work is finished the trip dog nearest the wheel is raised; the table then moves to the left until the power feed automatically disengages. The table can then be moved farther away by the large handwheel shown. After a new piece of work is inserted, the table is moved up by means of this handwheel until the work nearly reaches the grinding wheel, when the power feed automatically engages again.

Provision for Wet Grinding

The soda water for wet grinding is pumped from a tank located in the bed and is fed to the wheel through the hollow work-spindle. The pump consists of a simple fan, revolving in a case, and, as it is immersed at all times, no packing is required. The tank is readily accessible for cleaning. The hood or water guard shown on the machine is furnished for covering the work.

In other details, the construction of this machine differs but little from that of the Brown & Sharpe universal grinding machines. The swivel table, however, pivots on a stud located beneath the headstock. This gives a long leverage from that point to the end, thus enabling very fine adjustments to be made when setting to grind straight or when adjusting to an exact angle for taper work, after the headstock has been set as closely as possible by the graduations on its base. There are six changes of table feed, varying from 15 inches to 48 inches per minute. The equipment furnished with the machine is shown about the base in Fig. 1. The overhead works, which are not shown, are also included in the equipment.

WALKER SURFACE GRINDER

The Walker Grinder Co., Worcester, Mass., is building an improved design of "single-stroke" surface grinder which is adapted for grinding concave as well as flat surfaces. This machine is of the cup-wheel type and has a heavy column on which are mounted upper and lower vertical slides. The upper slide carries the grinding wheel, and the lower slide has a rotary magnetic chuck on which the work is mounted. When the machine is in operation, the wheel is fed down against the work until the latter is finished to the required thickness. The wheel slide is fed against a positive stop and the thickness of the work is varied by adjusting the lower slide which is equipped with a vertical feed-screw. This screw is operated by the large handwheel (seen at the left of the slide) which is graduated in thousandths of an inch. When this adjustment of the lower slide is once made, it is not changed for successive operations except to compensate for wheel wear. The feeding movement of the grinding wheel is effected by the hand lever seen at the right of the wheel slide. This same lever also controls the starting and stopping of the work spindle, the switching on or off of the magnetizing current for the chuck, and it also controls the de-magnetizing current for neutralizing the residual magnetism always found in a magnetic chuck after the electric current has been switched off.

All of the power movements for this machine are derived from a horizontal shaft at the rear on which are mounted

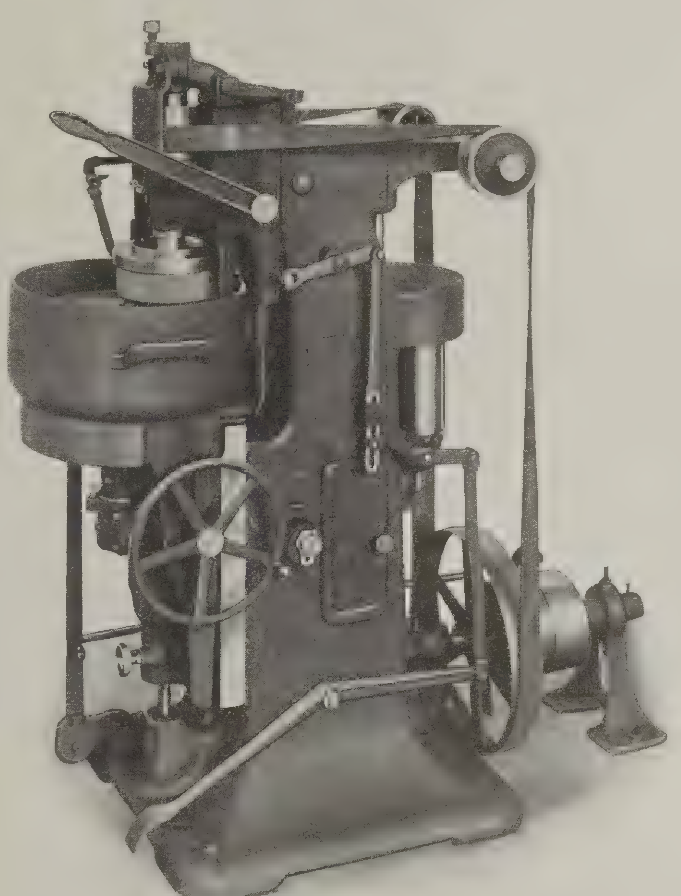

Fig. 1. Walker Surface Grinder

tight and loose pulleys. The wheel spindle is driven independently by a quarter-turn belt which passes over idlers as shown. The spindle pulley is wide enough to permit the required vertical movement of the slide. The work table is driven from the drum pulley seen at the rear of the column. This pulley receives its motion through gearing from an intermediate vertical shaft which, in turn, is driven by a quarter-turn belt connecting with the inner end of the horizontal driving shaft. The drum pulley is also wide enough to permit the necessary vertical movement of the lower slide. The wheel slide is counterbalanced by a weight inside the column, so that when the operating lever is thrown back, the slide returns to its upper position, thus leaving plenty of room under the wheel for placing or removing work. The link and lever connections seen at the side of the column, connect the wheel slide with a jaw clutch inside the work-table driving drum, and disconnect the latter from the shaft on which it is mount-

ed, when the wheel slide is in the upper position. By this means, the work spindle is automatically stopped whenever the wheel is raised from the work. It is sometimes advisable to clean the chuck face while in motion and, in such a case, the drum-clutch operating mechanism may be disengaged, thus giving an independent control of the work spindle through the foot lever seen at the base of the machine.

When this machine is to be used for concave grinding, the knee supporting the work table is tilted to the required angle. The knee is separate from the slide and has an overlapping ledge at the top, on the outer corners of which are set-screws. These set-screws provide means of correct alignment in one direction and form pivoting points. The tilting movement is effected by the knurled screw seen near the lower end of the knee. The latter is held against the slide by four cap-screws which have located quite near them, four adjusting set-screws. These set-screws are permanently set for aligning the knee, but can be re-adjusted at any time if necessary. The knee has an adjustment of two degrees and can be quickly reset in a level position without re-aligning.

Work having a concave surface is not held directly against the magnetic chuck, but on an auxiliary plate. The magnetic power of the main chuck is transmitted through this auxiliary plate, the upper surface of which is shaped to suit the work. The use of the auxiliary plate in connection with the grinding of a milling saw is illustrated in Fig. 2. After the saw is ground concave on one side it is held for grinding the opposite side on a plate having a convex face. If the saw were held for grinding the last side, against the flat face of the regular chuck, it would be pulled down in the middle, thus making it impracticable to concave both sides alike. Fig. 3 shows the method of grinding such work as dies, disks, etc., and Fig. 4 illustrates how piston-rings or similar parts are held. Fig. 5 shows how a number of small washers can be ground at one setting. These washers are separated by a perforated iron or brass disk, which acts as a retainer and holds the parts in the required position over the poles of the magnetic chuck. Fig. 6 illustrates how parts can be located on a chuck for multiple grinding, so that they support each other, thus making it unnecessary to use stays. These different views are shown to indicate, in a general way, how various kinds of work is ground on a machine of this type.

BAKER BROTHERS AUTOMATIC DRILLING MACHINE

Baker Bros., of Toledo, Ohio, have brought out a new type of drilling machine designed to reduce the idle or non-productive period connected with drilling operations. The maximum time required for drilling many classes of work is not consumed while the drill is passing through the material, but while the operator is placing the work in position, advancing the tool to the work through the jig bushing or clearance space, engaging the feed, withdrawing the tool and removing the work. After considerable study and experimenting, this company has developed a machine to perform these operations automatically—as far as the movement of the drill-spindle is concerned—and in a minimum of time. This machine, which is illustrated in Figs. 1 and 2, is so simple in construction that changes for different classes of work can be made quickly. The spindle is fed to the proper depth and returned by means of a cam which gives a powerful feed and a quick return movement. The feed also has a dwell at the end of the downward movement, which adapts the machine for accurate facing operations.

Either a plain work-table or one having an automatic index-

ing movement is provided. The automatic table is intended for work which is comparatively small, thus permitting a number of parts to be held in a suitable fixture around the periphery of the table, as shown in Fig. 2. As the forward and return movements of the drill spindle are automatic, the operator simply inserts new blanks and removes those that are drilled. The automatic indexing motion takes place as soon as the spindle is withdrawn and rotates the table to the next position, thus bringing a new piece of work under the drill or other tool. The period required for withdrawing the tool and indexing the table varies from two to three seconds. Change-gears are provided for indexing the table any required number of divisions from five to eighty. As the table can be adjusted in or out, holes can be drilled on circles of any radius within the capacity of the machine, by providing the proper change-gears for the indexing movement. The standard machine will drill holes in circles varying from four to twenty inches in diameter. A scale is provided which shows the diameter of circle on which the drill is set for any position of the table. When this machine is used for chuck work, the table usually has from six to eight chucks, and all the workman has to do is to insert and remove the work, as the machine itself requires no attention other than to see that the tools are kept sharp. If a drill should break, the machine can be stopped instantly.

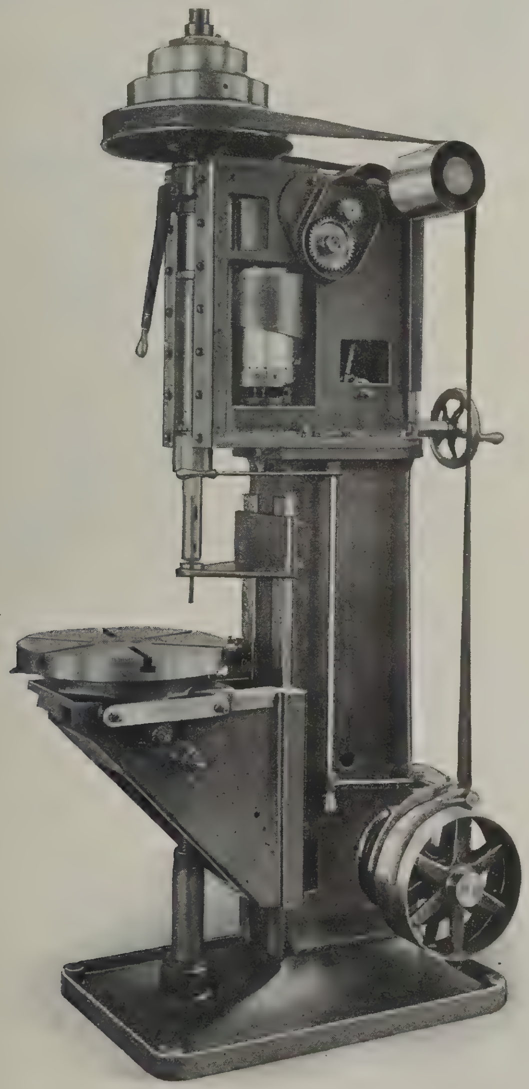

Fig. 1. Baker Bros. Automatic Drilling Machine

In case it should be desirable, the machine can be made to skip any number of chucks when indexing.

When a plain table is used, the operator places the work under the drill-spindle and trips the machine by a foot-lever, the same as he would a punch press. The spindle then advances and the drill passes through the work, after which the spindle returns quickly to its upper position. The operator then removes the finished piece of work, places another blank in position and trips the foot-lever as before, which causes the spindle again to feed down and return automatically. As the machine is entirely controlled by the foot-lever, the operator can use both hands for inserting and removing the work, thereby securing a very rapid production. The plain table is used for work which, because of its shape or size, could not be handled on a machine of the automatic indexing type, such as is shown in the accompanying illustrations.

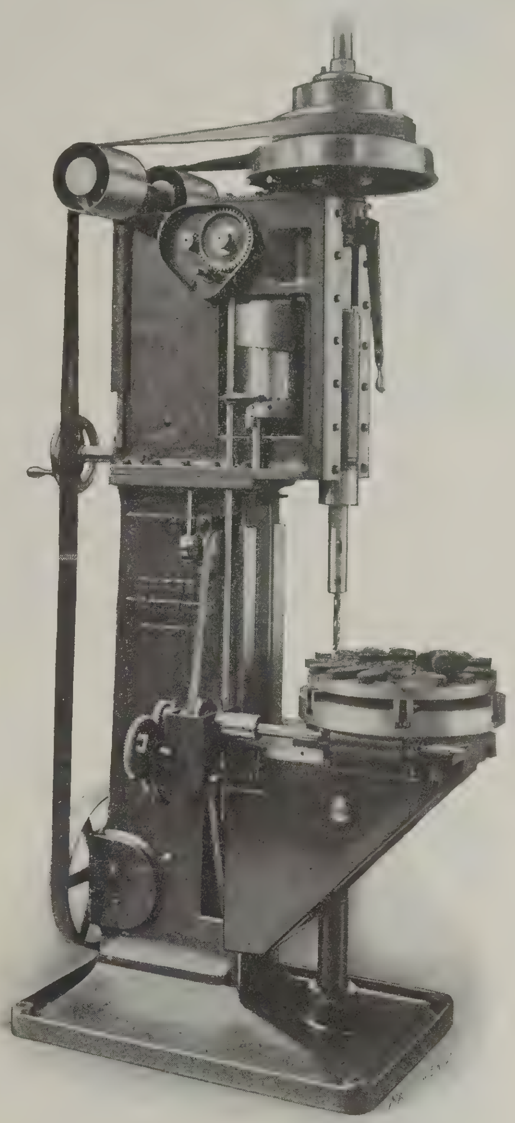

Fig. 2. View of Baker Bros. Drilling Machine showing Table Indexing Mechanism

This machine has a capacity for drilling 1-inch holes in steel when using high-speed drills. The automatic indexing type will drill ¾-inch holes through a piece of cast iron ¾ inch thick, at the rate of eight holes per minute. The spindle is mounted in a bronze-bushed slide which operates on carefully scraped ways. The revolving cam-drum, which imparts a feeding movement to the spindle, acts against a roll attached to the spindle saddle. This cam, in addition to "slip" change-gears, gives the required feed variations. One cam is provided with each machine.

The spindle has a vertical movement of 6 inches. It is made of high-carbon, hammered crucible steel and has a minimum section of 1¾ inch. The end is bored to a No. 3 or 4 Morse taper. There are six spindle speeds ranging from 200 to 800 revolutions per minute, the changes being obtained by means of the three-step cone pulley shown, and a two-speed countershaft. The idler pulleys at the rear are mounted on a vertical slide which can be adjusted to align the pulleys with different steps on the spindle cone, by means of the handwheel seen at the rear. The spindle is driven by a 2-inch belt and the distance from the center of the spindle to the frame is 8 inches. All the running bearings of this machine are equipped with ball bearings. The machine can be arranged for either motor or belt drive.

NEW BRITAIN SCRAPING STAND

The stand shown in the accompanying illustrations is used for holding work while scraping the bearing surfaces. This stand is especially useful in connection with the scraping and fitting of dovetail ways or bearing surfaces which are at an angle with the face of the work. The table to which the parts are clamped can be adjusted to hold the work in a horizontal position, or it may be tilted to locate the surface being scraped in a more convenient position for the workman, as indicated in Fig. 2.

Fig. 1. New Britain Scraping Stand

The table is locked in position by means of hinged clamping levers which are permanently attached to the stand. The table may be inclined to any angle up to 90 degrees. The face of the table is 16 by 30 inches. The work is held in position by means of bolts that engage T-slots cut in the table face. The height of the table can be varied from 28½ inches to 34½ inches. This adjustment is effected by means of a "quick-pitch" screw located within the column. After the table is raised to its extreme height, it still

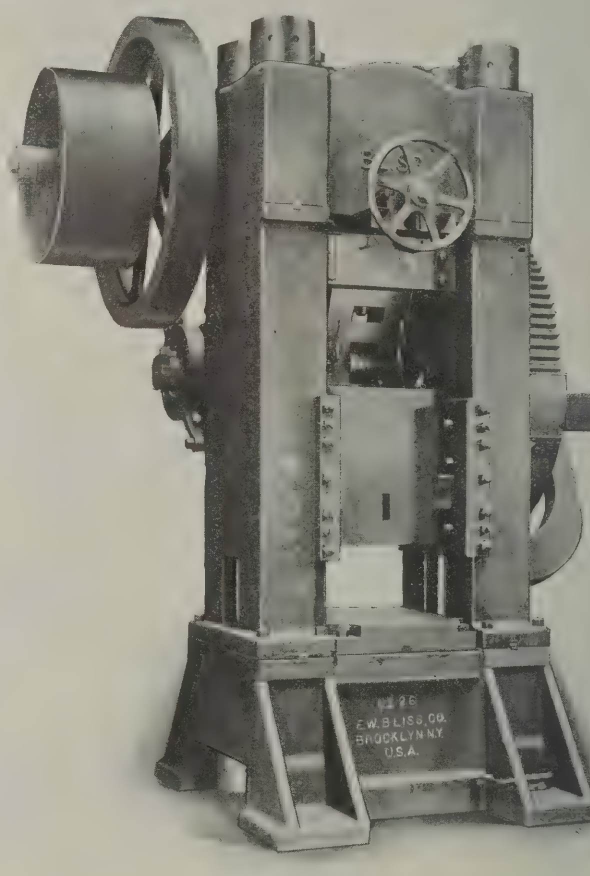
Fig. 2. Stand set for Scraping Angular Surfaces

has a bearing on the column so that it cannot be accidentally turned out of the base. The vertical adjustment permits the work to be held at the most convenient height for the workman. This scraping stand is made by the New Britain Machine Co., 64 Bigelow St., New Britain, Conn.

BLISS "KNUCKLE-JOINT" PRESS

Power presses of large proportions and great capacities are being used increasingly in connection with many manufacturing operations, owing to the fact that many articles can be produced more economically and uniformly in a press than by the methods formerly employed. The E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., is now building a new line of knuckle-joint presses, one size of which is shown herewith. These presses are used for heavy stamping and embossing operations on steel, brass, copper, silver, Britannia, etc., and they are particularly adapted for embossing operations in the manufacture of medals, coins, jewelry, etc. The toggle-joint gives a powerful movement to the slide at the end of the stroke when the work is being done. A comparatively slow movement is also obtained at the end of the stroke which is desirable when it is necessary to have the metal flow while under pressure, as in embossing.

This machine is capable of exerting a pressure of 800 tons. The toggle links are placed above the slide in the same position as the pitmans of an ordinary crank press, and they are operated by a crankshaft in the rear of the press. This construction permits the use of positive knockout attachments in the bed and cross-bar knockouts in the slide. The powerful



Large Toggle-joint Embossing Press

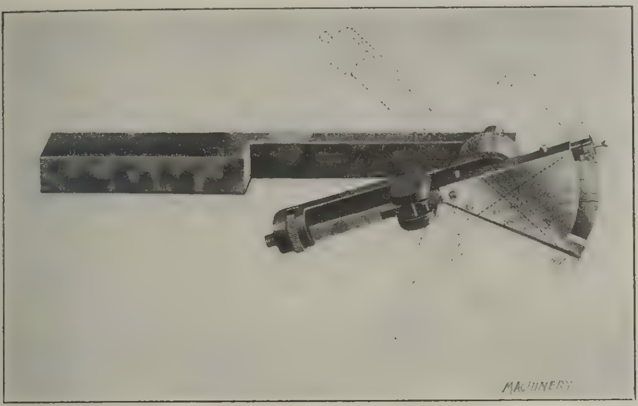
jaw clutch on this machine has three engaging points and is operated by the foot-treadle seen at the right. The necessary adjustment for dies and pressure is obtained by a taper wedge adjustment. The position of this wedge is changed by means of a screw, which, in turn, is operated by the handwheel shown.

This press is of the tie-rod construction, the bed and crown-piece each being separate castings. The side housings, which take any side strain and provide bearing surfaces for the slide and crankshaft, are also separate and of box section. Four large tie-rods pass through the side housings and take the entire strain when the press is at work. This construction not only prevents breaking the frame, but also provides a means for releasing the press should it become stalled on its center, as the tie-rods may be heated and expanded through suitable openings provided. The distance between the uprights of the press is 28 inches; the stroke of the slide is 2 inches, and the total weight of the machine is 45,000 pounds.

TEST INDICATOR

A new type of test indicator recently developed for use on a lathe, milling machine or in connection with tool-room work, is shown in the illustration. The instrument proper is very light and sensitive and has a scale with graduations reading to 0.0005 inch. Since these graduations are spaced ⅛ inch apart, a reading of 0.0001 inch can be obtained. As the tool is

mounted on an adjustable holder, it can be set in any direction as indicated by the lines. The position with relation to the work can be varied by an adjusting nut at the end of the tool, and there is an elevating nut for raising or lowering the indicator to bring it in alignment with the center line of the lathe. This indicator, when arranged as illustrated, can be used in an ordinary toolpost, and when the holder is removed, the stem fits the toolpost of any bench lathe or it can be clamped to the spindle of a surface gage in place of the scratch awl or scriber. Direct contact is made with work by



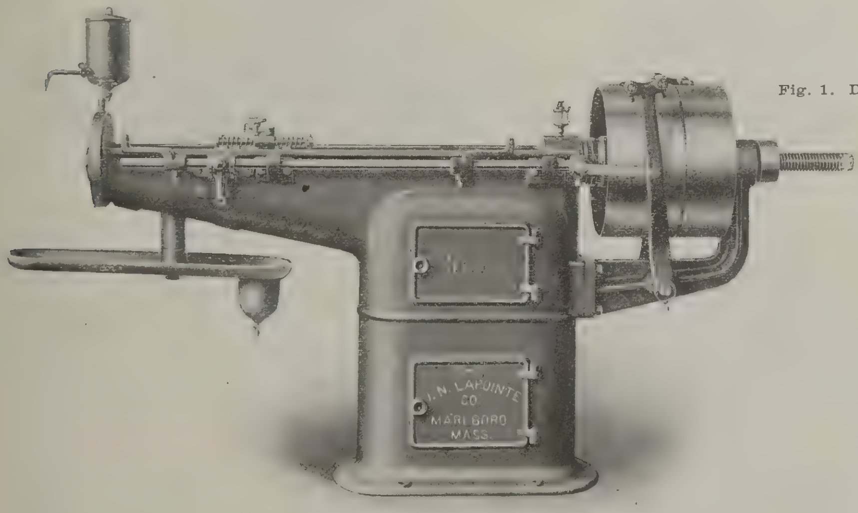
Test Indicator made by American Watch Tool Co.

a small ball point, which, through a system of levers, gives a reading on the scale that is multiplied about two hundred times. The contact point is removable and can be replaced by finer ball points, flats or any special shape required. The working parts of the indicator are all carefully protected from injury by a metal shield. This indicator has been placed on the market by the American Watch Tool Co. of Waltham, Mass. It is an accurate and inexpensive instrument for use in machine shops or laboratories.

LAPOINTE BROACHING MACHINE

A light type of broaching machine has been designed by the J. N. Lapointe Co., Marlboro, Mass., for keyseating comparatively small parts, such as the change- or feed-gears used on various types of machines. This machine is said to cut keyways in work of this kind at the rate of from 150 to 200 pieces per hour. It has a capacity for broaching keyways up to 3/8 inch in width, and usually from two to four parts can be broached simultaneously.

The construction of this machine is very simple. There is a sliding head having a stroke of 40 inches, which is actuated by a 2-inch non-revolving screw. This screw passes through a revolving bronze nut which is inserted in the hub of the driving pulley. Two loose pulleys are mounted on the hub of the tight pulley, this hub acting as a bearing for the driving mechanism. This combination of pulleys and also the belt shifting device, is similar to the arrangement used on planers. The driving belts can be shifted by hand, or automatically by means of adjustable dogs. The rod which carries the stop-dogs, is connected with two swiveling belt-forks which are mounted on a shaft passing through the bracket shown. When the sliding head comes in contact with one of the stop-dogs, either the forward or return belt is shifted onto the tight pulley, thus reversing the movement.



Lapointe No. 1 Broaching Machine

The stroke of the sliding head is varied according to the length of the broaching tools used, by simply changing the position of the stop-dogs. The driving nut is so arranged that it can be removed quickly for replacement, when necessary, by unscrewing a cap at the end of the driving pulley hub. This machine has a ball bearing thrust to eliminate excessive friction and wear on the nut and screw, especially when heavy broaching is being done. The ball bearing reduces the power required for operating the machine. This machine is also adapted for broaching square holes up to 5/8 inch.

DWIGHT SLATE AUTOMATIC DRILLING MACHINES

The multiple-spindle machines illustrated in Figs. 1 and 2 are automatic in that the feeding and return movements of

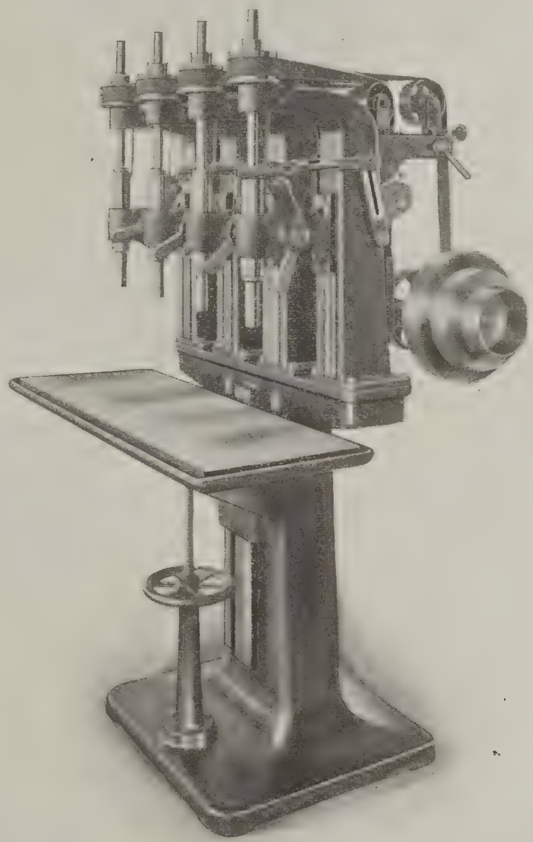


Fig. 1. Dwight Slate Cam-feed Automatic Drilling Machine

the drill spindles are obtained from cams. These cams are mounted on a shaft at the rear and are spaced at equal angles, thus giving the same intervals of time between the movements of each spindle. For example, the cams of a four-spindle machine are 90 degrees apart, whereas the cams of a six-spindle type are 60 degrees apart. When the machine is in operation, the various spindles move progressively and continuously, and the workman's entire time is utilized in loading jigs and removing the drilled parts, so that a very rapid production is obtained.

These machines are of an improved design now being manufactured by the Dwight Slate Machine Co., Hartford, Conn. The machine shown in Fig. 1 has four spindles, and Fig. 2 is a rear view of a six-spindle type. Any number of spindles ranging from two to eight can be furnished. The number that

one man can operate depends, of course, on the time required for drilling the work. The end view, Fig. 3, shows the arrangement of the cam feed. The required movement for each spindle is obtained from an independent cam *C* which engages a roller on slotted arm *A*. The latter is connected to the pinion shaft by rod *B* and the lever shown.

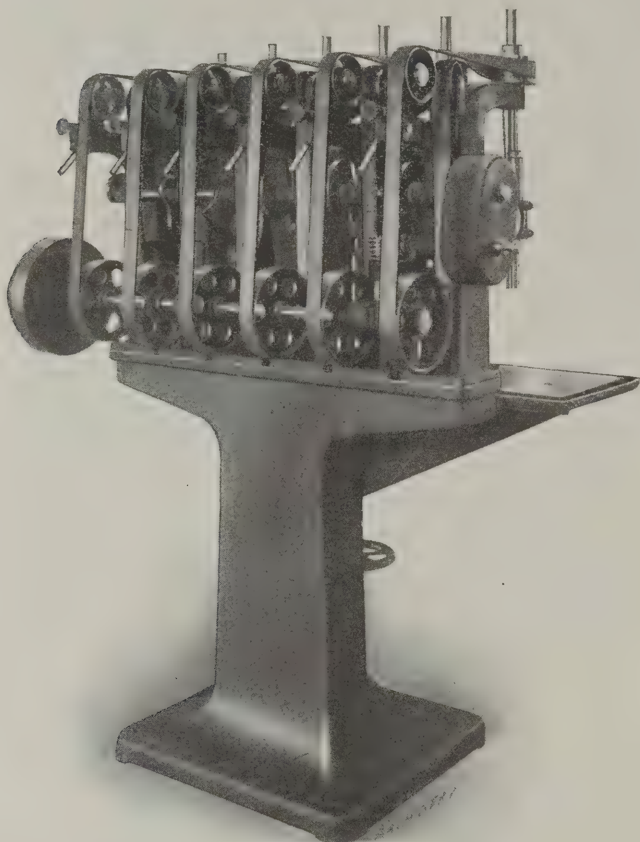

Fig. 2. Rear View of Six-spindle Cam-feed Drilling Machine

The stroke of the spindles is varied for drilling holes of different depths, by adjusting nut *a* on the slotted arm. The position of each spindle can also be adjusted independently for leveling the drill points, by loosening nut *D* and turning the

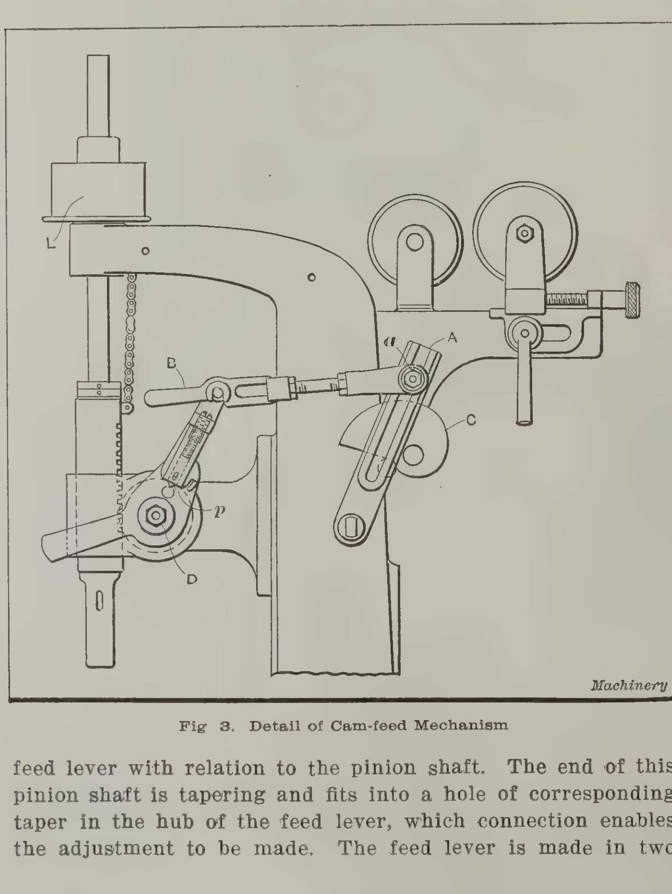

Fig 3. Detail of Cam-feed Mechanism

feed lever with relation to the pinion shaft. The end of this pinion shaft is tapering and fits into a hole of corresponding taper in the hub of the feed lever, which connection enables the adjustment to be made. The feed lever is made in two parts and is equipped with a safety device for stopping the feed in case of an overload at the drill point. The safety stop consists of a hardened, adjustable spring-plunger *p* which is inserted in the upper half of the feed lever and engages a notched stud attached to the lower half. If an overload occurs, plunger *p* is disengaged from the stud, thereby protecting the feed mechanism and preventing the breaking of drills to a large extent. The tension on this plunger can be varied for drills of different diameters. In case it is desired to feed one of the drill spindles by hand, this can be done by disengaging link *B*.

As the amount of feeding movement is limited to the throw of the feed lever, this machine is restricted to the drilling of holes not exceeding 1½ inch in depth. The cam-shaft is driven from the main shaft through worm gearing and the feed change mechanism seen to the right of the machine in Fig. 2. This gear box gives three feed changes which are obtained by shifting a small pull-pin. There are also three spindle speeds obtained by the three-step driving cone pulley. The spindle driving belts have adjustable idlers at the rear for varying the tension, and the spindle belt pulleys are equipped with oil reservoirs and an ingenious method of providing continuous lubrication.

The work table of this machine is securely locked to the column by a narrow gib located on one side of the central

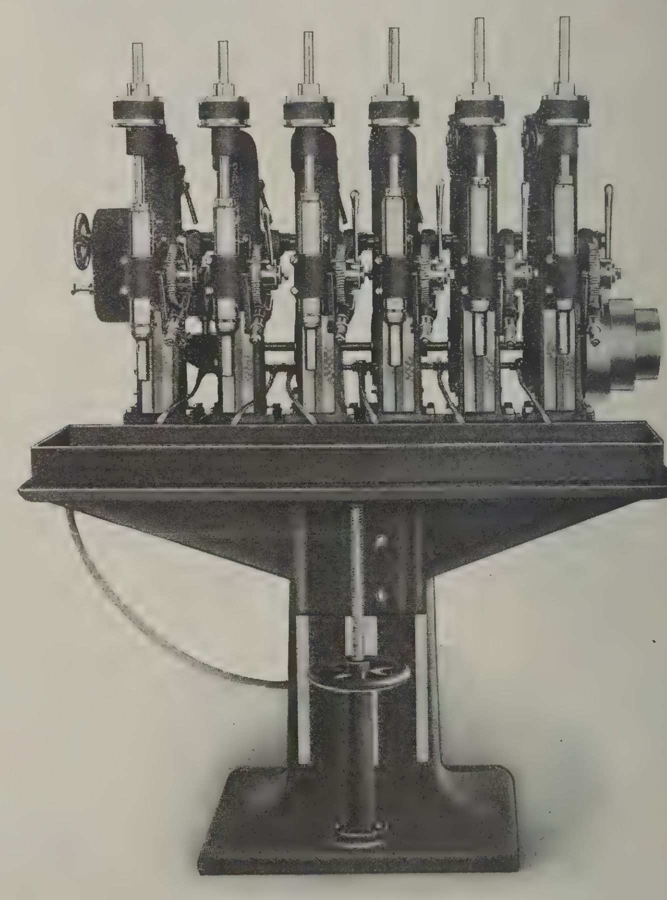

Fig. 4. Automatic Drilling Machine with Worm Feed

dovetailed way seen in Fig. 1. When this gib is drawn outward by a stud passing through the saddle, the table is clamped tightly against the outer bearing surfaces shown, and it is also securely locked to the central dovetailed way. The elevation of the table is effected by the screw and handwheel shown. This machine is especially adapted for drilling small duplicate parts such as are used in the manufacture of locks, light hardware, small tools and similar parts.

Fig. 4 shows another multiple-spindle machine of the same type but equipped with a different feeding mechanism. The arrangement of this feed is shown in Fig. 5. The feed movement is derived from a back shaft *U*, which is driven from the main shaft through a change-gear box, the same as with the cam-feed design. The feed worm *F* is supported and held in engagement with worm-gear *R*, by a latch-arm *A* which nor-

mally engages a supporting stud *I*. The adjustment of the automatic feed trip for drilling holes of any depth between 0 and 5¼ inches, is obtained by setting the adjustable ring *B* in the proper relation with the pinion shaft. This ring has a projecting lug, as shown, which disengages latch-arm *A* and throws out the feed. The distance that the projection on ring *B* travels before disengaging the latch, determines, of course, the depth of the hole drilled. The screw *N* and shoe *K* provide convenient means for securely locking ring *B* to pinion shaft *L*. The stop-pin *P* determines the maximum adjustment of ring *B*.

This machine also has an automatic safety release in case of an overload, which operates as follows: Worm *F* is keyed to rotate with its shaft, but is free to slide longitudinally. Under a normal load this worm is held in the operative position with respect to worm-gear *R*, by means of a ring *C* and compression spring *D*. When overload occurs, the worm moves longitudinally against the tension of compression spring *D*, and as the

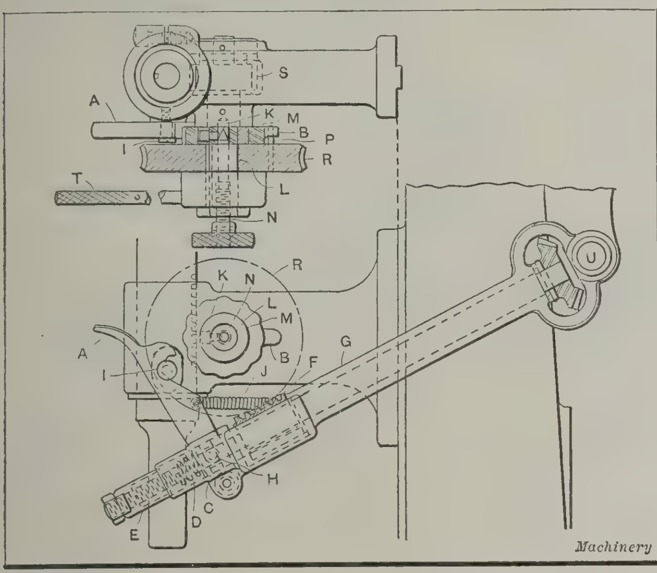

Fig. 5. Feed Mechanism of Machine illustrated in Fig. 4

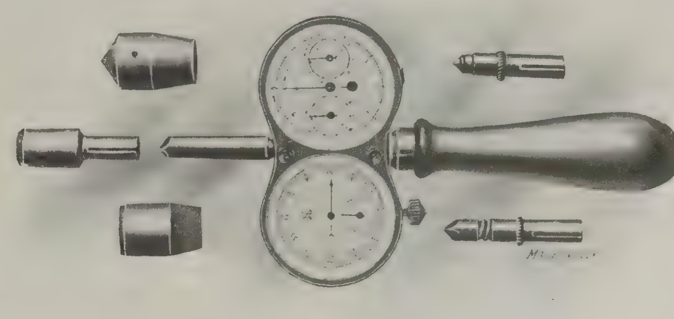
worm is connected to latch *A* through the ring *C* and pin *H*, this longitudinal movement results in disengaging the feed. The tension of spring *D* can be varied for drills of different diameter, by cap *E* and the locking nut shown. The feed can be stopped at any time by throwing out latch *A*, and it is engaged by simply lifting the worm-shaft supporting arm *G*, which causes the latch to hook over stud *I*.

A multiple-spindle machine equipped with the worm feed, is recommended when the drilling is comparatively deep, and, especially, for work which cannot be quickly inserted in or removed from the jigs. On the other hand, the cam-feed machine is adapted to that class of work which is quickly drilled and easily jigged.

SCHUCHARDT & SCHUTTE TACHOSCOPE

The instrument shown herewith is known as a "Tachoscope" and consists of a revolution counter and a non-magnetic, precision stop-watch, which are so connected that they operate simultaneously the moment a slight pressure is applied to the center spindle. As soon as the pressure is released, both the revolution counter and watch stop at the same time, thus indicating on the dials shown, the number of revolutions made

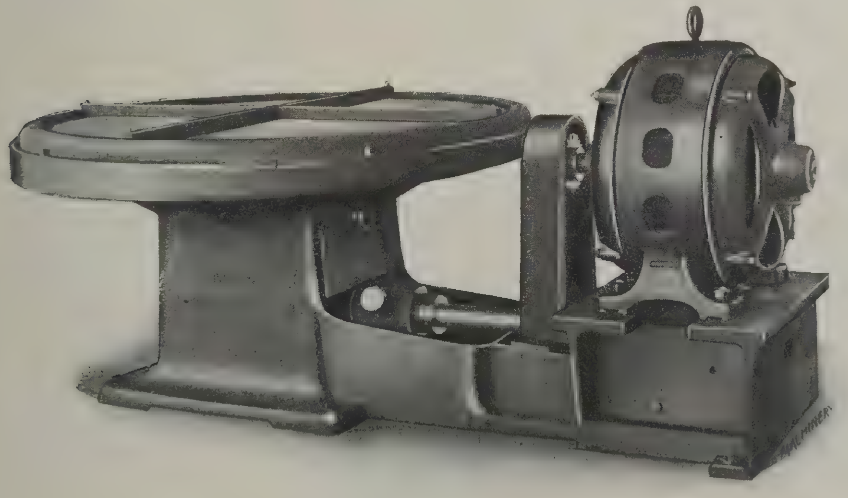


Combined Revolution Counter and Stop-watch

by whatever is being tested, and also the time elapsed. The small pointer on the watch dial records up to thirty minutes and then repeats, and the duration of the test is indicated in minutes, seconds and fractions thereof. The revolution counter has three pointers which indicate from 1 to 100, 100 to 1000 and 1000 to 10,000 revolutions per minute, respectively. This instrument can be used for right- or left-hand rotation and no adjustment or setting is required. The appearance of either a red or black disk on the counter dial, indicates whether right or left rotations are being counted, and the figures on the dials which correspond in color with this disk, are the proper ones to use. The counter and also the stop-watch, can be set back to the zero position instantly. The movements of the stop-watch and counter are said to equal in precision those used in high-grade time pieces. This instrument, which has been placed on the market by Schuchardt & Schutte, Cedar and West Sts., New York, is especially recommended for testing rapidly revolving parts and it can be used for speeds up to 30,000 revolutions per minute.

GARDNER MOTOR-DRIVEN DISK GRINDER

The large vertical spindle type of disk grinder which is built by the Gardner Machine Co. of Beloit, Wis., and was described in detail in the September, 1911, number of MACHINERY, is now equipped with a motor drive. The motor is mounted on an extension of the base and forms an integral part of the machine, as shown by the accompanying view. A 15-horsepower motor is used, and connection is made with the main shaft of the grinder by a silent chain. This main shaft, in turn, drives the disk wheel spindle through bevel gears which are fully enclosed and run immersed in oil. A guard covers the chain and gears as shown. The starting box for the motor is attached to the rear of the base and does not show in the illustration. The pedestal for the motor is made to accommodate any standard make that is specified.

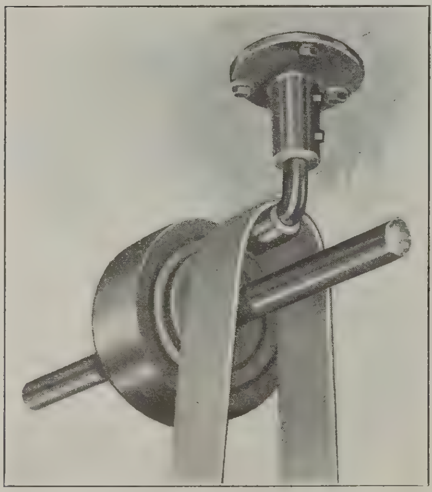


Gardner Vertical-spindle Motor-driven Disk Grinder

When these machines are installed in plants having no dust exhaust system, an exhaust blower is furnished. The pulley for driving this blower is attached to the main driving shaft, midway between the shaft collar and the silent chain gear. The disk wheel is driven at 500 revolutions per minute, and is 53 inches in diameter. This type of grinder is also made for a belt drive, from either overhead or underneath. The motor-driven type is often more convenient when it is desired to place the machine under a hoist or crane-way. The complete weight of the machine is 4500 pounds.

SAFETY BELT-HANGER

The Universal Stamping Co., 47 Poultney St., Buffalo, N. Y., is now manufacturing a safety belt-hanger which is designed to prevent the accidents caused by belts winding up on the shaft when they are thrown on or off the pulleys. This hanger consists of a cast-iron bracket which is fastened to the ceiling or shaft-hanger support, by three lag-screws or bolts. The hanger proper is made of steel tubing bent at right angles on the lower end. The horizontal part thus formed carries a roller which is held in place by a small casting driven in the end of the tube. The hanger is located over the center of the shaft, and on whichever side of the pulley the belt is usually thrown off. The supporting roller should be about one-half inch below the rim of the pulley. The end of the roller should also be close to the side of the pulley. When a belt is thrown off it runs onto the roller, and, if the other end of the belt is also thrown off the driven pulley, the belt will hang free from the shaft, as shown in the illustration. When a belt is being placed on the revolving pulley, it is first engaged with the stationary driven pulley, after which it is slipped onto the driving pulley by using an ordinary belt pole. As the belt is held close to the pulley rim by this hanger, it can be put on easily. This belt-hanger is made in three sizes for belts up to 6 inches in width.



Safety Belt-hanger

CHAMPION MOTOR-DRIVEN LATHES

The method of applying a motor drive to the 12-, 14-, 16, and 18-inch lathes built by the Champion Tool Works Co., 2422 Spring Grove Ave., Cincinnati, Ohio, is shown in Figs. 1 and 2.

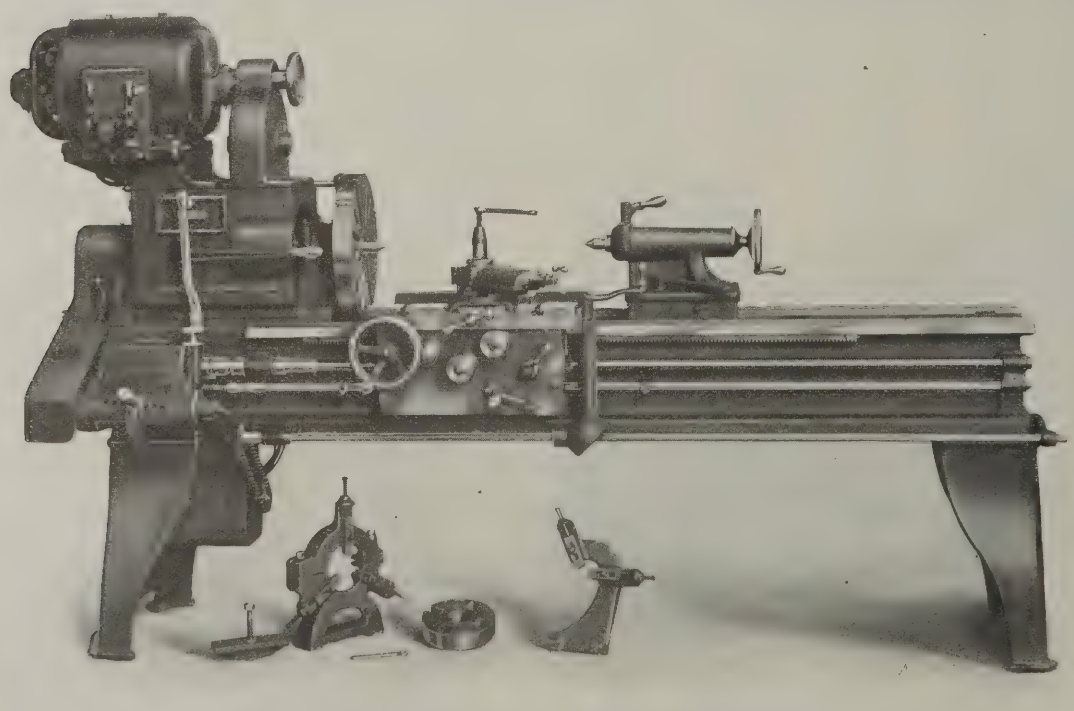


Fig. 1. Motor-driven Lathe built by the Champion Tool Works Co.

The power is transmitted from the motor to the lathe spindle as follows: A steel pinion mounted on the motor shaft, meshes with a raw-hide intermediate gear which makes the drive practically noiseless. This raw-hide gear drives a friction gear which runs freely on the spindle sleeve. Keyed to this sleeve there is a friction controlled by the horizontal lever seen in front of the headstock, and by means of this lever, the lathe can be stopped or started at will, independently of the motor. The drive from this point to the spindle is either direct through the face gear to which the friction can be connected by means of a locking pin, or through either one of the positive-clutch, double back-gears which are controlled by the vertical lever shown. These three mechanical changes in the headstock, in addition to those obtained by the three to one variable-speed direct-current motor, give a wide range of progressive spindle speeds. The spindle speeds vary (approximately) from 12 to 400 revolutions per minute, and the convenience of the control enables these changes to be obtained quickly and with little effort on the part of the operator.

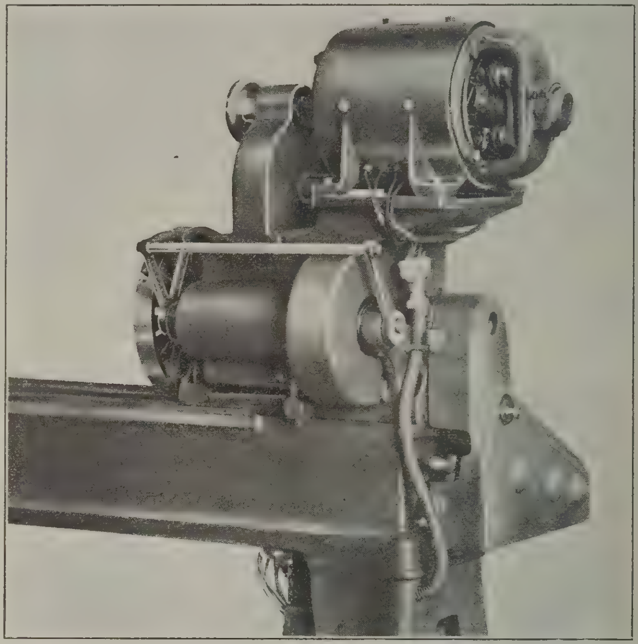

Fig. 2. Rear View showing Headstock End of Motor-driven Lathe

The speed of the motor is regulated by a drum-type controller located under the headstock end of the lathe. This controller is operated by the crank handle seen at the right of the apron. The connection between this handle and the controller is made through bevel gears, a splined rod and the chain and sprocket wheels shown. A handwheel on the outer end of the motor shaft, enables the operator to revolve the lathe spindle by hand, when this is necessary in connection with the chucking or inspection of work. Any standard make of motor having a speed variation of from 500 to 1500 R.P.M., can be used and the following sizes are recommended: For a 12-inch lathe, 1 horsepower; 14-inch lathe, 1 horsepower for medium duty, and 2 horsepower for heavy duty; 16-inch lathe, 2 horsepower; 18-inch lathe, 3 horsepower. These lathes can also be furnished for motors of the alternating current type.

The back-gears on this machine are so arranged that a change from the single to the double back-gear can be made without stopping the lathe. As previously stated, this change is effected by the vertical lever seen in front of the headstock. These gears have a positive internal key clutch, and the change

from fast to slow or *vice versa*, can be made quickly without shock or jar. The feeding movement of the lathe can be reversed either from the apron or headstock, and the longitudinal feed can be disengaged at any predetermined point by automatic stops. There is a chasing dial for thread cutting and an interlocking device to prevent engaging the screw and rod feed simultaneously. The quick change gear box gives forty changes for feeding and threading without removing any gears. Eight of these changes are obtained by a single lever, and one movement of a push-pin varies the entire range. All the gears are carefully guarded as will be seen by referring to the rear view, Fig. 2.

The 16-inch lathe has a swing of 17⅛ inches over the bed and a swing of 11⅝ inches over the carriage bridge. It has a capacity for cutting screws having from 2 to 56 threads per inch, including 11½ pipe thread. The ratio of the double back-gears is 8 1/3 to 1 and 3 to 1, respectively. A double friction countershaft, large and small faceplates, steady- and follow-rests, wrenches, etc., are included in the equipment. A taper attachment, chucks, chuck-plates, a draw-in attachment, spring collets, oil pan, pump, turrets for the carriage or bed, and similar equipment, can be furnished extra if desired.

SLOCOMB INSIDE MICROMETER SETS

The J. T. Slocomb Co., Providence, R. I., has recently placed on the market inside micrometer calipers in sets, contained in morocco-covered velvet-lined cases. Some of these sets contain only inside micrometers, and others have, in addition, regular outside micrometers, as shown in the accompanying illustrations. The set seen in Fig. 1 contains two inside micrometer handles, with two points for each handle for measuring diameters from ½ to 2 inches by thousandths of an inch. The set shown in Fig. 2 has one inside micrometer handle with two points for measuring from ½ to 1 inch, and it also contains a 1-inch outside micrometer. There are six sets, in all, which differ in the combination and number of tools they contain.

The form of the inside micrometer permits it to be used for measuring throughout the depth of any hole within its capacity and it is adapted for either tool-room or general machine shop work. This micrometer is a direct-reading instrument and can be set to given dimensions without using an outside micrometer. The inside micrometer is made in two sizes and each size has two measuring screws which are fitted with individual nuts graduated to read to thousandths of an inch. Adjustments for different diameters are obtained by turning these graduated nuts and the caliper is locked in any position by simply turning the knurled handle. The adjusting screw is prevented from turning with the nut by V-grooves engaged by a V-pointed spindle at the side, which is tightened by the handle and forms the lock. The V-groove has 1/10 inch graduations, which appear above the nut after every fourth revolution, thus giving a direct and continuous reading in addition to that obtained by finer graduations on the periphery of the nut.

Fig. 1. Inside Micrometer Set with Capacity for measuring from 1-2 to 2 Inches

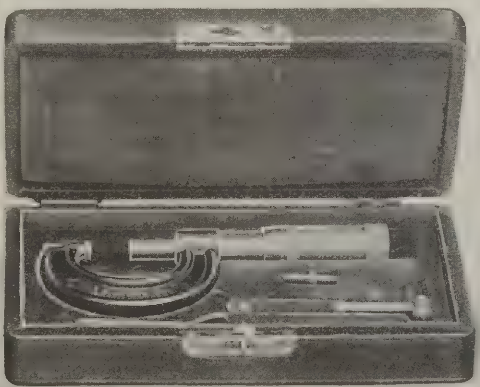

Fig. 2. Combination Set containing Inside and Outside Micrometer

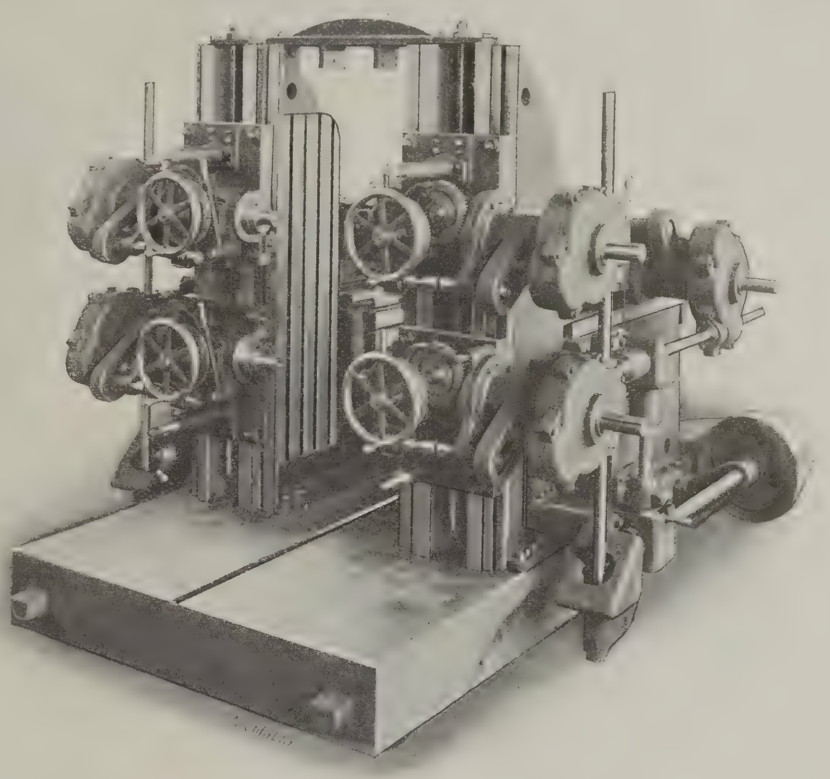
BEAMAN & SMITH SIX-SPINDLE BORING MACHINE

The boring machine illustrated herewith is a special design built by the Beaman & Smith Co., Providence, R. I., for boring and reaming heater sections. This machine has a heavy base or platen upon which are mounted two uprights. On the front face of each upright, there are two adjustable saddles, each of which carries a horizontal spindle. At the rear of the upright, there are horizontal beds and each bed also has a saddle and horizontal spindle, making six spindles in all. The work is held in a jig and it is bored or reamed simultaneously from both sides, by the different spindles, thus giving a rapid production.



Beaman & Smith Special Six-spindle Boring and Reaming Machine

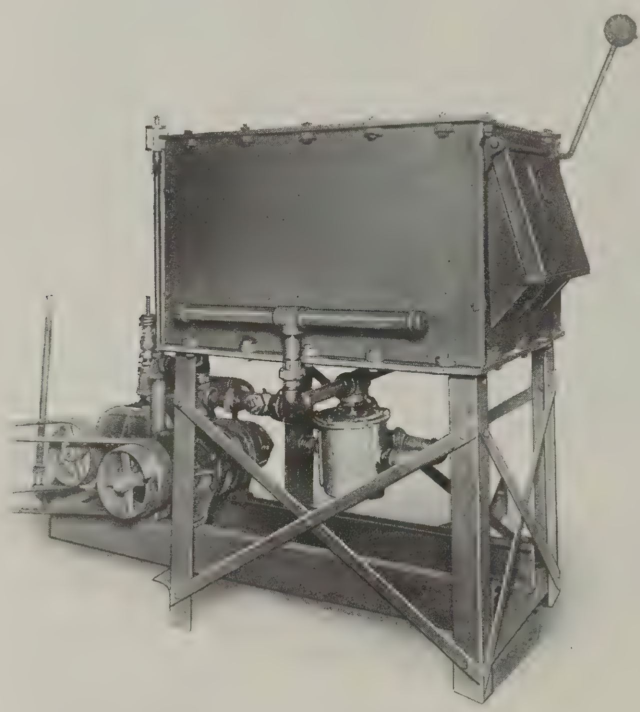
The platen is provided with a track on which a jig holding the work is rolled into position. Two jigs are required, so that one can be loaded or unloaded, while the other is in the machine. The spindles in each upright are driven in unison, and those on the beds at the rear are independent. All the spindles have a horizontal movement of 11 inches in their respective heads. There are four speeds ranging from 15½ to 32 revolutions per minute. The feeds for the spindles are automatic and vary from 1/64 to 1/16 inch per revolution. Variations of feed are obtained by change gears. Each side of the machine is driven independently by 5-inch belts which operate on four-step cone pulleys at the rear. The driving gears have a ratio of 14 to 1.

The spindles are all crucible steel and run in hard bronze boxes. The inner ends of the spindles are fitted to the particular form of cutter required. The platen of this machine is

6 feet wide and 10 feet long. The distance between the uprights is 23½ inches. The minimum distance between the centers of the front spindles is 18 inches and the maximum distance, 49 inches. The minimum and maximum distances between the ends of opposed spindles, are ¾ inch and 22¾ inches, respectively. The greatest distance between the front and rear spindles is 62 inches. The weight of this machine is approximately 31,000 pounds.

CASEHARDENING AND ANNEALING FURNACE

The casehardening and annealing furnace shown herewith is manufactured by the Wisconsin Foundry & Machine Co., Madison, Wis. The principal features claimed for this furnace are: high temperatures with a minimum amount of gas, ease of heat regulation for constant temperatures, and simplicity of operation. The furnace proper has a fire-brick heating chamber, 15 inches wide, 11 inches high, and 30 inches



Casehardening and Annealing Furnace

long. This chamber is thoroughly insulated from the iron shell by air spaces and asbestos board strips. The insulation is said to be so effective that the furnace chamber remains hot after the fire has been out about fifteen hours. The furnace door is easily opened or closed, owing to the ball counterweight provided. Each installation is supplied with two positive-pressure blowers of sufficient size to produce the best results. The air and gas enter, separately and under pressure, a mixer which is seen under the furnace. Here the gas and air are thoroughly mixed, and this mixture passes to the furnace through a single pipe. It is claimed that a temperature of 2500 degrees can be easily obtained. The installation illustrated is equipped with a gasoline priming system which is used to advantage in starting the furnace, or for enriching a poor quality of gas, in order to get the desired heat. This furnace can also be supplied in sizes varying from 15 by 15 inches to 15 by 36 inches.

SHUSTER STOCK STRAIGHTENER AND CUTTER

The machine shown herewith is designed to automatically straighten and cut to accurate lengths either square, hexagon or flat stock. It has a capacity for ¾ inch squares or hexagons and it will also handle flat stock 1¼ inch wide by ¼ inch thick. A maximum length of 20 feet can be cut, but

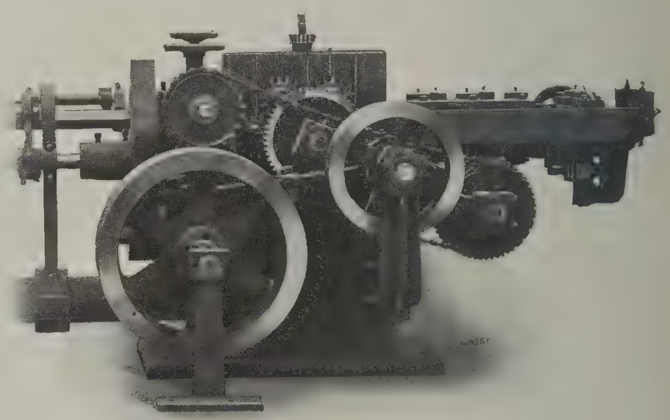


Fig. 1. Rear View of Shuster Stock Straightener

only part of the extension of the machine is shown in the illustration.

The machine is driven by a balance wheel (see Fig. 1), which connects with a train of gears operating the horizontal and vertical straightening rolls and feed rolls. There are five vertical and five horizontal rolls, all of which are gear driven. These rolls have grooves corresponding to the shape of the material they are to handle. The upper horizontal rolls and the rear vertical rolls are adjusted, by means of suitable screws, to suit the size of the material. The front feed rolls are adjusted by the handwheel shown above them, and they are driven in unison with the back feed rolls, by the chain and sprockets, seen in Fig. 1. The back feed rolls (at the left end of the machine) are also adjusted by a handwheel.

The extension consists of a guide-bar having a suitable groove for the shape of material being handled, and a cover or apron. There is an adjustable stop-gage which is set for the length to be cut. The coil of stock should be mounted on a suitable reel located at the end of the machine. The stock first passes through a guide and then enters the rear feed rolls. The straightening rolls are next encountered and then the front feed rolls. After passing the latter, the stock moves through a bush die, past the cutter knife and into the guide-bar until it strikes the stop gage previously referred to. Then

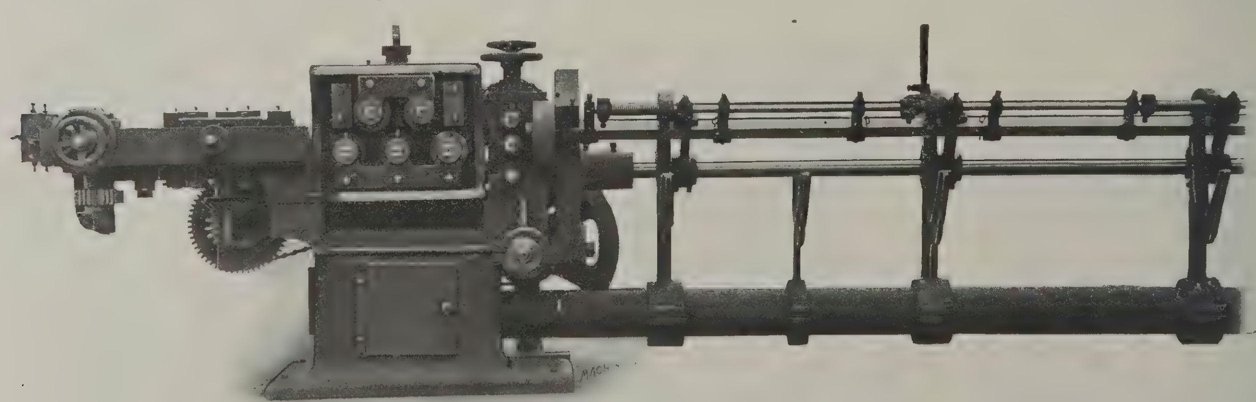

Fig. 2. Side View of Shuster Geared-roll Stock Straightener and Cutter

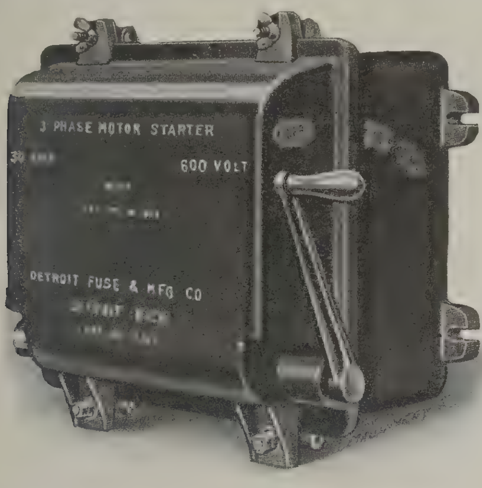
the cutting mechanism is automatically set in motion and the knife severs the piece, after which the guide-bar cover is thrown open and the cut rod drops out into the forked holders or brackets shown. As soon as the stock strikes the stop-gage, a clutch mechanism is thrown in, which releases the feed rolls and causes them to remain stationary while the cutting operation takes place. This machine is built by the F. B. Shuster Co., New Haven, Conn.

DETROIT THREE-PHASE MOTOR STARTER

A new type of three-phase motor starter is now being manufactured by the Detroit Fuse & Mfg. Co., 1400 Rivard St., Detroit, Mich. This starter makes it unnecessary to "fuse" a three-phase motor for the starting current, and it automatically protects the motor from injury, as well as the operator. The size shown in the illustration, has a capacity of 30 amperes at 400 to 600 volts, and it is especially adapted



Detroit Three-phase Motor Starter

for motor-driven machinery using alternating-current motors with any voltage above 250 and not exceeding 600.

The starter is of very substantial construction, and all the mechanical or moving parts are enclosed in a cast-iron box. The switch is operated by the hand lever seen at the side of the box. To start a three-phase motor, this lever is moved to the "start" position. This closes the circuit and places the fuses in the circuit, but "parallels" them with a solid copper bar which takes care of the starting load. It is necessary for the operator to hold the lever in the starting position until the motor reaches its normal speed; he then removes his hand from the lever and the parallel bars are thrown out of the circuit without opening it. This leaves the fuses completely protecting the motor at its running load, without at any time breaking the contact, as is done when a double-throw knife-switch is used for this purpose. There are no flimsy or complicated parts connected with this starter, and in its operation there is no possibility of accidental contact with "live" parts The three-phase starter is also made in a 200 to 250 volt size.

NEW MACHINERY AND TOOLS NOTES

Chuck Closer: Stark Tool Co., Waltham, Mass. Hand-operated chuck closer for bench lathes which enables the work to be released or clamped while the lathe is in motion. This chuck is operated by a lever at the left of the headstock.

Band Saw: Houghton & Richards, 26 N. Clinton St., Chicago, Ill. Tilting band saw designed for cutting metal. The saw is operated by gravity feed and the band wheels are mounted on a tilting arm which swings forward over the table and gives a continuous feeding movement.

Lathe Center: Stark Tool Co., Waltham, Mass. Self oiling lathe center which can be oiled without withdrawing it from the work. The hole through which the oil is inserted, is normally kept closed by an adjustable brass collar. This collar retains the lubricant and excludes dust or dirt.

Tapping Machine: Evans Stamping & Plating Co., Taunton, Mass. Vertical tapping machine having an automatic stop mechanism for tapping to any predetermined depth. This machine is built for either hand lever or foot lever operation. It has a capacity up to ¼ inch, and the work table is 11½ inches in diameter.

Drilling Machine: Richmond Stay-Bolt Drilling Machine Mfg. Co., 11 E. Broad St., Richmond, Va. Machine for drilling the tell-tale holes in boiler stay-bolts. The bolts are dropped into slots in a revolving carrier, and then all the operations are performed automatically. The carrier may be easily adjusted to accommodate bolts of different lengths.

Emery Wheel Guard: Challenge Machine Co., Inc., Philadelphia, Pa. Emery wheel protector and dust guard. The guard proper is made of four heavy steel bands which have great strength. At the ends of the guards in front, there are adjustable shields which deflect the grindings and protect the eyes of the workmen. The guard is attached to the machine by a heavy arm.

Pipe Threading Machine: The Loew Mfg. Co., Cleveland, Ohio. Pipe threading machine which will not only cut off and thread pipe, but also cut off and thread nipples without the use of a nipple chuck. This machine is a lathe bed type. The die-head is self-locking and self-releasing. There are two changes of speed obtained by shifting gears, and no countershaft is required, as tight and loose pulleys are provided on the machine itself.

Die-Sinking Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. Die-sinking machine designed to eliminate the use of special angular cutters by having a swiveling knee upon which the work table is mounted. By means of this angular adjustment of the work table, both internal and external clearances can be milled with straight cutters. The machine is equipped with both vertical and horizontal spindles and the latter is supported by an overhanging arm.

Speed Changing Mechanism: Burke Electric Co., Erie, Pa. Arrangement for changing the constant speed of alternating or direct-current motor, in connection with machine tool drives. It consists of a frame which supports a jack-shaft and the necessary pulleys for the speed adjustments. In the case of a lathe, the frame is attached to the headstock, and the jack-shaft is located above the main cone pulley, whereas the driving motor is mounted on an extension base at the rear.

Safety Device: J. H. Williams & Co., 61 Richards St., Brooklyn, N. Y. Safety device for drop-hammers, designed to automatically prevent accidents to the operator when inserting work by hand. The device is used in connection with work which has to be "restruck" after the "flash" or excess metal has been removed. A spring steel guard is clamped to the guide or upright, and when the ram descends, the guard swings outward, thus forcing the hand of the operator away from the danger zone.

Gear Testing Machine: Peerless Gear Tester Mfg. Co., 602 Schofield Bldg., Cleveland, O. Gear tester for determining the concentricity, pitch diameter and variation in the tooth thickness of spur and bevel gears. The machine consists of a horizontal base, having a stationary and a movable block carrying hardened and ground studs for holding the master gear and the gear to be tested. There is also the necessary mechanism for transmitting the motion caused by inaccuracy in the gear being tested to pointers swinging over graduated dials.

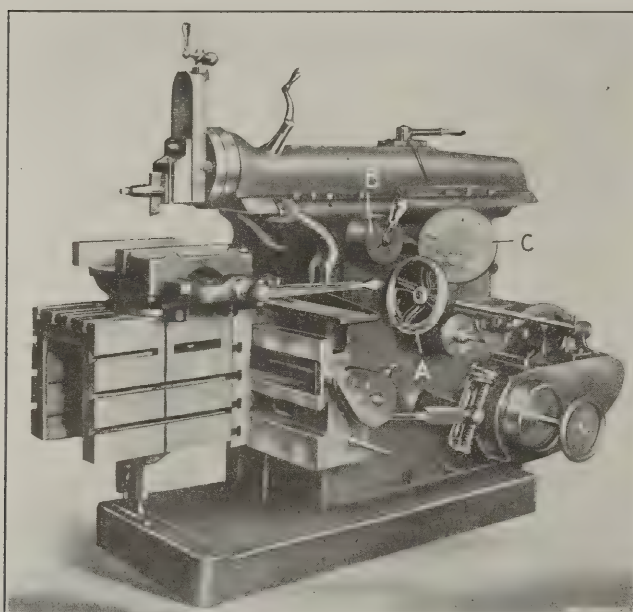
Surface Grinder: Northampton Emery Wheel Co., Leeds, Mass. Grinder for surfacing dies, chucks, straightedges, surface-plates, typewriter parts and all similar work within the capacity of the machine. This grinder is of the column-and-knee type and the table can be operated either by hand or automatically. The vertical feed is shown by a dial graduated in thousandths of an inch. Three sizes are built, the smallest of which has a table measuring 10 by 24 inches and the largest, 10 by 36 inches. A 12-inch wheel is used, and the side feed can be varied from 1/64 to 1/8 inch per stroke.

Motor Drive for Lathes: South Bend Machine Tool Co., South Bend, Ind. Double-belt reversible motor drive for lathes, consisting of a cast-iron bracket pivoted to a casting attached to the rear of the bed and carrying both the countershaft and motor. The motor is mounted on the lower end of this bracket and is connected to the countershaft at the upper end by open and cross belts. A cone pulley on the countershaft is belted to the headstock pulley, and the proper tension for this driving belt is obtained by simply adjusting the rear bracket by means of a screw in front of the lathe. The forward and reverse movements are controlled by a horizontal shifter rod which extends along the lathe bed and is within convenient reach.

The Periodograph: Gisholt Machine Co., Madison, Wis. Recorder for keeping accurate record of time required by workmen on various jobs. Each man is supplied with a card on which the recorder registers the time at which a piece of work is started. When the job is completed, the card is again placed in the recorder and the finishing time is automatically registered just above the starting time. By simply subtracting the lower figure from the upper, the net time is obtained. Spaces are provided on the card for several starts and stops, and by carrying the net periods to the right, it is easy to sum up the total time. The stamp automatically locates the card, so that the recorder can be operated by the workmen without chance of error.

SHAPER HAVING AUTOMATIC STARTING CONTROL AND SPEED DIAL

A motor-driven crank-shaper equipped with an automatic starting control and a speed dial for obtaining any desired cutting speed, is illustrated herewith. This is a Gould & Eberhardt machine and it is driven by a 5 horsepower Reliance adjustable-speed motor having a speed range of from 300 to 1500 revolutions per minute. The speed adjustments are obtained by mechanically shifting the motor armature by handwheel *A*. When the speed is properly set for a given operation, the motor can be stopped and started as often as desired, without further attention to the speed adjustment. This is due to the fact that the starting and stopping is entirely separate from the speed regulation and is controlled by an automatic



Motor-driven Crank Shaper equipped with Automatic Starting Control and Speed Dial

starter through the drum switch *B*. This switch has three positions, namely, the "start," "off," and "break" positions. To start the motor, it is simply necessary to throw the switch to the starting position. When the switch is moved to the "off" position, the power is shut off, and the time then required for the machine to stop will depend upon the time required for friction to overcome the momentum of the moving parts. When the switch is thrown to the "brake" position, the motor is automatically brought to a stop almost instantly. This simple method of stopping eliminates the necessity of a clutch, and the motor is never running idle, thus unnecessarily wasting power. The starter, which is mounted on a nearby post, is of the series control type and automatically takes care of all starting conditions. All wircs are carried in a conduit which is tapped directly in the drum switch, so that there is no exposed wiring.

The speed dial *C* is a device used with the Reliance adjustable-speed motors to enable the motor speed to be quickly regulated for obtaining any required cutting speed of the tool. This device is in the nature of a circular slide rule, and, in the case of a shaper, it takes into account all the variable factors, such as the ratio of the drive and the length of the stroke. The method of using this dial was described in the March number of MACHINERY. It is the product of the Reliance Electric & Engineering Co., Cleveland, Ohio.

* * *

PERSONALS

Henry L. Gantt spoke on "Scientific Management" before the American Society of Swedish Engineers, Brooklyn, N. Y., Saturday evening, March 23.

William H. Holland, of the Sibley Machine Tool Co., South Bend, Ind., has succeeded Mr. Walter A. Sibley as president and general manager.

E. H. Pratt, Lansing, Mich., has been promoted from the position of toolroom foreman to that of tool engineer of the Olds Motor Works of Lansing.

Frank P. Judge, formerly head of the mechanical department of the Wells Bros. Co., Greenfield, Mass., has been appointed general superintendent of the company's bolt cutter and gage shops.

George V. Rottweiler has resigned as chief engineer and factory manager of the Falls Machine Co., Sheboygan Falls, Wis. Mr. Rottweiler designed the line of gasoline motors built by the motor department of the company.

E. E. Barney of Syracuse, N. Y., the present manager of the Smith Premier Typewriter Works of Syracuse, has been appointed manager of the Remington Typewriter Works of Ilion, N. Y., to succeed Mr. John Calder, whose resignation takes effect May 15.

Albert G. Lea, who for the past five years was president of the Lea Equipment Co., New York and Philadelphia, has disposed of his interest in the company to Philadelphia parties, and has resigned as president. Mr. Lea will not enter active business for the present.

John Calder, who for several years has been manager of the Remington Typewriter Works, Ilion, N. Y., has resigned his position, effective May 15, to take a position with the Cadillac Motor Car Co., Detroit, Mich., where he will be associated with the management.

D. De Vries, manager of the well-known firm of dealers, R. S. Stokvis & Zonen, Ltd., Rotterdam, Holland, is in this country, where he arrived February 20. Mr. De Vries expects to remain for about eight weeks, visiting the principal machine tool concerns throughout the country.

George Langen, works manager of the Cincinnati Planer Co., Cincinnati, Ohio, sailed March 18 for Europe, where he will make a trip covering the entire continent. Mr. Langen expects to be gone four or five months. The trip is taken principally in the interests of his company.

Walter B. Snow, publicity engineer, 170 Summer St., Boston, has increased his organization by the addition of Mr. Charles L. Mulligan, late of the editorial staff of the Brooklyn *Standard-Union*, and for a considerable period associated with the publicity department of the Western Electric Co.

Howard D. Penney, for several years foreman for the Knox Automobile Co., Springfield, Mass., and for the past two years with the Parker Transmission & Appliance Co., of the same city, has taken a foreman's position with the Hendee Mfg. Co., manufacturers of the Indian motorcycle, of Springfield.

C. F. Barker of the firm of Gilbert & Barker Mfg. Co., Hartford, Conn., retired from the firm on January 1, 1912, having reached the age where he felt that he had earned a well-deserved rest. Shortly before retiring, his associates in the office presented him with a clock as a token of their esteem and good wishes.

Frank D. Chase, associate member of the American Society of Civil Engineers and architect of the Western Electric Co., has opened offices in the Peoples Gas Bldg., Chicago, Ill., for the practice of architecture and industrial engineering. Mr. Chase will make a specialty of manufacturing plants and mercantile buildings.

Allen D. Risteen, who for the past twenty-three years has been assistant editor and editor of *The Locomotive*, Hartford, Conn., has resigned to become connected with the Travelers' Insurance Co., of the same city. Dr. Risteen has contributed many valuable articles on steam boiler inspection and practice to the technical press.

Arthur B. Tilton, assistant advertising manager of Hoskins Mfg. Co., Detroit, Mich., has been made advertising manager, succeeding Mr. H. Ralph Badger, resigned. Mr. Badger, who had been with the Hoskins Mfg. Co. for three years as publicity manager and assistant manager of sales, will for the present confine his attention to personal interests.

H. E. Harris has been appointed general superintendent of the Wells Bros. Co.'s tap and die plant. He was formerly the company's assistant superintendent and production engineer and came to them from the Western Electric Co., with which he had been master mechanic and methods engineer. Mr. Harris read the paper "Taps and Tapping," presented before the monthly meeting of the A. S. M. E., March 12.

George J. Henry, Jr., who has had eighteen years' experience with the Pelton Water Wheel Co., San Francisco and New York, ten years of which were spent as the company's chief engineer, and the past six years as chief engineer and sales manager, has resigned, and opened an engineering office at No. 737 Rialto Building, San Francisco, Cal. Mr. Henry will specialize on hydraulic machinery and hydraulic installations.

George H. Graves, treasurer, and George T. Coppins, secretary, of the Walworth Mfg. Co., Boston, Mass., were recently presented with loving cups by twenty employes of the company, only two of whom have been in the company's service less than twenty years. The average term of service of the givers of the cups is thirty-one years. Mr. Graves has been with the company forty-seven years, and Mr. Coppins thirty years.

H. R. Setz, who has been chief engineer of the Struthers Wells Co., Warren, Pa., for the past two years, has taken the

position of chief engineer with the Otto Gas Engine Works of Philadelphia. Mr. Setz was formerly connected with several of the leading European and American gas and oil engine manufacturers. His attention will be chiefly directed toward the development of a complete line of Otto-Diesel engines of the horizontal type.

C. C. Owens was recently placed in charge of the Detroit sales office of the Westinghouse Electric & Mfg. Co., with the title of district manager. Mr. Owens was born in 1877 and graduated from Columbian University, Washington, D. C. He entered the employ of the Westinghouse Electric & Mfg. Co. in 1896, taking the apprenticeship course for three years in the engineering department, specializing on switchboards and controllers. For the past eight years he has been connected with the New York sales office.

William R. Wherry, a Pennsylvania R. R. passenger conductor, was retired March 22, at the age of sixty-seven, after fifty years of active service. In this period he was never suspended or disciplined in any manner. Mr. Wherry was born in Cambria County, Pa., and when seventeen years old was employed by the Pennsylvania R. R. Co. as a freight brakeman. One promotion followed another until he was made a passenger conductor on the Pittsburg Division, where he is employed at the present time. The record of this passenger conductor, who is the type of man the company puts in charge of its trains, is given in a letter written by him to his superintendent: "I have now been running a passenger train for almost forty-six years and in that time have never had a serious accident, never had a passenger seriously injured or killed, have never been fined or suspended, always got along well with the traveling public, was never reported by a passenger that I heard of, and never was the cause of any lawsuits, which, when you consider the number of people of all kinds I have handled, is a wonder. It has always been my aim to do everything in my power to take my train over the division safely, and I have always held the company's interests first and have been loyal to it. I have never been seriously injured, but have had some very narrow escapes, having fallen between freight cars, and been knocked down by an engine and squeezed between cars."

* * *

OBITUARIES

Henry W. Spangler, Whitney professor of dynamical engineering, University of Pennsylvania, Pa., died March 17.

Alanson H. Merriman, a manufacturer of drop presses for the past forty years, died in Hartford, Conn., March 4, aged eighty-four years.

Frank E. Eggleton, superintendent of the molding department of the Waterbury Farrel Foundry & Machine Co., died March 5, at his home in Waterbury, of pneumonia, aged forty-six years.

John H. O'Donnell, regarded as an authority on wire drawing machinery, died at his home in Waterbury, Conn., February 27, aged forty-eight years. He was the inventor of the diamond wire-drawing die, and was prominently identified with various concerns in Waterbury and Seymour, Conn., and Worcester, Mass.

Charles Hart, president of the Hart Mfg. Co., Cleveland, Ohio, died February 9, aged sixty-two years. He was a lifelong resident of Cleveland and established the company of which he was president and treasurer, thirty years ago. He is survived by a widow, daughter and son, Mr. Louis F. Hart, vice-president and secretary of the company.

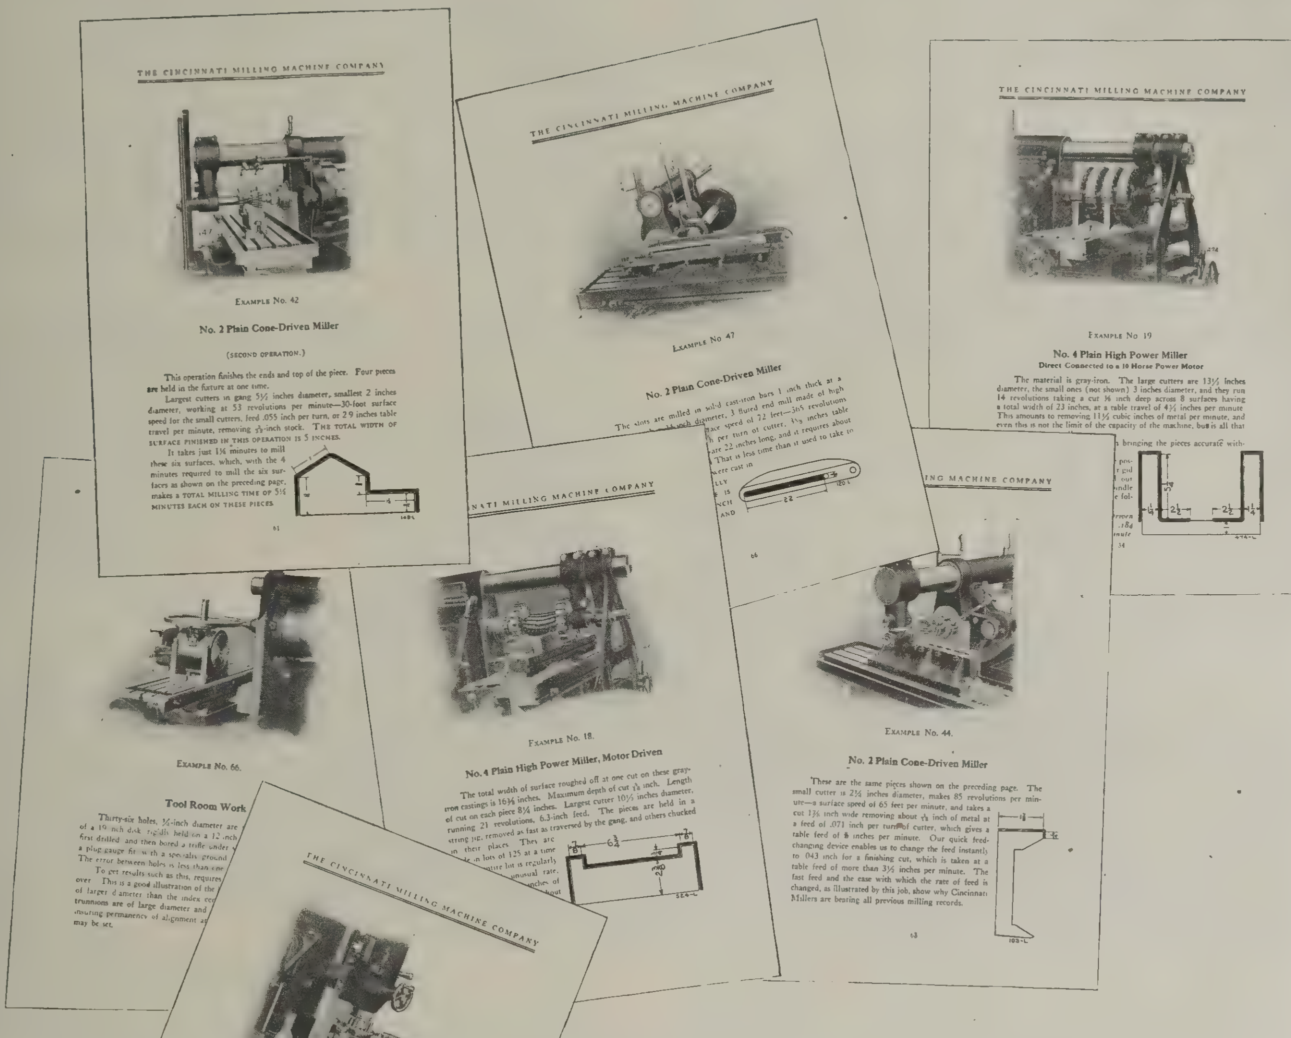
Elias G. Heller, president of the Heller Bros. Co., Newark, N. J., prominent steel and file makers, died at his home in the Forest Hill section of that city, March 22, of pneumonia, following apoplexy, in his seventy-fifth year. The firm of Heller Bros. was established in 1865 by the three brothers, Elias, Peter and Lewis, and a factory was built in the following year. The business soon outgrew the capacity of the building and a much larger plant was built in 1872. Lewis Heller withdrew from the firm in 1870 and Peter Heller in 1880, in which year the brothers George and John Heller were made members of the firm. Mr. Heller is survived by a widow and three sons, Paul E., Arnaud G., and R. Arthur Heller.

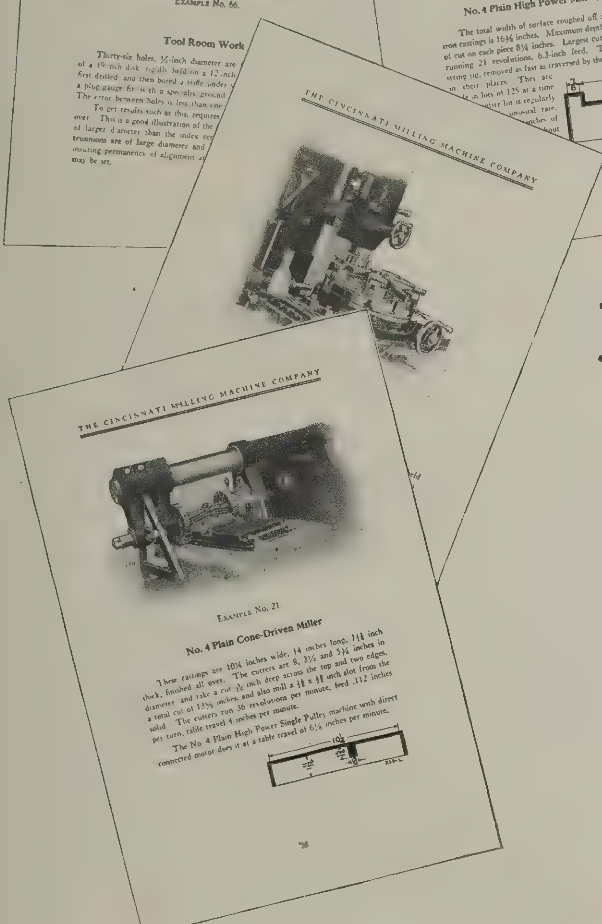
Rear-Admiral George W. Melville, formerly engineer-in-chief of the U. S. Navy, and world-famous as an engineer, inventor scientist and Arctic explorer, died at his home in Philadelphia, March 17 of paralysis, aged seventy-one years. At the outbreak of the Civil War, Melville, then twenty years old, entered the U. S. Navy and became an officer of the engineer corps. He saw much active service during the war and at its close was attached to the *Tacony*, with which vessel he served in the Gulf of Mexico during the occupation and evacuation of Mexico by the French. Melville's career as an Arctic explorer began with a trip to the North in 1873, when as assistant officer of the small sealing steamer *Tigress* he assisted in the search for the remaining members of the crew of the *Polaris*. Later he was the engineer officer of the ill-fated *Jeannette* expedition, and returned from this terrible experience in 1882. In the spring of 1884 he again went into the frozen North with the squadron dispatched to the relief of the Greeley expedition, the survivors of which were rescued in 1884. He was appointed engineer-in-chief of the Navy in 1887 for a term of four years and was reappointed four times successively, his retirement taking place in 1903. During this long period in the naval service one-hundred-and-twenty vessels were constructed, aggregating 700,000 horsepower. Rear-Admiral Melville was elected vice-president of the American Society of Mechanical Engineers 1895-97, president of the society in 1899, and in 1910 he was made an honorary member. Some years after his retirement from the Navy he and John Macalpine were associated in Philadelphia as a firm of consulting engineers and naval architects. During this association the Melville-Macalpine reducing gear was successfully developed for coupling steam turbines to marine propellers for the efficient propulsion of ships.

Milton Prince Higgins

MILTON PRINCE HIGGINS

Milton Prince Higgins, president of the Norton Co., and Norton Grinding Co., died Friday, March 8, at his home in Worcester, Mass., aged sixty-nine years. Mr. Higgins was born December 7, 1842 in Standish, Maine. He was the descendent of an old Cape Cod family which originally came from England in 1633. At the age of seventeen years he left home to serve an apprenticeship in the shops of the Amoskeag Mfg. Co., Manchester, N. H. While serving his time he studied evenings and saved enough money to enable him to go through Dartmouth College, from which he graduated in 1868. After his graduation he entered the employ of the Washburn & Moen Mfg. Co., under the late Mr. Charles Hill Morgan and later took a position as superintendent of the Washburn Shops of the then newly organized Worcester Polytechnic Institute, where he remained for twenty-eight years. In 1903 he was appointed a trustee of the Institute, which position he held until his death. Mr. Higgins took an active interest in the establishment of trade schools for mechanics, and his influence in industrial education has been wide-spread. During his association with the Worcester Polytechnic Institute he obtained a year's leave of absence to organize the shops of the Georgia School of Technology at Alabama. He also planned the shops of the Miller Manual Labor School of Virginia. In 1899, he presented a paper before the American Society of Mechanical Engineers on the education of machinists, foremen and mechanical engineers, thus being the first to introduce to the public the "half-time" school proposition. He was appointed a member of the state board of education by Governor Douglas of Massachusetts, and his vigorous efforts in this connection led to the establishment of the Worcester Trade School in 1908. While at the Washburn Shops, Mr. Higgins became interested in a small emery wheel business which he acquired in company with Prof. Alden. Under their management this business grew into the well-known firm of the Norton Emery Wheel Co., which later became the Norton Grinding Co. In 1896, the Worcester Polytechnic Institute sold its hydraulic elevator business to Mr. Higgins and Prof. Alden, who had been instrumental in building it up. Thus the Plunger Elevator Co. was established and carried on successfully until its absorption a few years ago by the Otis Elevator Co. In 1904, Mr. Higgins acquired an interest in the Worcester Ferrule & Mfg. Co., which in a few years greatly increased its business and was reorganized as the Worcester Pressed Steel Co. He was also president of the Manchester Supply Co., Manchester, N. H., and of the Sanford Riley Stoker Co., Providence, R. I. Mr. Higgins was a member and past vice-president of the American Society of Me-





Examples of Modern Milling Practice

Our new book "Examples" is now ready for distribution. It is a 96-page book, made up of live matter of the helpful sort, as indicated by these sample pages. Every one of the ninety-six contains information of value to you, if your job is in the Engineering, the Planning, or the Manufacturing Department.

We will send it anywhere, postage free, on request.

The Cincinnati Milling Machine Company

Milling Specialists — Cincinnati, Ohio, U. S. A.

chanical Engineers and a charter member of the Society for the Promotion of Engineering Education. He leaves a widow, two sons and two daughters. One of his sons, Alden C. Higgins, is with the Norton Co., and the other, John W. Higgins, is manager of the Worcester Pressed Steel Co.

* * *

COMING EVENTS

April 10-11.—Fourteenth annual convention of the National Metal Trades Association in New York, Hotel Astor headquarters. Robert Wuest, commissioner, New England Bldg., Cleveland.

May 13-15.—Triple convention of the American Supply and Machinery Manufacturers' Association, National Supply and Machinery Dealers' Association, and Southern Supply and Machinery Dealers' Association, at Norfolk, Va., Monticello Hotel, headquarters. F. D. Mitchell, secretary-treasurer, 309 Broadway, New York.

May 13-25.—Newark industrial exposition under the auspices of the Board of Trade of Newark, N. J., in the First Regiment Armory. It is claimed that one hundred thousand different articles are manufactured in the three thousand shops of the Newark industrial district, the diversity being proportionately greater than that of any other manufacturing district in the country. William G. Rose, manager, Newark, N. J.

May 14-17.—Sixth annual convention of the Master Boiler Makers' Association at the Fort Pitt Hotel, Pittsburg, Pa. J. R. Flannery, of the Flannery Bolt Co., Frick Building, Pittsburg, Pa., secretary and treasurer of the general committee of arrangements.

May 16-17.—Semi-annual convention of the National Machine Tool Builders' Association at Atlantic City, N. J., Hotel Chalfonte headquarters. E. P. Bullard, Jr., president, Bridgeport, Conn.; James H. Herron, secretary, Cleveland, Ohio.

May 20-22.—Railway Storekeepers Association's convention in Buffalo, N. Y. Hotel Statler, headquarters. Wm. E. Kelley, secretary-treasurer, 825 Wabash Ave., Chicago, Ill.

May 28-31.—Spring meeting of the American Society of Mechanical Engineers in Cleveland, Ohio. Hotel Hollenden, headquarters. Calvin W. Rice, secretary, 29 W. 39th St., New York.

June 12-14.—Annual convention of the American Railway Master Mechanics' Association at Atlantic City, N. J.

June 17-19.—Annual convention of the Master Car Builders' Association at Atlantic City, N. J.

July 9.—Annual convention of the American Railway Tool Foremen's Association in Chicago. H. L. Miller, secretary of the supply association, 835 Monadnock Bldg., Chicago, Ill.

August 20.—Annual convention of the International Railroad Master Blacksmith's Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7.—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; Hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

MANUFACTURERS' ASSOCIATION OF HARTFORD COUNTY, Hartford, Conn. Circular on a cooperative continuation course for shop boys offered by the Hartford Public Schools, which has been provided to fill the need of more efficient training for shop men, long felt by the manufacturers of Hartford. Charles B. Cook, manager of the Royal Typewriter Co., is chairman of the industrial educational committee of the Association.

FRANKLIN INSTITUTE, acting through its Committee on Science and the Arts, recently awarded the Elliott Cresson gold medal, the highest in the gift of the Institute, to the following gentlemen: Alexander Graham Bell, of Washington, D. C.; Samuel Wesley Stratton, of Washington, D. C.; Albert A. Michelson, of Chicago, Ill.; Alfred Noble of New York City; Elihu Thomson, of Swampscott Mass.; Edward Williams Morley, of West Hartford, Conn.; Johann Friedrich Adolph von Baeyer, of Munich, Germany; Sir William Crookes of London, England, and Sir Henry Enfield Roscoe, of London, England.

OSCAR E. PERRIGO, 6 Beacon St., Boston, Mass., has made an advance in the methods of correspondence school work whereby the courses of instruction are reduced in average cost and made of greater practical value to students. A special course is arranged for each individual to fit individual needs, and the tuition rates are made proportional to the requirements of the individual. The student is not required to spend time necessary to go over matter already well known, and he pays only for those parts of the course in which he needs specific instruction. The advantages of the system are obvious. Theory, practice and system for clerks, mechanics, engineers, accountants, manufacturers and other men connected with industrial work are taught.

NEW BOOKS AND PAMPHLETS

MECHANICAL STRESSES IN TRANSMISSION LINES. By A. GUELL. 31 pages, 6 by 9 inches. 10 illustrations. Price, 20 cents. 5 tables. Published by the University of Illinois, Urbana, Ill.

INDUCTANCE OF COILS. By Morgan Brooks and H. M. Turner. 72 pages, 6 by 9 inches. 25 illustrations and charts and 12 tables. Price, 40 cents. Published by the University of Illinois, Urbana, Ill.

BULLETIN OF SYRACUSE UNIVERSITY, Syracuse, N. Y. 509 pages, 5½ by 8½ inches. Contains general information on admission, courses, examinations, and list of students. Published by the University, Syracuse, N. Y.

ANNUAL REPORT OF THE DIRECTORS OF AMERICAN TELEPHONE AND TELEGRAPH CO. to the Stockholders, for the year ending December 31, 1911. 51 pages, 6 by 9 inches. Published by the American Telephone & Telegraph Co., New York.

FIFTY YEARS OF THE ARKWRIGHT MUTUAL FIRE INSURANCE COMPANY. By Edward V. French. 123 pages, 6 by 9 inches. Numerous illustrations, maps and charts. Published by the Arkwright Mutual Fire Insurance Co., Boston, Mass.

This book contains a history of the development of, and work done by the Factory Mutual Fire Insurance Companies during the past seventy-five years, and deals especially with that part of the work done by the Arkwright company in inducing manufacturers to cooperate for the prevention of fires in their plants, and for obtaining insurance at cost. The book is distributed to engineers, architects, manufacturers and others connected with and interested in fire prevention engineering. It gives a great deal of technical information, and should be very valuable to any one on whom it devolves to take precautionary measures against fire.

PRACTICAL PROBLEMS FOR VEHICLE DRAFTSMEN AND MECHANICS. By R. B. Birge and Hugh M. Sargent. 80 pages, 12 by 9 inches. Published by Ware Bros. Co., Philadelphia, Pa. Price $2.00.

This work is the outgrowth of practical experience in the classroom. The authors state that while intimately connected with the vehicle industry, they, in 1909, conducted an evening class in carriage drafting, and that the results of the first year were so encouraging that the work was continued through another year; the many problems which came up for discussion and solution in relation to the highly technical work of carriage body drafting were collected, and have formed the basis of the present treatise. The work contains first a number of geometrical definitions, followed by specific problems of particular interest to the carriage-maker. It is profusely illustrated, and contains not less than thirty-one full page plates with problems, and drawings of carriage bodies. The typographical execution of the book and the paper on which it is printed are of the best, making the intricate drawings extremely sharp and clear, and leaving nothing to be desired as regards distinctness in the execution of the design.

ENGINEERING AS A VOCATION. By Ernest McCullough. 201 pages, 5½ by 8 inches. Published by David Williams Co., New York. Price $1.00.

The subject matter of this work has been re-arranged from a number of addresses presented before technical schools, and is especially published for the information of parents in order that they may form a correct judgment in advising a career for their sons. In his preface the author states—certainly with considerable truth—that semi-technical periodicals and daily newspapers are the bureaus of information frequently consulted in matters of this kind, and perhaps more than one-half the students now in the technical schools are there because of the advice obtained from such sources. The book deals with the work of the engineer, the education of the engineer, and home study course. One chapter is entitled "How to Hunt and Hold a Job," and another, "Does it Pay to Study Engineering?" The work contains exact information on many subjects on which the prospective engineer should be informed, and will undoubtedly prove of value to anyone who is planning an engineering education for himself or for others.

WOOD-WORKING SAFEGUARDS. By David van Schaack. 217 pages, 6¾ by 9¾ inches. 320 illustrations. Published by Aetna Life Insurance Co., Hartford, Conn. Price $1.00.

This book offers a great number of practical suggestions for safeguarding workmen engaged in the lumbering and wood-working industries. It confines itself chiefly to machines, operations and conditions which are more or less common, but the suggestions contained should impress manufacturers with the possibilities in safeguarding, which, with some variation, will be applicable to many of the special machines used which it has not been possible to touch upon in a work of limited extent. The book is profusely illustrated, so as to clearly show the suggested safeguards. Different sections of the book are devoted to logging, saw mills, planing mills, circular saws, band saws, jointers, shapers, sanders, etc., and to the various wood-working industries. Special attention is also given to power generation and transmission, grinding wheels, and elevators. A carefully compiled index is an important feature of the book. It deserves a place on the desk of the executive of any industrial establishment employing wood-working machinery.

MARINE STEAM TURBINES. By G. Bauer and O. Lasche, assisted by E. Ludwig and H. Vogel. Translated from the German and edited by M. G. S. Swallow. 214 pages, 6 by 9 inches. 103 illustrations. 18 tables. Published by Norman W. Henley & Son, New York. Price $3.50.

The use of steam turbines for the propulsion of naval vessels has increased to a considerable extent during the last few years. The present book will therefore be welcomed by many engineers who are especially interested in this subject. The book is the work of men engaged in practical pursuits, and while it contains the necessary theory, yet the theoretical discussions have been presented in such a way as to be useful to any engineer with enough fundamental training to enter successfully upon the subject of the theory of steam turbines. The book is divided into ten parts headed as follows: Introduction; General Remarks on the Design of a Turbine Installation; The Calculation of Steam Turbines; The Turbine Design; Shafting and Propellers; Condensing Plant; Arrangement of Turbines; General Remarks on the Arrangement of Steam Turbines in Steamers; Turbine-driven Auxiliaries; and Tables. Being partly the work of an author who has already made himself favorably known to the steam engineering profession by his "Marine Engines and Boilers," it is safe to predict that the present book will be well received by engineers.

APPLIED METHODS OF SCIENTIFIC MANAGEMENT. By Frederic A. Parkhurst. 325 pages, 6 by 9 inches. 48 illustrations and 9 folding plates. Published by John Wiley & Sons, New York. Price, $2.00.

This book is based on a series of articles published by the author in *Industrial Engineering*, during 1911. A considerable amount of new matter, not contained in the original articles, is, however, included. The book does not deal with mere principles, but shows the actual application of these principles to every-day practice. As a concrete example, the history of the application of scientific management to the works of the Ferracute Machine Co., at Bridgeton, N. J., is recorded. The system adopted, closely follows the lines laid down by Fred W. Taylor, and is particularly suited to businesses employing one hundred people or more. The book is logically arranged, and commends itself particularly to the manager or superintendent on account of the practical, precise and detailed manner in which it has been written. The "glittering generalities" with which books and articles on scientific management have often been filled, are here reduced to distinct rules and descriptions of definite methods. The appendix, which contains most of the new matter not included in the original publication, and which covers over one hundred pages of the book, is especially profuse in definite information relating to the duties of the various officers and men in the shop, with instructions for each. The thoroughness of the treatment in this respect may be judged from the fact that instructions are included for the duties of the shop drawing boy, the night watchman, the janitor, the crane boss, etc. Altogether, it seems that this is the very kind of a book which persons who have looked for really practical and definite information on scientific management will welcome.

NEW CATALOGUES AND CIRCULARS

GENERAL ELECTRIC CO., Schenectady, N. Y. Booklet No. 4930 on electrically driven refrigerating machinery.

GISHOLT MACHINE CO., Madison, Wis. Leaf illustrating Gisholt 36-inch boring mill equipment for finishing flywheels in one chucking.

MAX AMS MACHINE CO., Mt. Vernon, N. Y. Circular of the Ams power presses, showing a few of the recent designs and additions to the line.

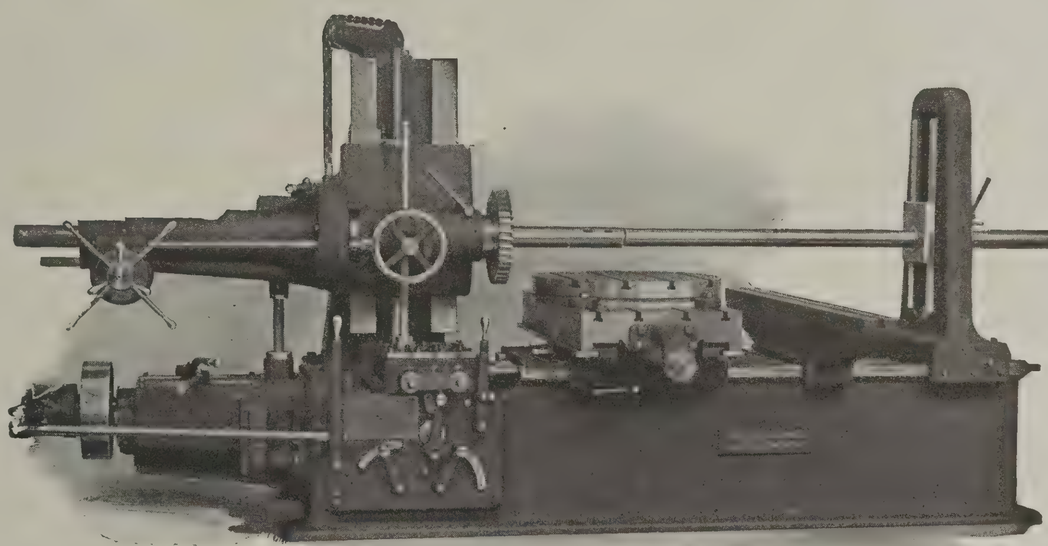
CHALLENGE MACHINE CO., INC., Philadelphia, Pa. Circular of the Challenge emery wheel protector and dust guard for the protection of workmen.

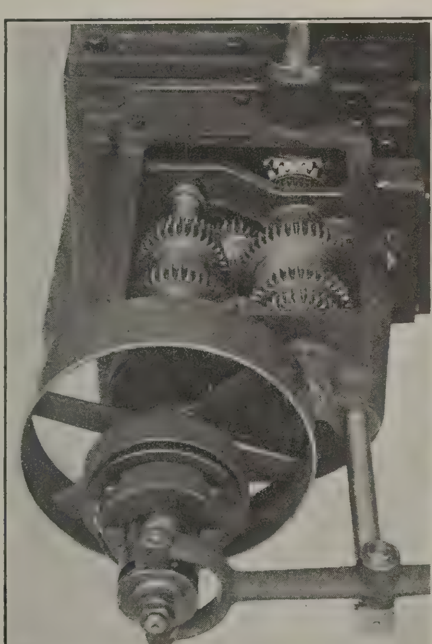
BLOOD BROS. MACHINE CO., Kalamazoo, Mich. Circular of universal

THIS IS THE

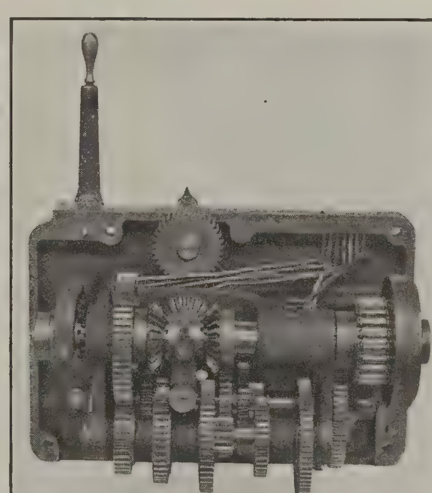
"PRECISION"

BORING, DRILLING AND MILLING MACHINE





THE SPEED BOX



THE FEED BOX

These boxes are shown approximately under the positions they occupy on the machine. Note that they are UNITS, each complete in itself, and involved in no way with each other, hence, **SIMPLICITY.**

Note also the **large size** of the boxes by comparing them with the bed, as shown in position on the machine, giving room for gears of **large diameter,** hence, **STRENGTH.**

These are two good things about the "PRECISION"—everything else about it has had the same careful attention in designing. The ACCURACY alone of the "PRECISION" would make it, as it is, the favorite of those who require something **RELIABLE.**

Lucas Machine Tool Co., NOW AND ALWAYS OF Cleveland, O., U.S.A.

AGENTS—C. W. Burton, Griffiths & Co , London. Alfred H. Schutte, Cologne, Berlin, Brussels, Paris, Milan, Barcelona, Bilbao. Donauwerk Ernst Krause & Co., Vienna, Budapest, Prague. Overall, McCray, Ltd., Sydney, Australia. Andrews & George, Yokohama, Japan. Williams & Wilson, Montreal, Can.

joints which are made in over one-hundred patterns, encased and open, single and double forms.

FORT WAYNE ELECTRIC WORKS OF THE GENERAL ELECTRIC CO., 1616 Broadway, Fort Wayne, Ind. Catalogue of electric fans; and bulletin No. 1134 on direct-current electric motors.

S. A. WOODS MACHINE CO., Boston, Mass. Booklet on inside wood molders, illustrating Nos. 107 and 107-B machines and details; also a universal side-head grinder and automatic knife grinder.

BROWN HOISTING MACHINERY CO., Cleveland, Ohio. Circular on "Brownhoist" rapid freight handling equipment, showing freight handling trolleys, roller bearing freight trucks, lumber trolleys, etc.

GILBERT & BARKER MFG. CO., Springfield, Mass. Catalogue A on oil storage systems for factory store-rooms, paint stores, hardware and commissary stores and mines, designed for handling heavy lubricating and non-lubricating "gummy" oils.

HOLUB-DUSHA CO., 93d St., and First Ave., New York. Catalogue of button machinery, comprising cutting lathes, blank splitters, thickness gages, emery stands, backing machines, button grinding machines, facing and turning lathes, drilling machines, etc.

GARWOOD ELECTRIC CO., Garwood, N. J. Leaflet illustrating a 5-horsepower "C & C" motor which has been running twenty-two years, driving the presses of the Hartfield Telegraphic Code Publishing Co. The motor is still in good condition and is in daily use.

CLING-SURFACE CO., 1018 Niagara St., Buffalo, N. Y. has issued Bulletin No. 321, a neat folder showing eleven noteworthy installations in Pennsylvania where "Cling-Surface" is profitably used on belts. Each illustration is accompanied by data concerning the belts shown.

GENERAL ELECTRIC CO., Schenectady, N. Y. Booklet No. 4927 on feeder voltage regulators, illustrating the various processes of manufacture and showing the facilities possessed by the company at its Pittsfield works for the manufacture of this type of apparatus.

SKF BALL BEARING CO., 50 Church St., New York. Bulletin No. 2 on SKF single- and double-thrust ball bearings, illustrating the self-aligning feature provided for both types; also single-thrust bearings, without self-aligning seats, capacities and sizes of all forms are listed.

E. G. SMITH CO., Columbia, Pa. Catalogue of "Columbia" beam calipers graduated in inches and metric measure, with and without verniers. The catalogue also lists and illustrates "Which Way" pocket levels, the "Columbia" spherometers, spring gages and other machinists' tools.

SUPERIOR MACHINE TOOL CO., Kokomo, Ind. Leaflet on sensitive vertical drilling machine equipped with high-duty roller bearing bushings, and having the features of constant drive, constant power factor, geared speed change box, unit spindle construction, and front control of all speeds.

FAIRBANKS CO., 416-422 Broome St., New York. Circular of the Osgood oil-groove cutting machine which cuts continuous spiral grooves in interior bushings or on the exterior of shafts, journals or studs. The capacity of the machine is from ⅝ inch to 7¾ inches in diameter and from 1½ inch to 20 inches long.

FALLS MACHINE CO., Sheboygan Falls, Wis. Catalogue of Falls gasoline motors of the tandem four-cylinder automobile type in three models of 40–45, 30–35 and 30–40 horsepower, respectively. The company also furnishes unit power plants in two models with or without foot pedals, control levers and transmission brake.

VEEDER MFG. CO., 39 Sargeant St., Hartford, Conn. Catalogue of Veeder products, comprising odometers for automobiles, tachodometer (a speed indicator or tacometer combined with an odometer) odometers for carriages, cyclometers, revolution counters, speed counters, mileage recorders for elevators, and die-castings.

NATIONAL-ACME MFG. CO., Cleveland, Ohio. Booklet on the adjustable screw-cutting spring dies which are carried in stock by the company. The advantages of spring dies are enumerated, as are also the special advantages of the "Namco" form, which are perfect rake and clearance for the teeth, ample chip room and correct temper.

CELFOR TOOL CO., Buchanan, Ill., Catalogue No. 11 on drills, reamers, flue-cutters, countersinks, chucks, sockets, tool-holders, tool-bits, and boring tools. The catalogue concludes with a table of feeds and speeds for cast iron, medium steel and hard or very tough steel, and a table of decimal equivalents comprising both English and metric measure up to 76 millimeters and 3 inches.

PERMANENT MANUFACTURERS EXHIBIT RAILWAY SUPPLIES AND EQUIPMENT, Karpen Bldg., 900 S. Michigan Blvd., Chicago. Pamphlet on scope and purpose, exhibition hall and equipment, division and allotment of space, power for working machinery, character of exhibits, and other matters of interest to manufacturers desiring to reach the buyers of railway supplies. The exhibition opened March 16.

NORTON CO., Worcester, Mass. February number of *Grits and Grinds* containing an account of the award of the *Scientific American* medal to the Norton Co. for grinding-wheel protective devices, description of the American Museum of Safety, New York, and an article on the safety movement in America and abroad. The protection hoods for grinding wheels made by the Norton Co. are also illustrated and described.

PEERLESS RUBBER MFG. CO., 16 Warren St., New York. Catalogue No. 100 of mechanical rubber goods comprising "Rainbow" sheet packings, "Peerless" piston and valve rod packings, combination packing, gaskets, rubber belting, elevator and conveyor belts, water and steam hose, air-brake hose, pneumatic tool hose, acid hose, pump valves, car vestibule diaphragms, gas engine bags, rubber cement, rubber matting, sheet rubber tiling, etc.

UNITED STATES BUREAU OF MINES has just issued Technical Paper No. 8, by Frederick M. Stanton and Arno C. Fieldner, in order to suppy the constantly increasing demands for information relating to the methods used by the Bureau of Mines in analyzing coal and coke. This technical paper describes the methods in use at the laboratories of the bureau for analyzing coal and coke and determining the heating value of these fuels. Copies may be obtained by writing to the Director of the Bureau of Mines, Washington, D. C.

HEALD MACHINE CO., 20 New Bond St., Worcester, Mass. Booklet giving the personnel of the company and its history. The business of the Heald Machine Co. was established by Stephen Heald in the year 1830, in Barre, Mass., and at first comprised the making of woodworking machinery and agricultural implements. In 1903 Mr. James N. Heald bought out his father's interest and moved the plant to Worcester, where it was organized under the name of Heald Machine Co. The plant now covers 50,000 square feet and employs 160 persons.

TAFT-PEIRCE MFG. CO., Woonsocket, R. I. Illustrated booklet showing the various departments and equipment of the plant, which is one of the largest and finest in the world devoted exclusively to the handling of light high-grade machine work on the contract basis. The company specializes on making equipment for manufacturing, comprising jigs, fixtures, dies, tools, etc., required for the economical manufacture of interchangeable machine parts. The toolroom equipment illustrated is without parallel in the United States. The booklet will be found of unusual interest to all concerned with toolmaking and high-grade machine production.

WESTINGHOUSE ELECTRIC & MFG. CO., E. Pittsburg, Pa. Special publication R. L. 57, entitled "Synchronous Motors for Power Factor Correction." This booklet, which has an art cover, contains some of the most valuable common-sense data on the phenomena of power factor and on the bad effects of low power factor and power factor correction with synchronous motors, that has been published. The publication gives much more specific data on synchronous motor installations, including curves and diagrams by means of which anyone can determine, with a few simple calculations, the capacity of a synchronous motor necessary to corrrect a given load from and to given power factors. The booklet is sent free to any address on request.

LUCAS MACHINE TOOL CO., Cleveland, Ohio. Circular of new model No. 33 precision horizontal boring, drilling and milling machine; and leaflet on the vertical milling attachment which is now furnished for the Nos. 32 and 33 machines. The No. 33 machine, like the intermediate model No. 32, has constant-speed quick power movements to all parts, having feeds so arranged that no matter what feed is used the quick return for that feed is obtained by simply moving the feed and quick-return lever in the reverse direction. The vertical milling attachment is of the bridge form of construction with both ends supported and rigidly tied by the uprights. The attachment can be quickly removed, leaving the machine unencumbered for use as a regular horizontal boring and milling machine.

J. T. SLOCOMB, Providence, R. I. Catalogue No. 13 of machinists' tools, comprising external micrometers up to 18 inches capacity, internal micrometers, standard end measures, standard reference disks, screw thread micrometers, special micrometers, centering tools, combination center drills, etc. The new catalogue is bound in a red waterproof cover, printed in black and gold. The size is 5⅞ by 7⅝ inches, which is more convenient for the pocket than the common catalogue size, 6 by 9 inches. The tools illustrated and listed are fully described, a feature that is appreciated by intending buyers. A number of valuable tables for machinists which apply particularly in the use of these tools is included. Copies of the new catalogue will be sent to any address upon receipt of request.

GEOMETRIC TOOL CO., New Haven, Conn. Book entitled "Special Threading Tools," illustrating and describing the "Geometric" screw cutting die heads of the self-opening and adjustable type made in styles D, C, and DD; "Geometric" solid adjustable die head for use on automatic screw machines where the direction of rotation of the piece is reversed on the completion of the thread; "Geometric" adjustable collapsing taps; "Geometric" adjustable hollow milling tools; "Geometric" chaser or die grinder; "Geometric threading machine." The book is virtually a treatise on the special threading tools, showing their form and component parts with fine halftone views, and giving valuable information for users of modern threading equipment. It contains several pages of valuable data useful to makers of bolts, screws, nuts and other threaded work.

DODGE MFG. CO., Mishawaka, Ind. Catalogue C-12 containing 413 pages, beautifully illustrated and printed, is being distributed to the trade. The first pages are devoted to interior views of Dodge foundries, machine shops, power plant and branch houses; then follow tables for laying out shafting, horsepower of steel shafting, dimensions, etc. Every product of the company—a complete line of power transmission machinery and appliances, elevating and conveying equipment, rope driving system, and water softener apparatus—is completely described and listed. Considerable space is devoted to the Dodge friction clutch as an accident prevention device. The concluding pages give a little history of the transmission of power by Manila rope with illustrations of a number of striking installations, heavy engineering work, etc. The business was established in 1878 by Wallace H. Dodge, inventor of the split wood pulley with interchangeable bushings which effected a revolution in the pulley art. At that time, the plant occupied only a few acres of ground in Mishawaka. To-day there are 63 acres of ground space and over 21 acres of floor space.

TRADE NOTES

DOEHLER DIE-CASTING CO., Court & 9th Sts., Brooklyn, N. Y., is about to erect a reinforced concrete addition to its present plant, consisting of seven floors, 50 by 100 feet.

LANSING CO., Lansing, Mich., recently purchased the entire hoist building plant of the Butcher & Gage Co., Jackson, Mich., and in the future will manufacture the Wolverine contractors' hoist in Lansing.

FAVOR, RUHL & CO., 49 Barclay St., New York, have taken the sales agency for the "Tec" line of drafting-room supplies for New York City and vicinity, controlled by the Technical Supply Co., Scranton, Pa.

EDGAR ALLEN & CO., LTD., 86 John St., New York, agents for Allen's high-grade tool steel are now located at the foregoing address. A complete stock of steel is carried, and all requirements of customers can be promptly met.

HAUCK MFG. CO., 149 Livingston St., Brooklyn, N. Y., had a small fire in the office March 5. The fire destroyed some furniture, unimportant records and papers, but in no way affected the manufacturing facilities. There will be no delay in handling orders.

METALLIC SHELL & TUBE CO., has removed from Pawtucket, R. I., to a large three-story building at 129 Valley St., East Providence, R. I. The change of quarters was made necessary by the rapidly increasing growth of the business. The company is installing new machines and equipment, and will be in a better position than ever to take care of seamless tube wants.

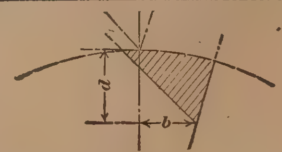
BLOOD BROS. MACHINE CO., Kalamazoo, Mich., manufacturer of universal joints, is running its factory with full force night and day. Although new buildings and equipment have been added during the past four months, nearly doubling the original capacity, the company is still barely able to keep up with orders. The entire factory is at present devoted to the manufacture of universal joints.

PARKER TRANSMISSION & APPLIANCE CO., has moved from Springfield, Mass., to Fulton, N. Y., where it will continue the manufacture of the Parker "all-in-mesh" transmission gears for automobiles. The company will also develop several of Mr. Parker's inventions. The capitalization was recently increased from $250,000 to $1,000,000, and plans have been made for pushing the business aggressively.

E. L. ESSLEY MACHINERY CO., Chicago, Ill., had a fire in its store at 555-557 Washington Blvd., March 7, which completely destroyed its office records. The large warehouse, 817 Washington Blvd., containing 10,000 square feet of floor space was untouched by the fire however, and the company's offices are temporarily located at this address. The warehouse is filled with new and second-hand machinery, and the fire will not seriously interrupt the business.

JOSEPH DIXON CRUCIBLE CO., Jersey City, N. J., has just put on the market a new chain graphite, especially intended for lubricating the chains of motor trucks and pleasure cars. This preparation is put up in cylindrical sticks, 2 by 8 inches, encased in a neat cardboard carton and weighing about one pound each. This convenient chain lubricant can be carried ready for use at any time, and is simply applied by rubbing the bar against the sprocket side of the chain. Unlike oils and greases, graphite does not rapidly collect dust and dirt.

SETTING DOUBLE-ANGLE FLUTING CUTTERS—I



Elevation Formula:
$d = R_1 - x R$
R_1 = radius of blank,
R = radius of finished cutter,
d, see illustration; x, see table.

Cross-movement Formula:
$b = y R$
R = radius of finished cutter,
b, see illustration; y, see table.
In table, W = width of land.

Number of Teeth in Cutter	$\frac{W}{R} = \frac{\text{Land}}{\text{Rad.}}$	Value of x for "Elevation" Formula						Value of y for "Cross-movement" Formula

May, 1912

THIRTY-TON ELECTRIC LOCOMOTIVE FOR THE FREDERICK RAILROAD, FREDERICK, MARYLAND

THE Frederick Railroad Co., of Frederick, Md., recently purchased a 30-ton Baldwin-Westinghouse electric locomotive for hauling freight between Thurmont and Frederick, a distance of 17.37 miles, and for occasionally hauling grain between Frederick and Middletown—approximately eight miles. The sharpest curves have a radius of 80 feet. The maximum grade between Frederick and Middletown is 7 per cent, and is part of a continuous rise of 600 feet in 2.5 miles. The maximum grade between Thurmont and Frederick is 2.588 per cent for 3450 feet.

The mechanical parts of the locomotive were furnished by the Baldwin Locomotive Works, Philadelphia, Pa. The locomotive has a single rigid wheel-base with two axles. It has a steel box cab and is arranged for double-end operation. The entire weight of the locomotive is carried by the two axles. The frame of the locomotive is built of structural shapes wherever practicable. The longitudinal sills are four in number, the two center sills consisting of 6-inch channels and the outside sills of 10-inch channels. (See Figs. 2 and 3). The end bumpers are of wood, backed by steel plates. Diagonal bracing is worked in between the center and outside sills, and special attention has been given to providing ample transverse strength. The journal boxes are guided in rigid pedestals, which are of cast steel and riveted to the outside frame channels. The pedestal boxes are of cast iron with bronze bearings, and are placed outside of the wheels, each box being surmounted by a half elliptic spring which supports the frame. The wheels are steel-tired with cast-iron centers.

The cab covers the entire frame and is substantially built of Z-bars and steel plates, covered with No. 14 B. W. S. sheet steel. It is 18 feet 4 inches long and 9 feet wide. Both end and side doors are provided. A clear space approximately 10 feet long is left in the center of the cab in which freight can be carried. The locomotive weighs 25 tons complete. However, provision is made for increasing the weight to 30 tons in order to obtain the adhesion necessary for hauling the maximum loads. This is done by means of a cellar under the floor between the two axles, which may be filled with five tons of steel rails in 6-foot lengths.

The principal dimensions of the locomotive are:

Diameter of driving wheels	36 inches.
Total wheel-base	10 feet.
Length of cab over bumpers	20 feet.
Width overall	9 feet.
Height from top of rail to center of drawbar	2 feet 10 inches.
Height from top of rail to top of cab	12 feet.
Weight including 10,000 pounds ballast	60,000 pounds.

Fig. 1. Thirty-ton Baldwin-Westinghouse Electric Locomotive for the Frederick Railroad

The air brake equipment is of the type 14-EL built by the Westinghouse Air Brake Co., Wilmerding, Pa., and has both the straight and automatic features. Air for the locomotive and train brakes is supplied by one D-3-EG compressor having a delivery capacity of approximately 25 cubic feet of free air per minute. The electrical equipment was furnished by the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., and consists of two No. 308-B-2, 600-volt commutating pole railway motors and type HL unit switch control.

To handle the large overload and the normal operating current of the locomotive, the Westinghouse unit switch, electro-pneumatic system of control was installed. This is the same as that employed in the locomotive built for the New York,

New Haven and Hartford Railroad, the Hoosac Tunnel service (Boston & Maine R. R.), and the Pennsylvania Tunnel and Terminal Co. The success this system has given in the Frederick locomotive, as well as in many other small engines, proves that the electro-pneumatic control is equally adaptable to large and small equipments. The hour-rating of the 308-B-2 motor at 600 volts is 120 H. P. Because of the large size of the motor, the box type frame is used. This is made of steel cast in a single piece with large holes bored out at each end for seating the housings and for taking out the armatures endwise. The complete weight of the motor is approximately 6500 pounds. Part of this weight is borne by the two axle bearings, while the remainder is supported by a nose cast on the frame and resting upon the truck bolster.

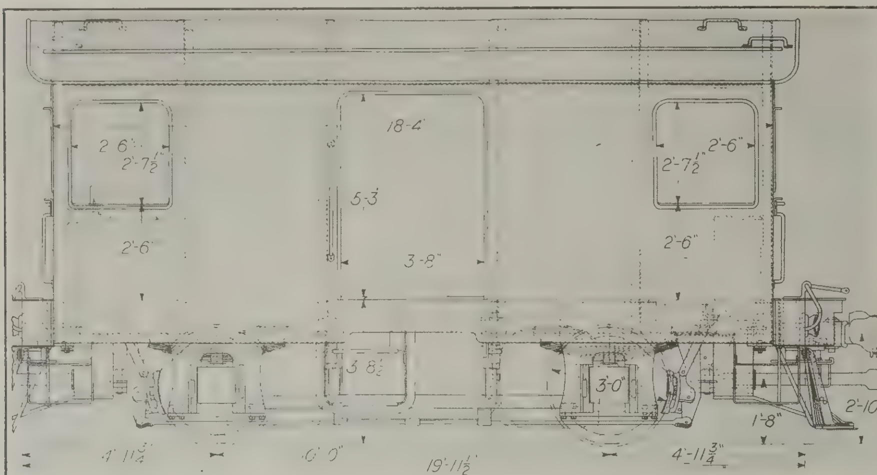

Fig. 2. Side Elevation of Electric Locomotive

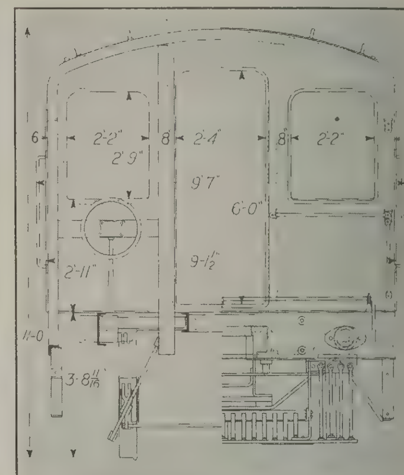

Fig. 3. End Elevation of Electric Locomotive

The speed characteristic is inherently slow, which, with the resulting high tractive effort and low power consumption, makes this motor particularly adapted to freight locomotive service. By virtue of the commutating-poles, enormous overloads in the motors are safely commutated. For one hour on 600 volts the locomotive will exert a tractive effort of 12,000 pounds at a speed of 7½ miles per hour. Momentarily the locomotive with sanded rails will exert a tractive effort of 17,500 pounds without ballast, or 21,000 pounds with ballast. Expressed in terms of weight of train and grade it has sufficient capacity to handle a load of 200 tons on a grade of 2.59 per cent, and may occasionally be required to haul a trailing load of 50 tons on a short grade of 7 per cent.

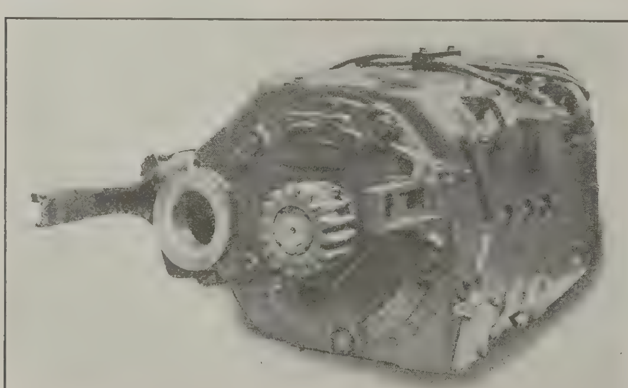

Fig. 4. Westinghouse No. 308-B-2 Commutating Pole Railway Motor—Pinion End

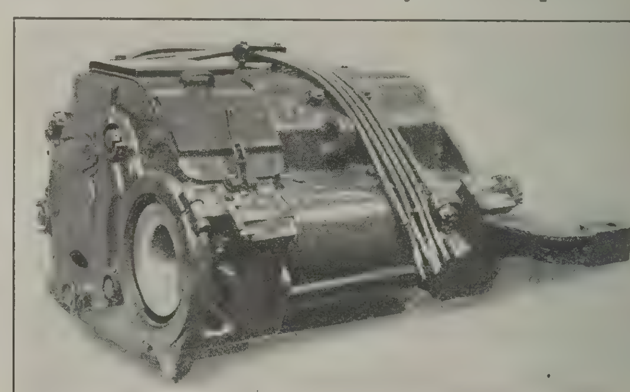

Fig. 5. Westinghouse No. 308-B-2 Commutating Pole Railway Motor—Commutator End

In switching service, on a straight level track, 31 cars, each weighing 45 tons with load, may be handled at 8.5 miles per hour at 600 volts; and 8 cars at the same speed on a one per cent grade.

The auxiliary apparatus supplied with the locomotive consists of a No. 13 Union standard Nuttall trolley, automatic M. C. B. radial couplers and bumpers. Tomlinson automatic radial couplers, Leach pneumatic sanders, and type LA Crouse-Hinds arc headlights. The latter are so arranged that both may be lighted at the same time, which is useful in switching. With the automatic M. C. B. radial coupler the locomotive can traverse a curve of 80-foot radius without uncoupling and with the Tomlinson coupler a 40-foot curve.

SUGGESTIONS FOR MACHINISTS, DRAFTSMEN AND ELECTRICIANS

Don't think that a horse can stand the same amount of current as a man.

Don't think you are an electrician just because you have been struck by lightning.

Don't think that it takes more than half a second to demagnetize a piece of steel.

Don't forget that electricity (like water) will go where it meets the least resistance.

Don't leave the windows open, so that dust can blow directly onto a generator or motor.

Don't run two lines of conduit side by side (carrying alternating current wires) without bonding them.

Don't forget that a wire will only carry its capacity in current, very much after the same manner as a water pipe.

Don't forget that some types of generators will not produce even a light until you get a certain amount of load on.

To use hot water for cooling while grinding may sound like a paradox, but some people think that it is a good thing.

The man with skilled hands and a cracked brain is like a modern machine shop with an inefficient power plant.

The thing that keeps many a man from making a fool of himself is the fact that he can't always do as he pleases.

The split pulley has its time of favor during the repair season, for it lends itself readily to removal and alterations.

Don't forget that a motor is more efficient when worked up to its full load, than when it is run either below load or over load.

Don't forget that many times (not always) the success of a machine is up to the man who makes the detail and shop drawings.

The older heads in the business may not know the most about it, but it is well for the young minds to remember that they have been at the game longer and have the best chance to know more.

Don't think that the old type of lathe is done away with yet, and when you have occasion to cut a thread, the number of threads to the inch of which is not exactly divisible by the number on the lead-screw, stop the lathe, drop the nut out,

and move the carriage back any even number of inches and throw the nut in again, for by this rule the tool will always engage the thread.

Don't make regular parallels for general work without making them of such proportion that a workman will see quickly which way they must lie to be of the same height; in other words they should be at least thirty per cent thinner than they are wide, with a large range of difference between the different sets, so a workman will be able to see by glancing at two or more different sets whether they are mated or not.

WATCH MOVEMENT MANUFACTURE*—1

METHODS EMPLOYED BY THE SOUTH BEND WATCH CO.

By DOUGLAS T. HAMILTON†

Fig. 1. Dial View of South Bend "Studebaker" Railroad Watch

A WATCH movement, when we consider its dimensions, the usage to which it is subjected, and the exacting requirements of its performance, is one of the most wonderful pieces of mechanism that man has devised. It may truthfully be called an automatic counting machine, which, with unerring regularity, counts every one-fifth second, day and night, and registers the count in larger units of seconds, minutes and hours on the dial. This is done without human aid, and without the pressing of buttons and the pulling of levers. All that is necessary is to wind up the main spring once in every twenty-four or thirty-six hours.

The South Bend 16 size watch movement shown in Fig. 3, the manufacture of which is to be described in the following, is made in the three-story brick building shown in Fig. 2. The main building is 402 feet long by 33 feet wide. This has several wings and extensions, the entire floor space being 55,220 square feet. All of the movements are made, assembled and tested in this building. The dials are made in a smaller two-story building at the rear. This company employs 500 men and women—most of them experts—and turns out 200 movements per day, quality and not quantity being the main consideration. The cases for the movements are produced by a well-known maker of watch cases, and as a watch is of little value as a timepiece without a case to protect it, some of the methods employed in their manufacture will be described in a future article.

Fig. 2. Factory of the South Bend Watch Co., South Bend, Ind.

Through the courtesy of Mr. C. T. Higginbotham, consulting superintendent of the South Bend Watch Co., South Bend, Ind., the writer is enabled to give a general outline of the methods employed by this company in the manufacture of watch movements. It is not intended that this article shall deal with the construction of a watch, except so far as is necessary to make clear the description of the methods employed in its manufacture. The illustration Fig. 4 is presented for this purpose. With this in view, a description will be given of the various steps followed in designing a new model; that is, a watch which differs in construction from that previously manufactured.

Designing and Making Watch Movements

The first step that is taken in designing a new model is to make all the mathematical calculations for the complete watch movement. These calculations embrace the size and strength of the main spring, the strength and dimensions of the hair spring, and also the balance. Calculations are also worked out to determine the pitch diameters of the wheels and pinions, the number of teeth and leaves and the center distances in the plates and bridges.

After all the calculations pertaining to the various parts of the movement have been completed, an artist's drawing similar to that indicated in Fig. 3 is made. This of no practical value in the manufacturing, except that it gives an idea of what the completed watch will look like. Profile and assembled drawings, plan and developed elevations are then drawn to an enlarged scale. An assembled plan and elevation drawing of the 16 size watch is shown in Fig. 5. The elevations of the complete watch are made in two different scales on the profile drawing—the second drawing made, the first working drawing being a plan view. The developed length is made 10 to 1, and height 50 to 1, which facilitates the laying out of the movement. For the plan views the scale is 10 to 1. The plan and elevation views of the assembled drawing shown in Fig. 5 are made 10 to 1. The developed length of a watch is laid out in the order in which the power is transmitted from the main spring to the escapement, as illustrated in Fig. 4 by the zig-zag dot-and-dash line joining the wheel centers.

From the profile and enlarged drawings the various details are taken and separate sketches of each part are made, giving the number of operations required and the dimensions of the piece after each operation. Upon the completion of all the detail drawings, prints are sent to the model-maker, who, by the use of a transfer chuck, which will be described later, makes a complete model watch. The model maker also makes the master plates, which are steel disks, 1.9 inch in diameter by 0.22 inch thick. In these, are carefully bored holes, exactly 0.1 inch in diameter. The location of every hole, the center of every turning, every curve center, milling, etc., is determined by these holes. The master plates are then used to determine the forms, and relative positions required in all

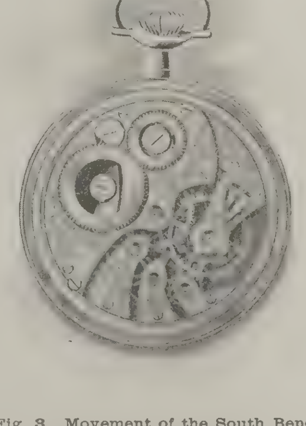

Fig. 3. Movement of the South Bend "Studebaker" Railroad Watch

† Associate Editor of MACHINERY.

dies, chucks, jigs, and other tools used in the manufacture of the watch. All the curves in watch plates and bridges are made true arcs of circles—no irregular curves being used—so that there is not one part of a watch plate which cannot

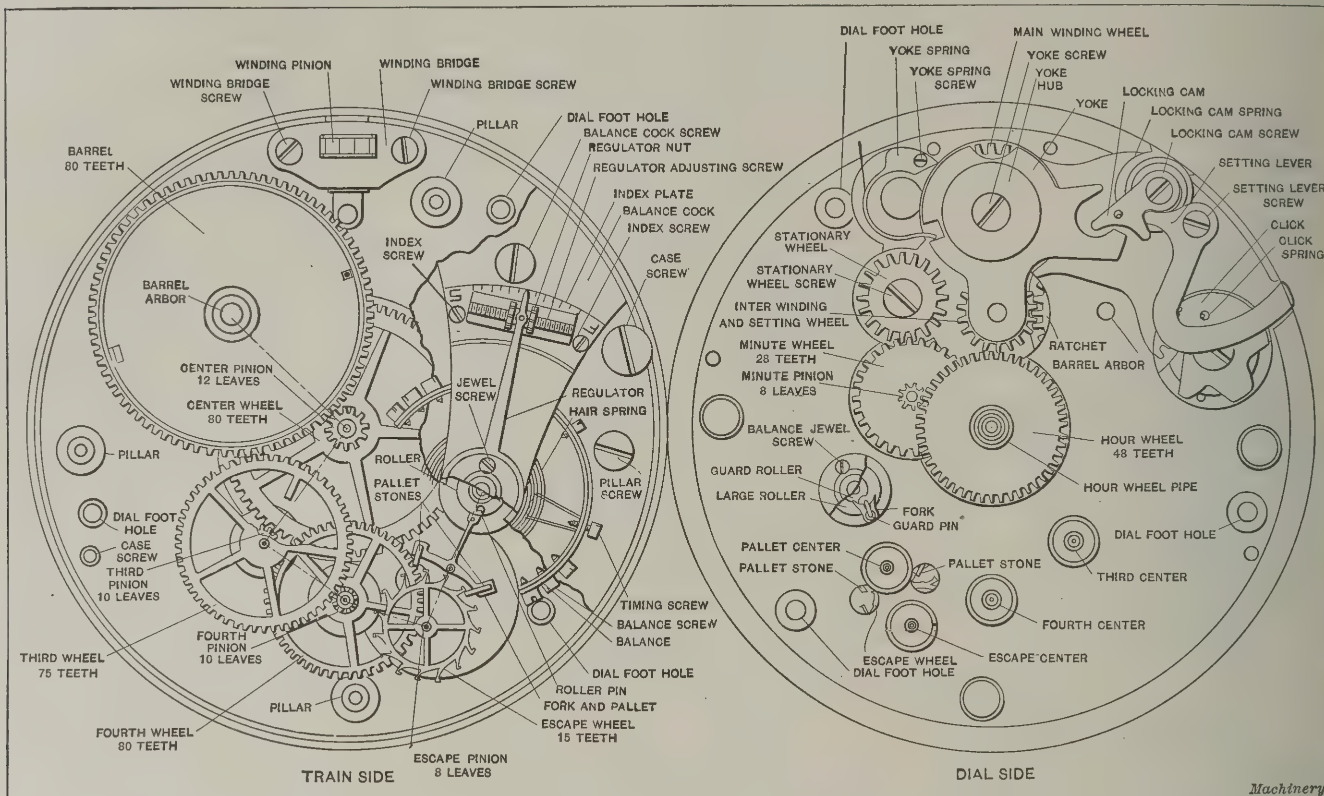

Fig. 4. Dial and Train Side Views giving the Names of the Parts of an 18-size South Bend "Studebaker" Railroad Watch

be produced on the transfer chuck. In order to enable the model-maker to reproduce the form on a greatly reduced scale, the holes in the plates and bridges are laid out in their rela-

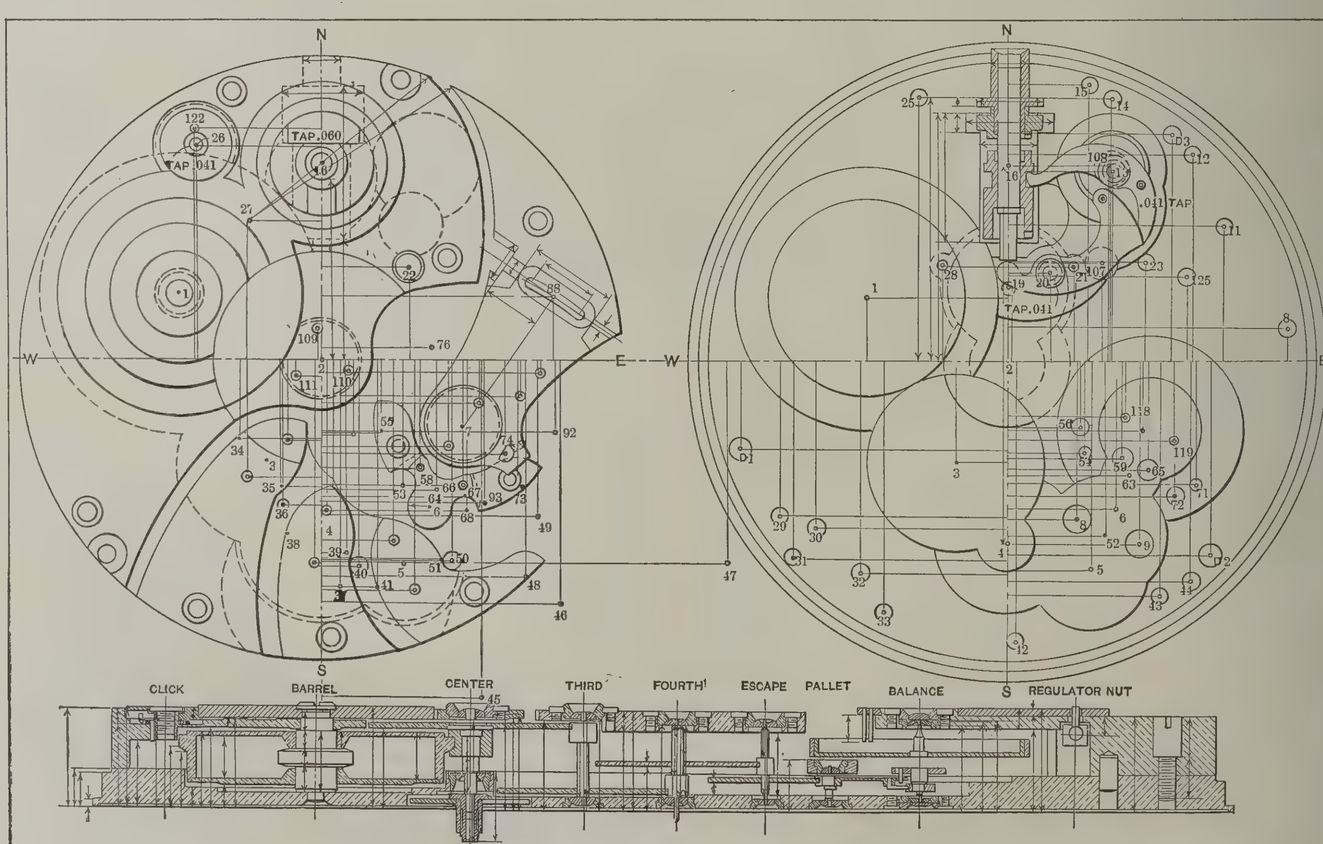

Fig. 5. Plan and Developed Elevation Views of the 16-size South Bend Watch, Enlarged

tion to what are called north, south, east, and west lines, radiating from the center of the watch. These lines are drawn in relation to the pendant which is always north; the position of the east and west in relation to right or left depends on whether the dial is facing up or down. This is illustrated clearly in Fig. 5.

Fig. 6 shows the upper section of a chart of the 16 size, L model watch, open face, which gives the numbers of the holes and the numbers of the master plates in which they may be found. Any hole determining a certain position in a watch always bears the same number, and is frequently placed in two or more master plates. The numbers in the columns are the numbers by which these different master plates are designated. This system enables the model-maker and toolmakers to produce the parts exactly as called for on the drawings.

The model-maker, by means of the transfer chuck, produces a complete watch which is thoroughly tested. If found to be all that is required as a time-piece of accuracy, the tools for making the various parts are then designed and made. These are sent out into the factory to the various departments in which they are to be used, and the work of making watch movements in quantities on a commercial basis is begun.

Watch Gearing

The calculation for watch gears or wheels, as they are called, is carried out in a slightly different manner from that pursued in the design of gears for other mechanical work. The pitch diameter, and the diametral pitch are calculated in just the same manner, of course, as for any other gear, but the shapes of the teeth of the wheels and the leaves of the pinions differ. The addendum or working face of the tooth is an epicycloid curve starting at the pitch circle and extending to the point of the tooth.

Where the wheel is the driver and the pinion the driven member, the face of the wheel tooth and the flank of the pinion leaves only come in contact. The tops of the pinion leaves are circular for convenience in finishing. These tops never come into action. The wheel tooth and pinion leaf should come into contact on the line of centers to give the best results. To accomplish this, the flanks of the teeth and leaves in the wheel and pinion are made radial with the center. The proper diameter of circle to use for generating the epicycloid curve of a watch wheel tooth is half the diameter of the pitch circle of the pinion with which the wheel is intended to mesh. The addendum is made 2.25 of the diametral pitch for the driver, and 1.0 of the diametral pitch for the driven pinion.

Fig. 6. Chart of Master-plate Holes for the 16-size Model L, Open Face South Bend Watch

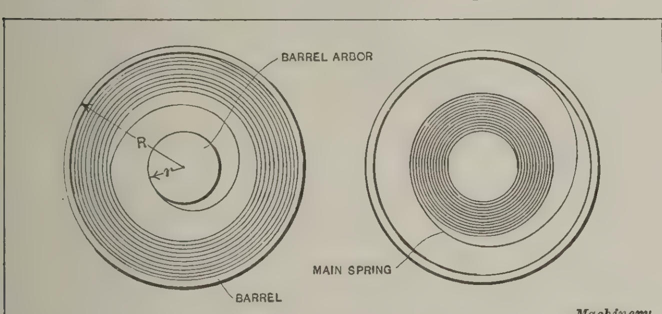

Fig. 7. The Main Spring wound and unwound—Note Space between Arbor and Inside of Chamber

In determining the width of the teeth in the wheel, nine-twentieths of the circular pitch is allowed, and seven-twentieths of the circular pitch for the width of the leaves of the pinion, leaving four-twentieths of the circular pitch for play, which is necessary in watch gearing to obviate dirt stopping the watch. There is no back-lash in watch gearing, because the drive is at all times in one direction.

Watch Train Computations

In laying out a watch train there are certain requirements which must be met. The essentials are, in this watch, that 18,000 vibrations per hour be imparted to the balance wheel, which gives 129,600 vibrations to 7 1/5 turns of the barrel which contains the main spring, and that the intermediate wheels driving the hour, minute and second hands rotate in the correct relation to each other. Another requirement in a railroad watch is that the main spring take 48 hours to unwind.

To proceed with the computation, refer to Fig. 4, which shows the gear train of an 18 size South Bend "Studebaker" railroad watch. The numbers of the leaves in the pinion are first considered, and as practice has determined different sets, we select those most suitable for the case in hand. For instance, the center pinion can have 10, 12 or 14 leaves; the third and fourth pinions 8, 10 or 12 leaves; and the fifth or escape pinion 6, 7 or 8 leaves. The main spring barrel is constructed to make 7 1/5 turns in 48 hours. In this case we select 12 leaves for the center pinion; 10 leaves for the third pinion; 10 leaves for the fourth pinion; and 8 leaves for the escape pinion.

Having decided on the number of leaves in the pinions, the next problem is to find the number of teeth in the barrel and intermediate wheels.

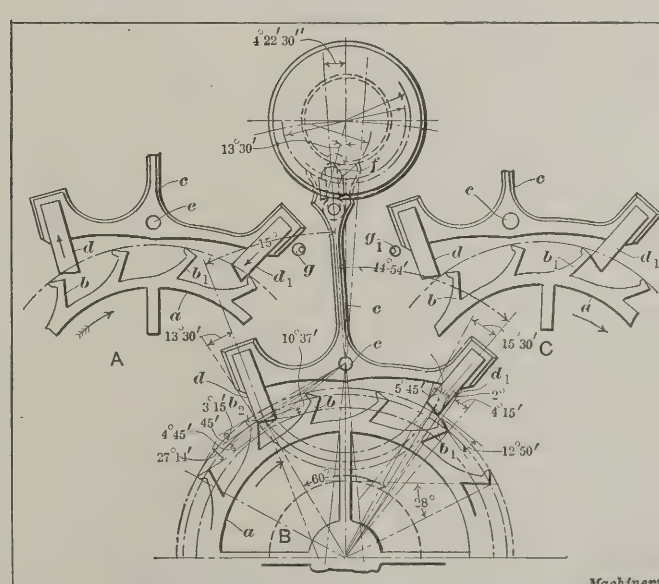

Fig. 8. Diagram illustrating Function and Action of the Detached Lever Escapement

The number of teeth in the barrel is:

$$\frac{48 \times 12}{7\,1/5} = 80 \text{ teeth}$$

As the balance wheel is to make 18,000 oscillations to one revolution of the center wheel, and as two oscillations of the balance wheel correspond to one tooth of the escape wheel, the latter having fifteen teeth, it follows, that the escape wheel will make:

$$\frac{18{,}000}{15 \times 2} = 600 \text{ revolutions per hour.}$$

The fourth wheel which is attached to the second hand must make 60 revolutions per hour, and as the escape pinion has 8 leaves, and makes 600 revolutions per hour, the number of teeth in the fourth wheel equals:

$$\frac{600 \times 8}{60} = 80 \text{ teeth.}$$

The numbers of teeth in the intermediate or third and the center wheels, are in a certain ratio to the number of leaves in the pinions with which they mesh, the product of which ratios must equal 60. The ratio in this case between the fourth pinion and third wheel is 1 to 7½, and between the third pinion and center wheel, 1 to 8. This multiplied by 10 give us, 7½ × 10, or 75 teeth in the third wheel, and 8 × 10, or 80 teeth in the center wheel; the ratio between the fourth

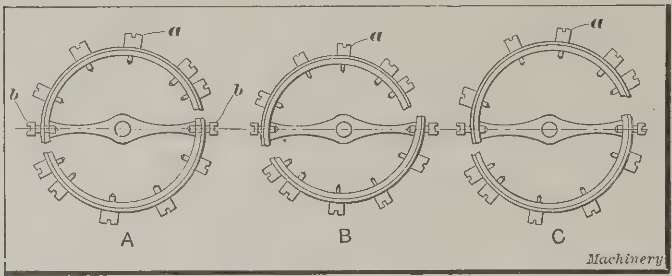

Fig. 9. The Compensating Balance in its Normal Condition and affected by Heat and Cold

wheel and escape pinion is 10. These ratios give the desired relation between the center wheel and escape wheel, the ratio between which is 1 to 600.

The dial train wheels and pinions are now worked out so that the hour and minute hands will be revolved in their proper relation to each other. The dial train is driven by the cannon pinion, which is frictionally held on the center staff. In this case the cannon pinion has 14 leaves, the minute wheel 28 teeth, the minute pinion 8 leaves, and the hour wheel 48 teeth. As the cannon pinion makes one revolution per hour and drives the minute hand direct, it follows that the hour hand will make $\frac{14}{28} \times \frac{8}{48} = \frac{112}{1344} = \frac{1}{12}$ revolution per hour.

The Main Spring

The main spring furnishes the power for driving the entire mechanism of a watch, and is made from the best steel obtainable, carefully hardened and tempered. To give the best action, the main spring has to be made in certain proportions to the barrel or chamber which contains it. The radius r of the barrel arbor, see Fig. 7, is made equal to one-third the radius R of the chamber, the space outside the barrel arbor being divided into two equal areas.* The main spring occupies half this area irrespective of whether it is wound or unwound. Owing to one of the laws governing the action of the main spring, it will give the greatest number of turns when made to these proportions.

The number of turns of the main spring which is necessary to carry the watch a given number of hours is found by the following formula:

$$N = \frac{H \times n_1}{n}$$

in which, N = number of turns of main spring,
H = number of hours the watch is to run,
n = number of teeth in barrel,
n_1 = number of leaves in center pinion.

Applying this formula to the watch shown in Fig. 4, we have:

$$N = \frac{48 \times 12}{80} = 7.2 \text{ or } 7\ 1/5 \text{ turns.}$$

The calculations involved in determining the strength and torque of a main spring are too complicated to be presented here; suffice it to say that if the main spring is made to conform to the requirements previously given, thinner or thicker material can be used until a main spring having the proper strength is obtained.

* For further information regarding flat spiral springs, see the article entitled "The Design of Flat Spiral Springs," which appeared in the July, 1910, number of MACHINERY, engineering edition.

The Detached Lever Escapement

The escapement of a watch movement transforms the rotary motion of the train of wheels into the vibratory motion of the balance. It also acts as a break to prevent the watch mechanism from "running away," retarding the motion of the train, and imparting the proper movement to the hands on the dial. To properly design an escapement, requires considerable study and is considered the most difficult problem in watch movement design. Ideal conditions are impossible to arrive at, so that compromises must always be made if an escapement to suit all requirements is to be obtained.

In action, the escape wheel a, Fig. 8, receives its motion from the wheel train, and by means of its peculiarly shaped teeth b coming in contact with the jewel pallets d and d_1 oscillates the fork c. To illustrate how this action takes place, we will assume that the fork c and escape wheel a are in the positions shown at A.

Now as the escape wheel a revolves, tooth b glides across the face of the pallet d lifting the latter up and forcing the upper portion of fork c, which is fulcrumed at e, to the right. This action lowers pallet d_1, bringing it in contact with the locking face of tooth b_1, as shown at C, and consequently stops the rotation of escape wheel a.

As the upper end of fork c is forced to the right, its forked end carries jewel pin f around, rotating the balance wheel, and putting the hair spring under tension. The hair spring, in unwinding, reverses the rotation of the balance and unlocks the tooth b_1 from the pallet d_1. The instant that this unlocking action takes place, the passage of the tooth b_1 across the inclined face of the pallet d_1 gives another impulse to the balance. This brings the fork and escape wheel into the positions shown at B, which happens as the fork c is returning to the banking g. Tooth b_2 now imparts an impulse to pallet d, and the order of actions is continued. The bankings g and g_1 stop the motion of the fork c in its oscillation from side to side.

The Compensating Balance

The balance wheel, or compensating balance, as it is called, is the heart of the watch. It regulates and controls the movement of the gear train from which it receives its motion. The

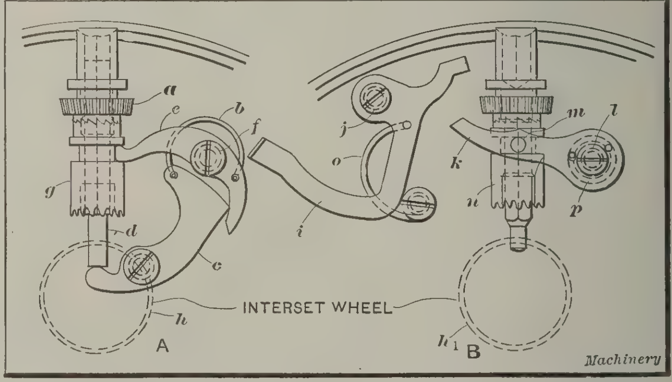

Fig. 10. Watch Setting Mechanisms

motion of the gear train is intermittent, while that of the balance is practically continuous. Five times every second the train starts up from a dead rest, and for a brief space of time moves forward, again coming to rest. In this same time the balance reverses its direction of rotation, stopping for such a brief period of time that the cessation of movement is almost impossible to detect.

A compensating balance is composed of a steel center arm and rim made from one piece of metal, to which a brass ring is fused. The brass ring has twice the coefficient of expansion of the steel rim, and the proportion between the thickness of the rims is approximately two-fifths steel to three-fifths brass. The construction of a compensating balance is clearly shown in Fig. 9. At A it is in its normal position; at B it is affected by heat; and at C by cold. The conditions of the balance are exaggerated here to make the changes in its shape more perceptible. Located around the rim of the balance are what are called "balance" screws a. These are made from either brass

or gold, and are employed for regulating, poising and altering the weight of the balance wheel in relation to the strength of the hair spring. The two screws *b* at each end of the arm are what are known as "timing" screws. These are employed to bring the watch to time without disturbing the regulator, which is always set at zero when it leaves the factory.

When a watch movement is subjected to heat, the tension of the hair spring is decreased and thereby weakened, and the balance arms are lengthened, thus increasing the diameter of the balance which adds to the load on the hair spring. The effect of this action, if not counteracted, would be to cause the watch to lose time. To compensate for this, the brass rim expands more than the steel rim and center, which effect causes the balance to become smaller in diameter tending to throw the mass of its weight more toward the axis, as shown at *B*. When a watch movement is subjected to cold, the hair spring contracts and becomes stronger. The steel rim and center of the balance contract, as does also the brass rim, but as the brass rim contracts more than the steel rim, it has the effect of straightening the rim, thus increasing the diameter of the balance wheel, and carrying the mass of its weight further away from the axis, which has a retarding effect. This condition is shown exaggerated at *C*.

The rim of the balance is provided with more holes than it has screws, so that more screws can be added, or their positions changed as conditions may warrant, when poising and subjecting the movement to temperature tests. These screws add to the weight of the balance and change its radius of gyration, thus compensating for changes in temperature and positions. All first-class watches are regulated for five positions, *viz.*, dial up, dial down, pendant up, and pendant to right and left.

Many ingenious devices have been developed for setting the hands and winding the main spring of a watch. They can,

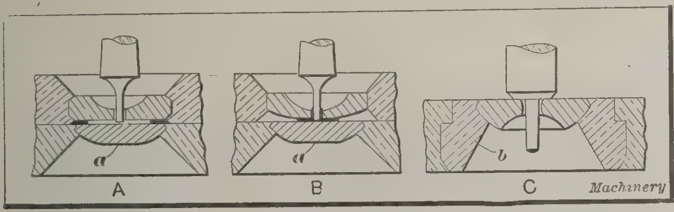

Fig. 11. Jewels, Settings and Pivots

however, be divided into two main classes, *viz.*, pendant and lever sets. A simple pendant and lever set which is used in the South Bend watch is illustrated at *A* and *B* in Fig. 10. At *A* is shown a pendant set mechanism in the position which it occupies when acted upon normally by the stem fastened to the crown, which is used for operating the mechanism. In this position, if the crown were rotated, the main spring would be wound up by means of the winding pinion *a* and intermediate wheels, not shown.

When the crown is pulled out, the stem is withdrawn, releasing the tension on spring *b* and allowing it, through the setting lever *c*, to force up the stem *d*. The spring and lever *c* also act on clutch lever *e*, raising its rear end, and as it is fulcrumed on screw *f*, the forward end is lowered thus carrying down the setting clutch *g*. This clutch, in lowering, meshes with the teeth in an interset wheel *h*, which operates the wheels and pinions connected to the hands on the dial.

The setting mechanism shown at *B* is what is known as a lever set, and is used principally in railroad watches. It is shown in the position that it occupies when the main spring can be wound up by rotating the crown. When setting lever *i*, which is fulcrumed on screw *j*, is withdrawn from the case, its forward end is rotated downward coming in contact with the end of the clutch lever *k*, which is fulcrumed at *l* and connected by a pin *m* to the clutch sleeve *n*. It is evident that this action disconnects the clutch *n* and brings the teeth in its lower end in mesh with the interset wheel h_1, which in turn, operates the hands on the dial. As setting lever *i* is pushed in again, it is returned to its normal position by spring *o*, and as it is released from clutch lever *k*, spring *p* returns this lever to its normal position connecting the clutch with the winding mechanism. With this mechanism it is impossible to set the hands without first pulling out the lever *i;* this is not the case with the mechanism shown at *A*, which is likely to be operated by simply removing the watch from the pocket by the crown, thus making the latter an objectionable mechanism for use in railroad watches.

Jewels

Jewels are introduced into a watch movement to reduce friction as much as possible and also to increase the life of the watch. The shape of the hole in the jewel has a considerable bearing on the reduction of friction and in obtaining the best results. At *A* and *B* in Fig. 11 is shown the incorrect and correct method of finishing the holes in a jewel. The hole in the jewel at *A* is called a "straight hole," having parallel sides and a flat bottom. This type of jewel allows the oil to be drawn between the settings, leaving the jewels dry and keeping the oil at the outer rim, as is clearly shown in the illustration.

At *B* is shown what is called the "olive hole." This reduces the retarding effect of the thickening of oil to a minimum. The face of the jewel has a hemispherical oil cup, and the back is well rounded. The hole is also rounded and is made slightly larger than the diameter of the balance pivot. Having a jewel shaped in this manner increases capillary attraction toward the center, the pivot acting as a piston to keep the supply of oil at this point until the last particle is exhausted. The distance between the hole jewel and its end stone *a* should be just sufficient to allow the interception of a thin oil film. At *C* is shown a common type of jewel for the wheel pivots. This, as shown, is held in a setting *b* and is provided with the olive hole previously mentioned.

* * *

WHY ARE OUR FOUNDRIES NEGLECTED?

In the September, 1911, number of MACHINERY, an editorial appeared, entitled, "Why are our Foundries Neglected?" As an answer to this question we may appropriately quote a few paragraphs from an address by Mr. H. M. Ramp, superintendent of the Modern Foundry Co., before the Superintendents' and Foremen's Club, Oakley, Cincinnati, Ohio. Mr. Ramp says:

"While the foundry deserves much criticism and correction, it has never had the attention, the brains, the research work, or the finances poured in upon it that the machine end of the iron industry has had to elevate and develop its possibilities. It has been considered more as a necessary evil than as a branch of the business that could be mastered and developed and controlled. The foundry, until the last few years, has been the last place to receive improvements and advice, and it is not as yet burdened with a load of either.

"The individual who entered the foundry as a life's business was always regarded as sinking his intellectual or mechanical abilities, if he had any. The foundry has been demeaned and often referred to as a place where the qualifications are 'a strong back and a weak mind,' and yet there is no business under the canopy of heaven that requires greater judgment and a more thorough knowledge of fundamental principles than the art of molding. When properly done it most certainly deserves to be classed as an art, and yet this is the atmosphere in which the foundries of our country were developed and the foundrymen of our country were made until the past few years, while the machine shop was commanding the gray matter and finances of the brightest men in our land. This prejudice against the foundry in the past, as a place of dirt and grime fit only for occupation by hewers of wood and haulers of water, has done much to retard the development of the foundry business and to keep the bright, ambitious and energetic men from mastering its science. But these are not the only reasons why the foundry fails to give the machine shop what it asks.

"When the machine shop seeks to improve its tools or methods, it does not put blacksmiths or candy makers on the job—it uses the best educated brains and experience in the machine business that money can buy. Yet too often the pattern, the very foundation of the foundry's work, is constructed as the designer, the pattern foreman, the engineer directs, without even consulting the experience and preference of the foundry, and in as great a measure as this prevails just as great is the handicap placed upon the foundry."

The prize of $5000 for an aerial engine, which has been offered by Mr. P. Y. Alexander through the three British aeronautical associations, the Aerial Society, The Aero Club, and the Aerial League of the British Empire, has been awarded to the Green Engine Co., the engine of which developed, during the competition, 61.6 H. P. at 1150 R. P. M. during two nonstop runs of twelve hours each.

RE-CUTTING MILLING CUTTERS WITHOUT ANNEALING

By F. B. JACOBS*

In an article published in the December, 1911, number of MACHINERY the writer outlined the method used in re-cutting ordinary milling cutters without annealing them. In this article the re-cutting of thin milling saws, and of the end teeth of large end-mills will be explained. Great numbers of milling cutters find their way to the scrap box before their days of usefulness are over. These could, at slight expense, be re-cut and put in service again. The saving is especially marked with the high-priced, high-speed steel cutters in common use.

To re-cut milling cutters without annealing them does not call for special skill, or the services of a high-priced toolmaker. All that is required is the ordinary cutter grinding machines found in nearly every tool-room, wheels of the proper materials in the correct grits, grades and bonds, and an operator possessed of a little originality and ordinary mechanical skill. In fact, when re-cutting worn out milling cutters about the same methods are used as when cutting new cutters, except that grinding machinery and abrasive wheels are used in place of the milling machine and milling cutters.

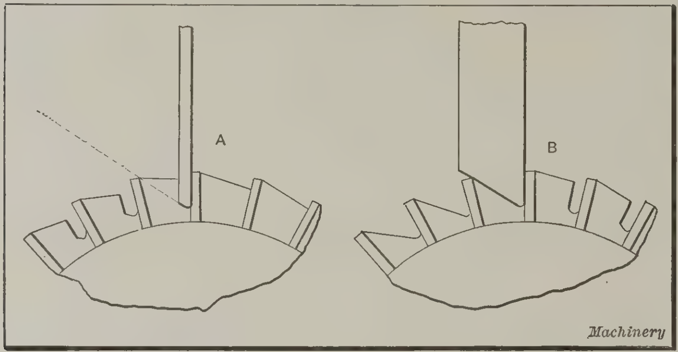

Fig. 1. The Two Steps taken in Re-cutting Milling Cutters by Grinding

The method followed can be readily understood from Fig. 1. This method applies to both peripheral and side teeth. The teeth are first gashed out as shown at *A*, with a thin vulcanite wheel, the object of this gashing being to preserve the corner of the wheel used in the re-cutting operation. At *B* is shown the re-cutting operation, the face of the wheel being trued to the proper angle. To re-cut milling cutters in one operation is not practical, as a hard and, therefore, slow cutting wheel would have to be used to preserve the corner of the wheel. With a thin elastic wheel of just the proper grain and texture for the gashing operation, and a fast cutting vitrified wheel to cut away the superfluous stock between the bottoms of the gashes and the points of the teeth, very economical and satisfactory results can be obtained with a little practice.

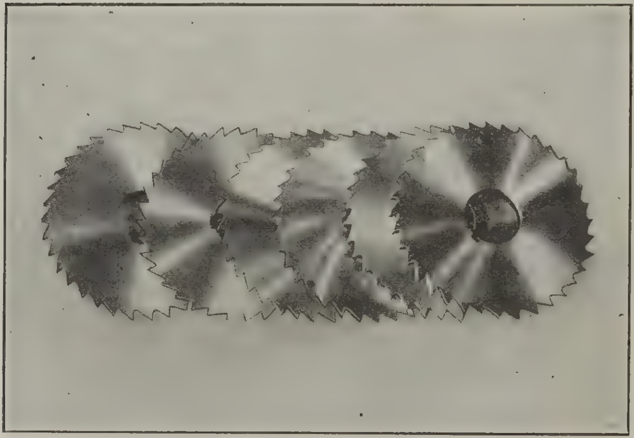

Fig. 2. A Number of Re-cut Slotting Saws

In Fig. 2 are shown six milling saws that for all practical purposes are now as good as new. These, however, were taken from the scrap box; four of them being 4 inches in diameter and 1-16 inch thick, and two of them, 5 inches in diameter and 1/8 inch thick. They were first located on an ordinary work arbor such as used in turning up thin collars, etc., paper washers being placed between the cutters to compensate for the side taper. They were then ground on a Walker grinder to a diameter of 3 9/16 inches. This work was done dry with an aloxite wheel 6 inches in diameter, 1/2 inch face, 1 1/4 inch hole, 50 grit, M grade, D496 bond. This operation ground all of the old teeth away from the large saws, and nearly so from the smaller ones.

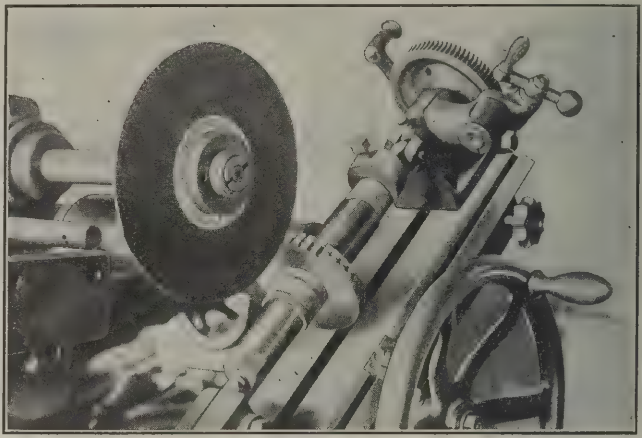

Fig. 3. The Gashing Operation

The work was then placed between the centers of the form cutter attachment of a Brown & Sharpe No. 3 cutter grinder, and the teeth gashed out to the required depth. This operation is shown in Fig. 3. The wheel used for this purpose was aloxite (vulcanite), 7 inches in diameter, 1/8 inch face, 1 1/4 inch hole, 30 grit, V-K-9 bond, run at a speed of about 4200 R. P. M. In this operation the wheel loss was very slight—only 0.008 inch. The depth of cut was 0.003 inch for each stroke, the graduations on the cross-feed screw being relied on for the correct depth. The work was fed under the wheel with a fairly rapid motion, one tooth being gashed to its full depth at a time.

Fig. 4. Cutting the New Teeth

The next operation, which consists of cutting the new teeth, is shown in Fig. 4. This operation is practically the same as the gashing operation, the difference being that a wide wheel is used, its face being trued to the correct angle, as shown at *B* in Fig. 1. The wheel used for this purpose is aloxite, 6 inches in diameter, 3/4 inch face, 1 1/4 inch hole, 40 grit, 0 grade, D497 bond, run at a speed of about 4200 R. P. M. The teeth were fed one at a time under the wheel, taking a cut of 0.002 inch at each stroke until the land of the tooth was of the correct thickness, or about 1/32 inch. The wheel loss in this operation was 1/64 inch. The teeth were then backed off as shown in Fig. 5. For this purpose an aloxite wheel 5 inches in diameter, 3/8 inch face, 1 1/4 inch hole, 50 grit, 0 grade, D496 bond, was used, the speed being 3650 R. P. M.

The total time consumed in re-cutting these cutters was divided as follows:

* Address: Care of The Carborundum Co., Niagara Falls, N. Y.

Getting ready and setting up for first operation	10 minutes
Grinding time on Walker grinder	30 minutes
Setting up cutter grinder for gashing operation	15 minutes
Gashing out teeth	60 minutes
Setting up for re-cutting operation	5 minutes
Re-cutting teeth	50 minutes
Setting up for backing off teeth	10 minutes
Backing off teeth	13 minutes
Time consumed in truing wheels, etc.	10 minutes
Total time	3 hours 23 minutes

In Fig. 6 are shown five high-speed steel end-mills, 3 inches long, 2⅜ inches in diameter, having sixteen teeth each; *A*

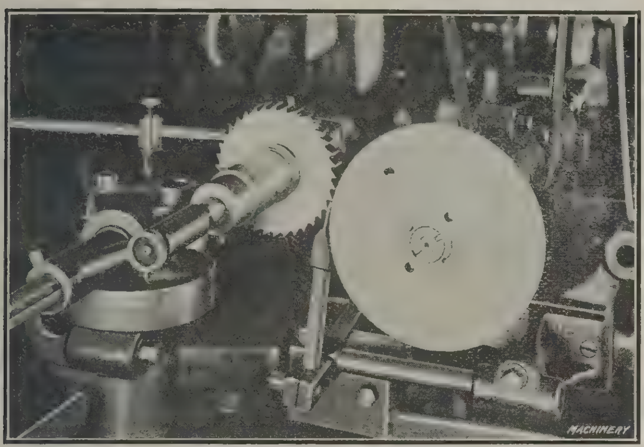

Fig. 5. Grinding the Clearance

shows a mill the end teeth of which are practically worn out, *B* illustrates a mill after the gashing operation, and *C*, *D* and *E* give a good idea of how the mills looked after the second or re-cutting operation.

Before re-cutting, the operator should first decide on the correct angle for the teeth, and then true the face of both wheels to this angle. For this purpose the writer has always used a carborundum stick 9 by ¾ by ¾ inches, 20 grit, H grade. With the wheels in question this will be found more satisfactory than a diamond. In the gashing opera-

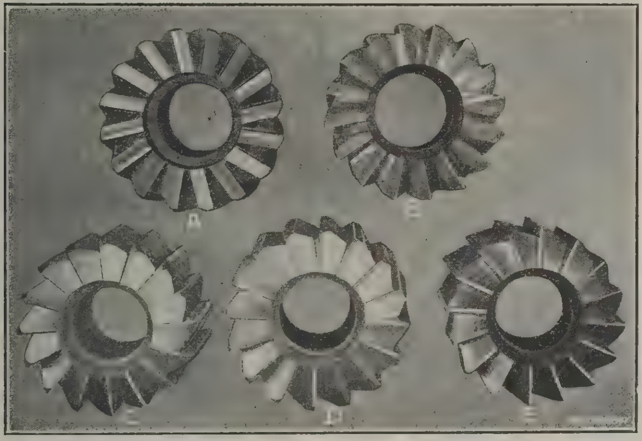

Fig. 6. Various Stages in the Re-cutting of End-mill Teeth

tion the cut should be carried to a depth where a line drawn parallel to the face of the wheel comes nearly to the edge of the tooth. (See *A* in Fig. 1.) In re-cutting end teeth it is necessary to use a machine equipped with a head that can be set at any angle in order to bring the lands of the teeth parallel. The writer used a Brown & Sharpe No. 3 cutter grinder, equipped with an end-mill grinding attachment, as shown in Figs. 7 and 8. In setting the head to the correct angle the cut-and-try method can be used, or the angle can be figured out when the operator has decided on the angle for the wheel face and knows the number of teeth to be cut.*

The gashing operation is shown in Fig. 7, the teeth being fed one at a time under the wheel with a cut of 0.002 inch, until the correct depth is reached. This is easily determined for all of the teeth by the graduations on the cross-slide screw, after the proper depth for the first tooth is decided on. In re-cutting four mills having sixteen teeth each the loss of the gashing wheel was only 1/64 inch. The re-cutting operation is shown in Fig. 8, the teeth being fed

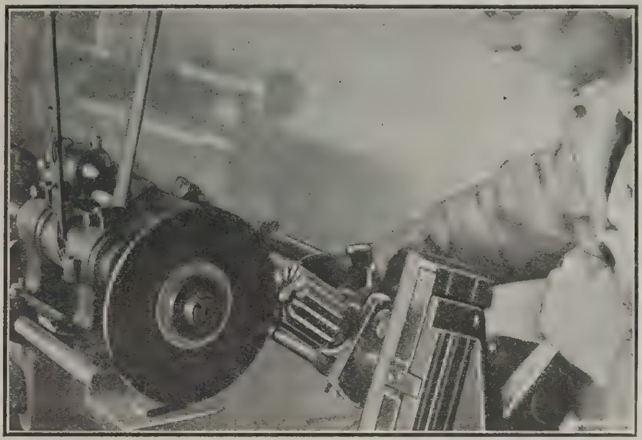

Fig. 7. Gashing the End-mill Teeth

under the wheel until the lands were of the correct dimension, or 1/32 inch. The wheel loss in this operation was ⅛ inch for re-cutting four mills having sixteen teeth each. As the width of the land is relied on in this case to determine the proper depth of the cut, the wheel loss is of no consideration, provided the wheel wears true, thus preserving ap-

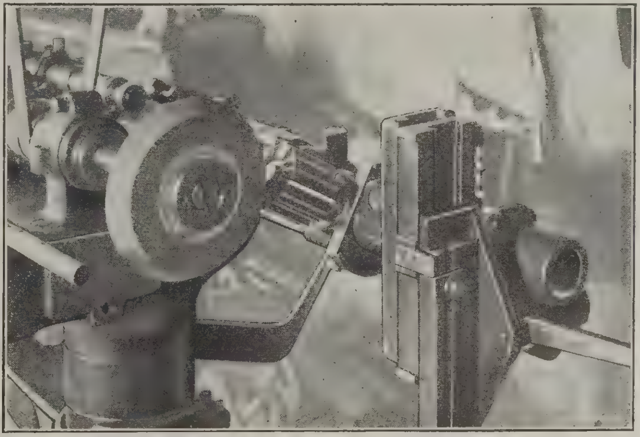

Fig. 8. Cutting the End-mill Teeth

proximately the correct angle. In this operation the most satisfactory results were attained with a soft coarse wheel, run at a comparatively high speed. When finer wheels in harder grades were used the tendency was to cut slow and burn.

After re-cutting, the teeth were backed off as shown in

Fig. 9. Grinding the Clearance on the End-mill Teeth

Fig. 9, this work being done on a Walker grinder equipped with a universal cutter grinding head. The wheel used for this operation was aloxite (cup), 5½ inches in diameter, 2 inches face, 1¼ inch hole, ¾ inch back, ⅜ inch wall, 50

* See MACHINERY, engineering edition, November and December, 1911, "Milling Radial Teeth in Cutter Blanks," and the Data Sheet Supplements accompanying these articles. Also see MACHINERY, April, 1904, "To Calculate the Setting of the Dividing Head when Cutting the Teeth of End-mills"; MACHINERY'S Data Sheet No. 32, "Tables of Angles for Headstock of Milling Machine when Cutting End Teeth in Mills, etc."; and MACHINERY'S Data Sheet Book No. 4, "Reamers, Sockets, Drills and Milling Cutters," page 32.

grit, 0 grade, D496 bond, run at a speed of about 3650 R. P. M.

The total time consumed in re-cutting four end-mills of the dimensions mentioned above was divided as follows:

Setting up cutter grinder for gashing operation and cutting and trying to determine the correct angle	30 minutes
Gashing out teeth	120 minutes
Re-cutting teeth	120 minutes
Setting up Walker grinder for backing off teeth	15 minutes
Backing off teeth	30 minutes
Time consumed in truing wheels, etc	15 minutes
Total time	5 hours, 30 minutes

As the work as explained was wholly of an experimental nature, it is fair to assume that any machinist of ordinary intelligence could, with a little practice, do the same work in much shorter time. However, for the sake of argument we will suppose that a machinist at thirty cents per hour consumed 8 hours 43 minutes in re-cutting the cutters described in this article. After figuring his time, adding a certain amount for fixed overhead charges, and noting the value of similar cutters as bought on the open market, it will readily be seen that it is more profitable to re-cut them by the method described than it is to sell them as scrap.

AUTOMATIC BOTTLE BLOWING MACHINES

Automatic machinery for some classes of manufacture has reached a remarkable stage of development. The Owen Bottle Blowing Machine Co., Toledo, Ohio, has glass bottle blowing machines in operation that automatically blow twenty-three ketchup bottles a minute, twenty-four hours a day, seven days a week and fifty-two weeks a year, neglecting the short shutdowns necessary to change the bottle molds. The machine consists of a large turntable carrying two sets of molds, one set being "gathering" molds and the other "bottle" molds. The molds are carried over a hearth filled with molten glass, and as a gathering mold passes over the hearth, a rod of hot glass is drawn into it by suction. The gathering mold opens, leaving a rod of hot glass standing vertically. The bottle mold closes over the gathered glass and air pressure forces the molten glass out to fill the die the same as a glass blower would blow it.

The blown bottle is automatically deposited in a cast-iron bar containing thirty holes in a line. The bar shifts one place for each bottle until it is filled, and then it is taken up by a traveling chain conveyor and carried sideways through an annealing oven. At the far end of the annealing oven two men stand who inspect the bottles and pack them into cases. The cast-iron bars are returned by the chain conveyor to the bottle blowing machine to pass through the same cycle as before.

The bottle molds are made of cast iron and a mold is good for 12,000 to 15,000 gross of bottles before it requires scaling. Compressed air plays an important part in actuating the dies, and natural gas is used for melting the glass. The batch is automatically mixed and fed to the furnace, thus reducing the manual labor required for the operation of a machine and furnace to three men, two of whom are packers. The machine tender regulates the furnace also and looks after the general operation of the apparatus.

* * *

There are more telephones in proportion to population in the United States than in any other country in the world. Canada ranges second in this respect, and Sweden third. It is interesting to note that in New York City alone there are as many telephones as in Germany. In Ohio there are as many as in Great Britain; and Boston has double the number of telephones of Paris. Apparently, most of the European countries have been much slower to appreciate the advantages of the telephone than has the United States. One reason for the slow introduction of the telephone in Berlin, however, is stated to be that the postal system, with its tube post, is so perfected that for less than one cent one can send a message through the mails within the city, receiving a reply within an hour or less.

JIG-BORING AT THE UNITED SHOE MACHINERY CO.'S FACTORY

By CHESTER L. LUCAS*

The illustration Fig. 1 does more to give a general idea of the appearance of the plant of the United Shoe Machinery Co., at Beverly, Mass., than paragraphs of reading matter could do, and as nine-tenths of the employes are machinists, it will be realized that the output of the factory is very large. As a matter of fact, over 20,000 machines for the manufacture of shoes are shipped annually. The plant consists of sixteen buildings of reinforced concrete construction, having twenty-five acres of floor space. Over sixty tons of steel are used each week in the manufacture of machines, and the drop-forging department alone turns out 60,000 forgings per week.

The toolmaking department of this factory is one of the best equipped in the country. The principal work of the toolmaking department is the building of jigs and fixtures, in addition to maintaining the thousands of jigs which are in daily use in the factory. The important part of the work of jig- and fixture-making is the proper location and boring of the holes for bushings, studs, etc. Fig. 2 shows one of the toolmakers engaged in locating the position of a hole to be bored in the jig shown on the machine. Boring machines made by the Universal Boring Machine Co., Hudson, Mass., are used almost exclusively for boring jigs and fixtures in this factory. As indicated in the illustration, the machines are used without the left-hand supports for the boring-bars. In setting up the work, all measurements are taken either from the table or from an angle-iron that is permanently mounted on the rear part of the table of the machine. This angle-iron, a rear view of which is shown in Fig. 3 (on the floor), is somewhat unusual in type. The ribs at the back are spaced very closely, and the angle-iron is clamped to the machine by means of four slots placed between the ribs. The angle-iron shown has been rough-planed, and is now left to "season," before being finished and put into use.

Fig. 1. Plant of the United Shoe Machinery Co., at Beverly, Mass.

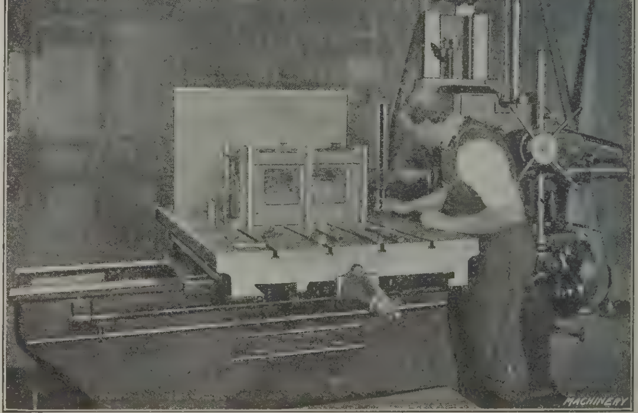

Fig. 2. Locating the Spindle in Position vertically for Boring a Hole in a Jig

In locating a jig in its proper position on the table of the boring machine, special height-gages are employed. In the toolmaking department there are about twenty-five of these special tools, which are made by the Brown & Sharpe Mfg. Co. These tools have extra wide and heavy bases. The jig is first placed against two stops that may be seen in the left-hand T-slot in the table in Fig. 2. With the height-gage, the jig is placed parallel with the angle-iron on the table, which, of course, is parallel with the spindle of the boring

* Associate Editor of MACHINERY.

machine. In locating the spindle of the machine for boring a hole, measurements are taken vertically from the table, either to the spindle itself, or to a plug which is fitted in the end of the spindle. Needless to say, the spindle must be abso-

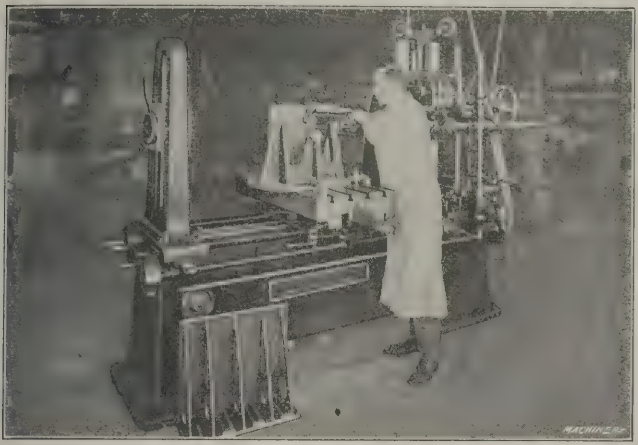

Fig. 3. Locating the Spindle laterally for Boring a Fixture

lutely without shake or play, and this condition is insured by a "take-up" at the head of the machine. After locating the spindle for the vertical dimension, the horizontal measurement is taken, as shown in Fig. 3, from the angle-iron to the plug

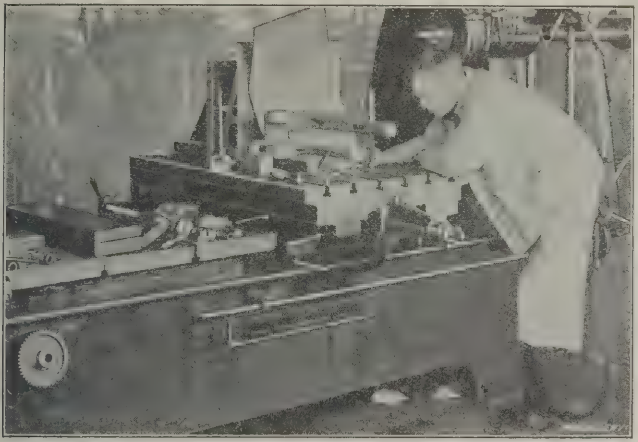

Fig. 5. Setting-up and Locating Experimental Work on Boring Machine

or spindle, as the case may be. After the spindle is properly located, the hole is bored for the bushing, and then attention is given to the next hole. Should there be two holes in line

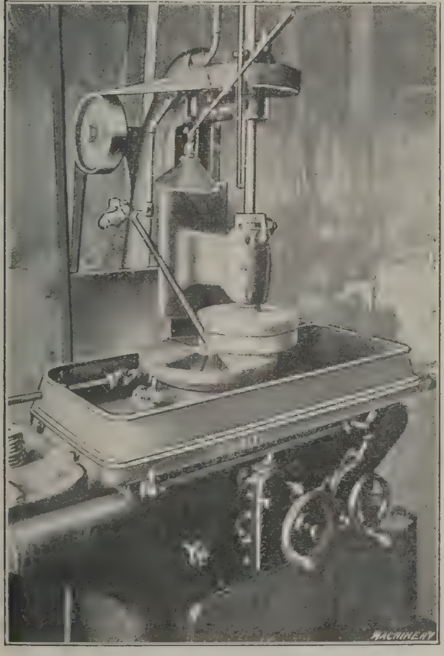

Fig. 7. Face-grinding the Drop-forgings

with each other on opposite ends or sides of the jig, they are not bored at one setting, as might be supposed, but the jig is reversed on the table of the machine and re-located for the second hole. This method is considered to be the best practice, because long boring-bars are not required, and it is not necessary to use the left-hand boring-bar support. Fig. 4 shows the toolmaker boring the hole in a fixture. The type

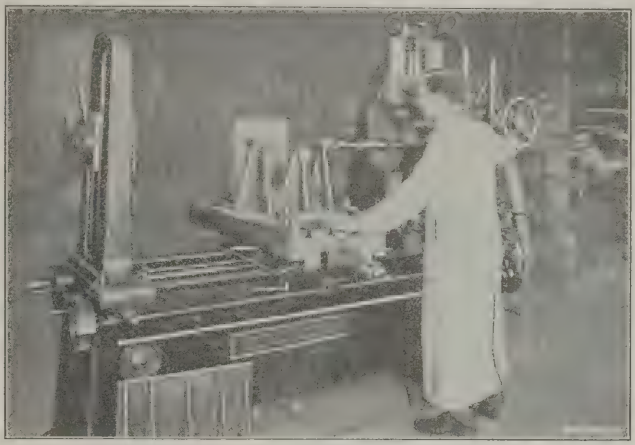

Fig. 4. Drilling one of the Holes in a Fixture

of machine used is particularly well adapted for jig-boring, because the operator can run the machine with his right hand, and at the same time watch the work of the cutter. It also has an added advantage over machines in which the head is at the

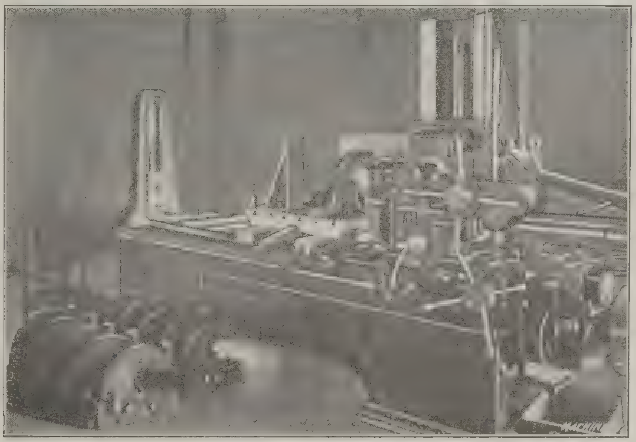

Fig. 6. Boring the Heads for Monogram-embossing Machines

opposite end, in that the operator can caliper holes without being obliged to use his left hand in so doing. This same advantage applies, of course, when trying size plugs.

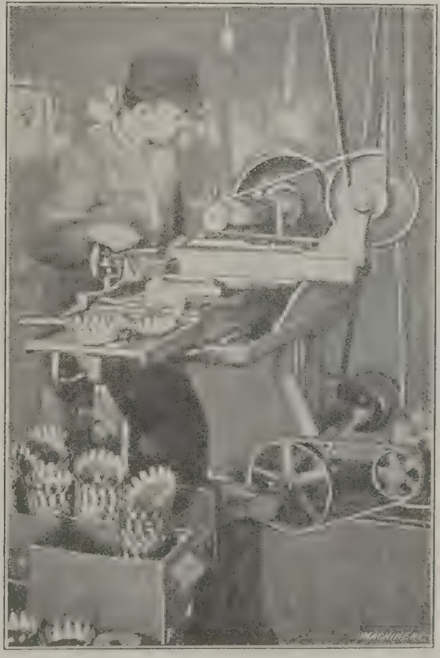

Fig. 8. Grinding Shoe-trimming Cutters

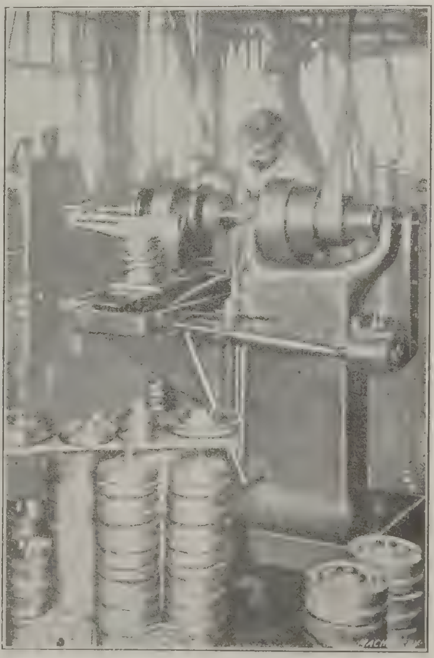

Fig. 9. One of the Cam-cutting Machines

Fig. 5 illustrates the method used in boring work in the experimental department, where trial machines for shoe manufacturing are built in small lots before the work has been

jigged for regular production. The piece shown on the machine is one of the parts of a shoe-leveling machine, and the machinist is setting up the piece and locating each hole to be bored, in accordance with the drawing which he has before him. On a job of this kind it takes a great deal longer to set up the work properly and lay out the positions of the holes than it does to do the actual machining which follows.

The machine in Fig. 6 is shown working on the heads of monogram-embossing machines, a group of which appears on the floor near the base of the boring machine. From the foremost of this group it will be seen that there are numerous

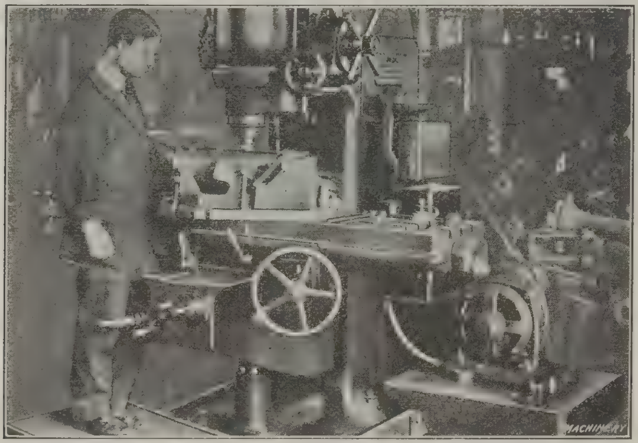

Fig. 10. Milling Fixture for Use on the Vertical Miller

small holes to be located and bored for the various shafts and rocker-arms. This work is essentially the same as in the jig-boring operations, a small angle-iron being used as shown. In this instance, however, the angle-iron is at the side of the table, instead of at the rear.

The Pratt & Whitney Co.'s face grinder shown in Fig. 7 is used extensively in the grinding department for facing small drop forgings, some of which are shown on the machine. The surfaces of these forgings must be parallel within limits of 0.0005 inch. In order to show this machine to better advantage, the water-guard is removed, thus exposing the table to view. The drop forgings, which have central holes, are located by placing them over a stud at the center of the table; a magnetic chuck is not required, for the pressure of the wheel is sufficient to keep the piece flat against the face-plate while it is being ground.

Another interesting grinding job is shown in Fig. 8, where

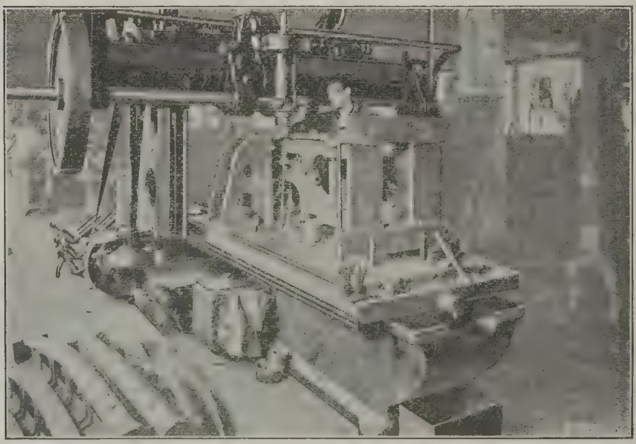

Fig. 11. Milling the Seats and Recesses on a Nailing Machine Column

the knives for shoe trimming machines are ground internally and externally on Heald No. 70 internal grinders. Two machines are used on the work, one being set up for grinding the inside and one for the outside. The machine shown is working on the insides of the cutters, and the same operator, running two machines, turns out two hundred finished cutters per day. The cutters are located by being slipped over a stud that engages the central holes, and are held in place by a nut and washer.

Cams are cut in large numbers and great variety in the United Shoe Machinery Co.'s plant, and a special department is maintained for the sole purpose of turning out the cams used on the various machines. While several makes of cam-cutting machines are employed, the favorite seems to be the machine made by the Kearney & Trecker Co., Milwaukee, Wis. One of these machines is shown in Fig. 9, and some of the various cams which have been cut on it are shown piled up about the machine. Special attention is called to those resting upon the board on the top of the piles in the foreground. This machine, like most other cam-cutting machines, must be provided with a master cam that governs the movements of the work in relation to the cutter.

The Cincinnati miller shown in Fig. 10 is working on tack-puller heads, one of which is shown in the fixture on the table of the machine. As will be noticed, provision is made on the base of the fixture for clamping it in various positions to facilitate the milling of the different parts of the work. It is obvious that it would be impracticable to shift the fixture around in this manner, if the milling being done were other than that of facing off parts in which the relative height is the only consideration.

On the Ingersoll upright type of milling machine shown in Fig. 11 the large columns for nailing-machines are milled to receive the different parts of the machine attached to it. One of these columns is shown at the right of the illustration. This particular job is well suited to this type of machine, because the short cuts that are required can be easily taken with a milling cutter, whereas, if the work were planed, the machine used would necessarily have to be out of all proportion to the amount of cutting to be done, on account of the difficulty of accommodating the extremely large casting.

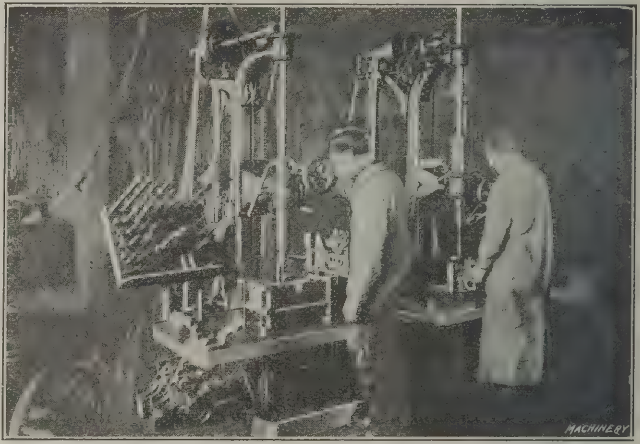

Fig. 12. Racks for Holding Tools used in Drilling Machines

Drilling operations are everywhere to be seen in this large factory, there being hardly a department that does not employ several hundred spindles. The manufacturing work, of course, is all jigged, and to facilitate the many changes which must be made in drills, reamers and counterbores, the large drill presses are fitted with tool-holding racks. In these the different tools used on the job are kept in regular order, so that they may be quickly gotten when wanted. At the same time, they are protected from being injured or mislaid, so that altogether the idea seems to be a good one. Fig. 12 shows a drill press with a rack.

Aside from the work done in the factory, much might be written on the conveniences installed in the factory for the workmen, in the form of metal lockers, washrooms, restaurant, etc. In addition there is a fully equipped emergency hospital. Here a trained attendant is in charge, who is qualified to administer first aid to the injured.

* * *

It appears from an article in *Zeitschrift des Osterreichischen Ingenieur und Architekten-Vereines*, that the water power available for industrial purposes in Switzerland is equivalent to 90 horsepower per square mile. The available water power in Sweden and Norway is about 45 horsepower per square mile of area. In Switzerland, nearly one-quarter of this available water power has already been made use of, while in Sweden and Norway but a small fraction, probably not more than one-fiftieth of the available water power has as yet been harnessed.

DRAWING A DEEP STEEL SHELL*

By JOSEPH V. WOODWORTH†

Fig. 1 shows the six successive operations required to produce the shell shown in Fig. 10, indicating clearly the evolution, proportions and dimensions. The material for which the tools were designed was 0.0359 inch dead soft cold-rolled drawing steel. The shell had to be true to size in diameter and height, smooth inside and out, and a strictly first-class product in every way.

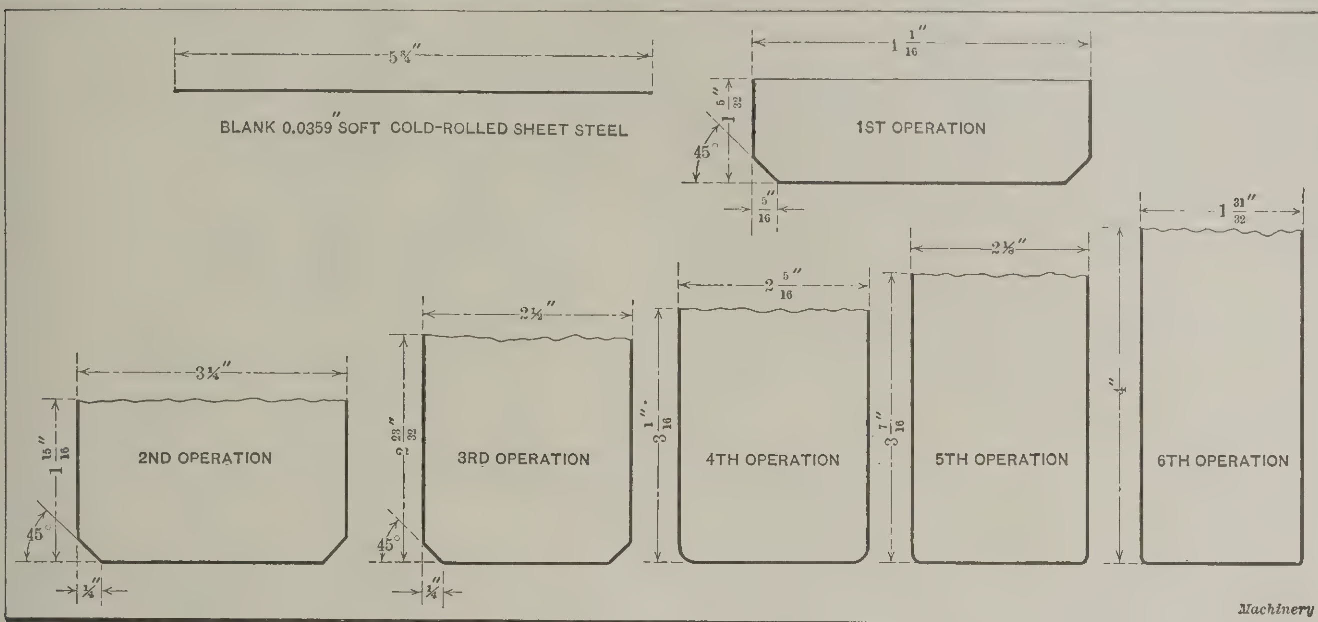

Fig. 1. Successive Operations in the Drawing of a Deep Shell

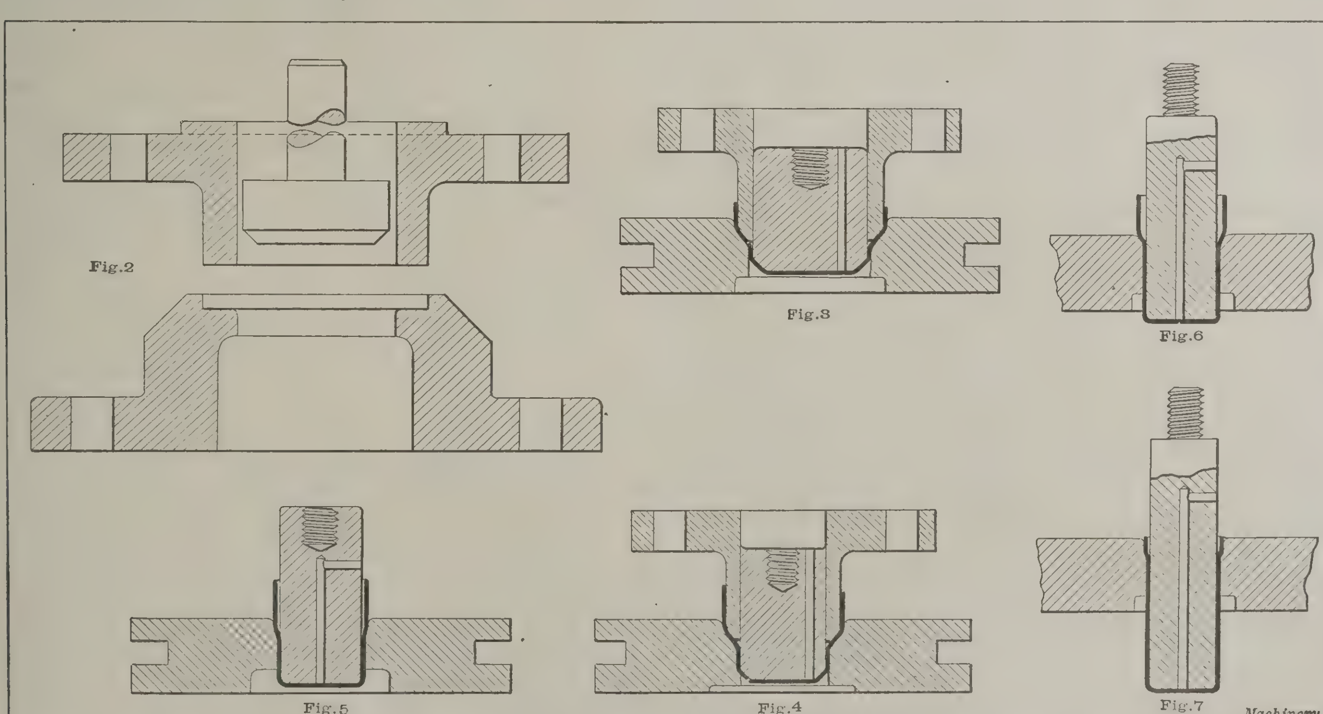
Fig. 2 shows the double-action blanking and drawing die for the first operation; Fig. 3 shows the tools for the second operation; Fig. 4, the double-action dies for the third operation; Fig. 5, the single-action reducing die for the fourth operation; Fig. 6, tools of the same construction for the fifth operation; and Fig. 7, the punch and die for the sizing and finishing operation. The illustrations show clearly the design, construction and operation of the tools. The shell was annealed four times and trimmed but once—after the last redrawing. A thin mixture of lard oil and white lead was used to lubricate while reducing.



Figs. 2 to 7. Tools for the Operations shown in Fig. 1

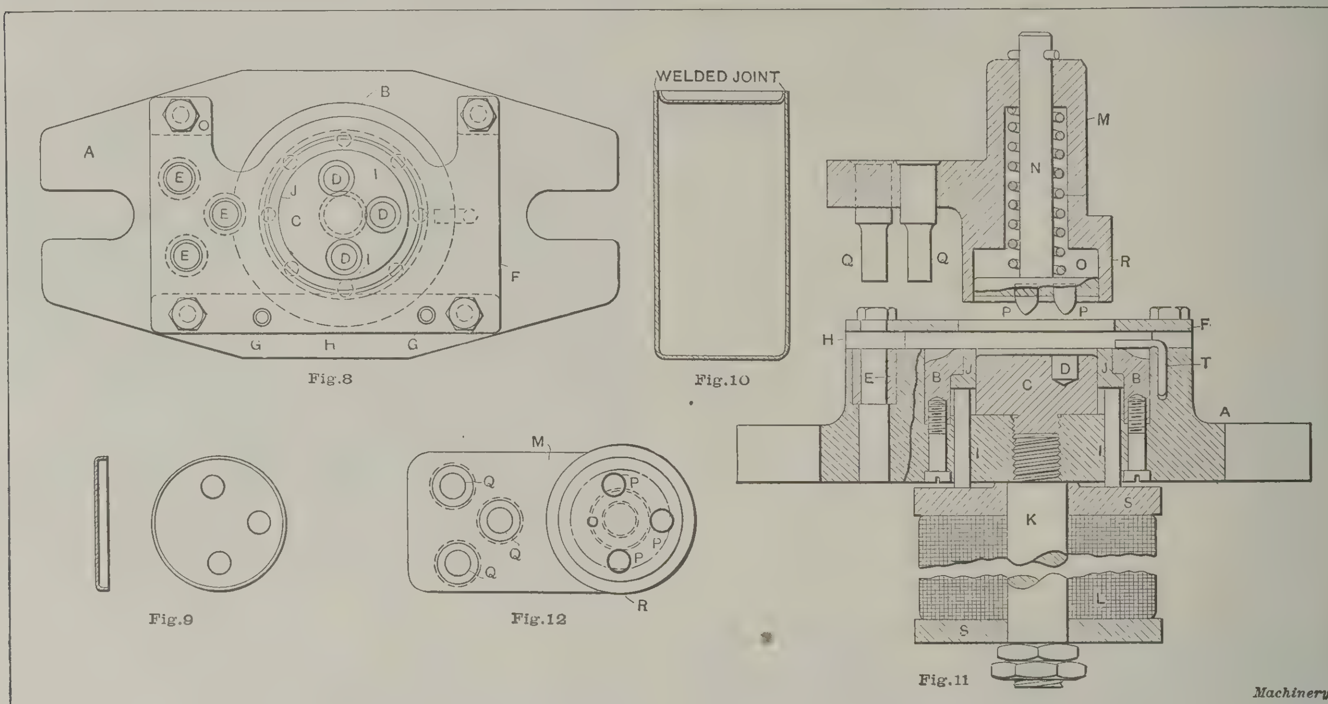
* See also MACHINERY, March, 1912, "Drawing a Flanged and Tapered Cylindrical Shell," and the articles there referred to.
† Consulting engineer, 165 Broadway, New York City.

Fig. 8 is a plan view of the single-action combination piercing, blanking and drawing die used for producing the drawn and perforated cover shown in Fig. 9, made of the same material as that for the shell. This cover was welded into the shell as shown in Fig. 10, the whole serving as a can receptacle for parts of an electrical device. Fig. 11 is a cross-sectional view of the complete punch and die designed for the cover, and Fig. 12 is a plan of the punch. A brief description will make plain the construction and action of the tools.

In the die, Figs. 8 and 11, *A* is the cast-iron die bolster; *E* are the interchangeable piercing die bushings of Blue Chip steel; *B*, the blanking die of the same material; *C*, the drawing pad; *D*, the pilot holes for pilots *P* in punch; *F*, the stripper of cold-rolled stock; *H*, the gage plates; *G*, the gage plate and stripper locating dowels; *I*, the eight blank-holder pressure pins; *J*, the blank holder ring; *K*, the spring barrel stud; *S*, the spring barrel washers; and *L*, the rubber spring barrel. In the punch, *M* is a tool steel forging machined to the shape shown; *R* is the blanking punch; *O*, the drawing die; *N*, the ejector pad with pilots at *P*; and *Q* the three piercing punches forced into slightly tapered holes in the punch proper.

Cold-rolled strips of the proper width are used for the

stampings, the metal being fed in at *H*, Fig. 11. The end is trimmed and the three holes punched, and then the strip is moved forward against stop pin *T*. The punch descending again, pilots *P* engage the pierced holes, and before the blanking punch touches the metal, locate the strip accurately. By laying out the operations and the evolution of shape as here shown, and making the drawings so as to show clearly the operation of the tools upon the metal to be worked, the expense of designing is reduced to a minimum, the tools can be put through the shop with few "cut and try" troubles, their cost will be reasonable, and their efficiency assured.



Figs. 8 to 12. Completed Can and Cover and Tools for the Latter

* * *

In an address on "Comparison between Industrial Conditions in the United States and Europe," read before the American Society of Swedish Engineers, Mr. A. L. Valentine, superintendent of the small tool department of the Pratt & Whitney Co., Hartford, Conn., quoted some figures which show how far the United States is behind Europe in the matter of safeguarding the workers. Figures show, said Mr. Valentine, that in this country 100 men are killed every day as a result of industrial accidents. Two million in a year are injured. For 1908 very reliable figures are obtainable, and these show that there were between 30,000 and 35,000 fatal accidents that year. Of the deaths of male workers between the ages of 15 and 44, 15 per cent are due to accidental causes, and of these, at least half, or 7½ per cent, are incurred in the act of making a living. If such a proportion were lost in battle, it would be considered a disaster. Figures also show that the loss of life per thousand in the mines in the United States is greater than in France, Belgium and Great Britain combined. Manufacturers in Germany, which country has been at work preventing accidents for a quarter of a century, are compelled to be members of protective associations. These associations employ inspectors whose duty it is to inspect factories, nearly always, semi-yearly, especially those where women are employed. Seventy-five per cent of our accidents could be avoided by precaution. Better light and ventilation and better spacing of machinery should be insisted upon. It is better to build right, than to furnish safeguards after things are done wrong. Laws which this country has relating to employers' liability should at least be enforced, and those responsible would give a little more thought to the value of human life.

* * *

The aerial navy of France is assuming large proportions. Increases have been made in former appropriations and according to the latest decisions of the French war department, the French army will, during the present year, have 322 aeroplanes and 15 dirigibles at its disposal.

DRILLING AND COUNTERBORING FROM CROSS-SLIDE IN THE AUTOMATIC

By S. NEVIN BACON

Hand screw machine operations are frequently performed on work partly made in the automatic machines, because in order to complete the work in the automatic machine it would require seven tools, which it is not possible to hold in the turret of a Brown & Sharpe automatic screw machine. At *A*, in Fig. 1, is shown a piece of work knurled on one end, which was made in a No. 2 Brown & Sharpe automatic screw machine. Now unless we wish to use a combination counterbore, the list of turret tools required will be a stop, center, drill, reamer, two counterbores and a knurl.

The method used in holding the extra counterbore is shown at *A* in Fig. 2. The counterbore is held in a holder placed on the cross-slide, and when the counterbore is in line with the hole in the work it is fed forward by means of the stop in the turret coming against the rear end *a* of the counterbore. The counterbore is made a good sliding fit in the hole

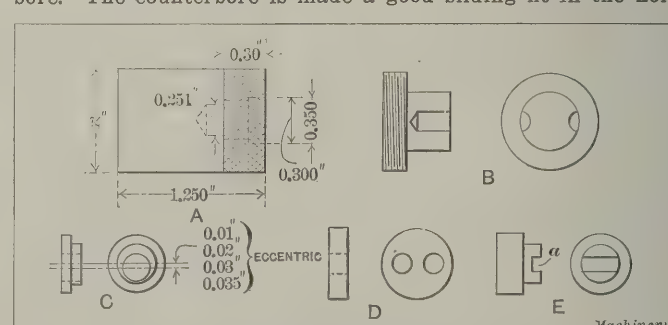


Fig. 1. Samples of Work Operated on by Counterbores and Drills held on the Cross-slide

in the boss, and is prevented from turning by the headless screw *b*. A pin driven into the shank of the counterbore and a helical spring assist in keeping the counterbore in the "back" position. The order of operations for producing the piece shown at *A* in Fig. 1, is as follows:

Order of Operations	Revolutions	Hundredths
Clearance	19.6	2
Feed stock to stop	19.6	2
Revolve turret	19.6	2
Center, 0.125 inch rise at 0.0063 inch feed	19.6	2
Revolve turret	29.4	3
Drill, 0.500 inch rise at 0.0056 inch feed	88.2	9
Revolve turret	29.4	3
Ream, 0.500 inch rise at 0.0072 inch feed	137.2	14
Revolve turret	29.4	3
Counterbore, 0.150 inch rise at 0.0014 inch feed	107.8	11

Revolve turret	29.4	3
Knurl on, 0.300 inch rise at 0.0102 inch feed.	29.4	3
Knurl off, 0.300 inch rise at 0.0153 inch feed.	19.6	2
Revolve turret	29.4	3
Advance front slide and dwell.............	88.2	9
Counterbore from cross-slide, 0.125 inch rise at 0.0021 inch feed....................	(58.8)	(6)
Clearance	(19.6)	(2)
Cut off, 0.477 inch rise at 0.00167 inch feed..	284.2	29
Total	980.0	100

The cams for producing the piece shown at *A* in Fig. 1 are shown in Fig. 3, where the various functions of the lobes are clearly indicated. The most interesting lobe on this set of cams is the lobe on the cross-slide cam from 63 to 71,

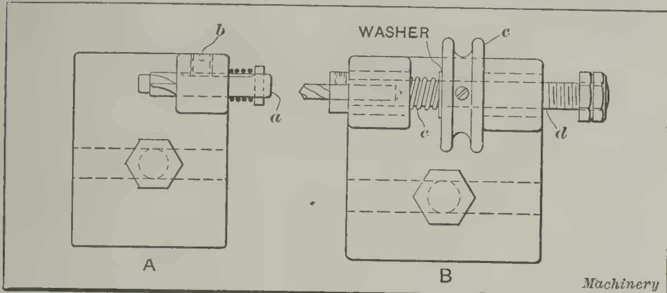

Fig. 2. Holders for Carrying Drills and Counterbores in the Cross-slide

which brings the special counterbore shown at *A* in Fig. 2 in line with the hole in the work. The stop in the turret used for feeding in this counterbore, and which is also used for gaging the stock to length is operated by the lobe from 63 to 69 on the lead cam. It will be noticed that this lobe is much lower than the lobe from 2 to 4 gaging the stock to length, the reason, of course, being that the counterbore projects much further from the chuck than does the stock when fed out.

Another simple method of holding an extra tool on the cross-slide is illustrated at *B* in Fig. 2. Here the holder is made

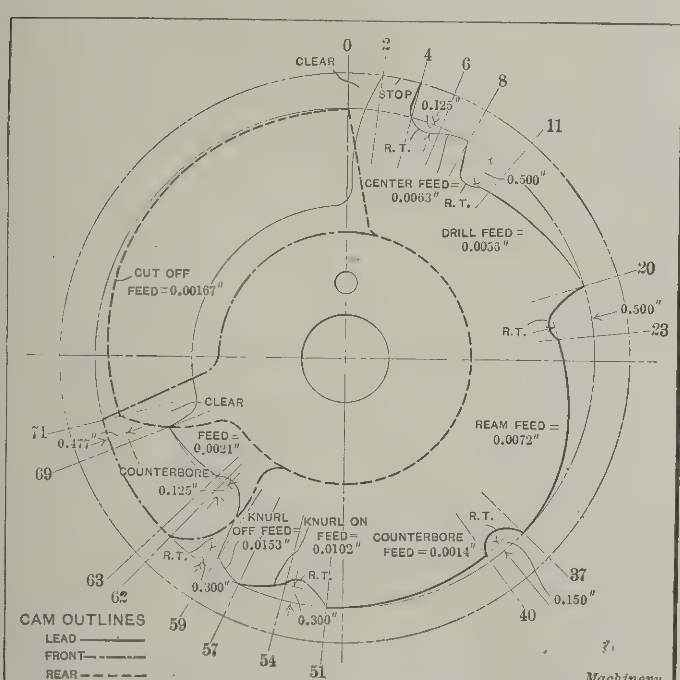

Fig. 3. Cams used in Producing the Piece shown at A in Fig. 1

so that it will take either a drill or a counterbore, as the case may be, which is held in it by means of a headless screw. The tool is rotated by means of the grooved pulley *c*, which is fastened to the spindle *d* as shown. This pulley is driven from the overhead works by a round belt, which is left sufficiently slack to allow the front cross-slide to advance to a position in line with the work. The drill is fed forward by a stop held in the turret, and is withdrawn by the coil spring *e*.

Other operations performed with drills and counterbores held on the cross-slide are shown in Fig. 1 at *B*, *C*, *D* and *E*, respectively. At *C* is shown a piece made with an eccentric hole. This is easily produced by means of a drill held in a holder fastened to the cross-slide. Of course it is necessary to lock the spindle when the hole is being drilled. A drill holder similar in construction to that shown at *B* in Fig. 2 is used. It will be noticed that the piece shown at *C* is made with holes having different degrees of eccentricity; otherwise the pieces made with an eccentric hole are of the same size and shape.

It is interesting to compare this method of drilling with the old method, which consisted in holding the stock in an eccentric chuck or in drilling each piece in a drill jig. The method last mentioned is expensive, and the eccentric chuck method is very destructive to the cut-off tools owing to the pounding of the stock against the cutting edge.

At *B* is shown how wrench slots were produced in a special nut. The holes were first drilled, after which the shank was turned down by means of a box-tool, leaving only one-half of the drilled holes in each side. To produce this piece, the cross-slide cam moves the drill and holder forward part way, then dwells while the first hole is being drilled, by means of a stop in the turret forcing the drill into the work. After the first hole is drilled, the cam advances into position for the second hole, when the same operation is repeated. At *D* is shown a washer provided with two holes which were also drilled in this manner. At *E* in Fig. 1 is shown a piece which requires a different movement. The lead cam is not used at all, and the groove *a* is cut with a reamer instead of a drill. After the machine spindle is locked in position by means of the brake, the reamer starts at one side and is fed across by the cross-slide cam operating the slide upon which the reamer is mounted. These special operations give little trouble especially on brass work, the material from which the parts described were made.

BRITISH VIEW OF BRITISH CONDITIONS

The following editorial from the *Mechanical World* gives an interesting view of some industrial conditions in Great Britain that are very different from the conditions here. That it should be considered remarkable that a firm should pay wages to its engineering apprentices, and that a business career should be considered "undignified," is strange to us, and while we have seen frequent allusions to the latter subject in stories and novels, yet we were hardly prepared to accept it as a plain fact with a practical bearing on the administration of engineering undertakings in Great Britain at the present day.

"A remarkable offer has just been made by an electrical company in order to attract into the shops and offices men of superior education and some social standing. Instead of asking a premium of three hundred pounds or more for the training of young men in electrical engineering, the company is prepared to receive a number of promising university men and make them a reasonable remuneration. The men are required for good positions and salaries in an administrative capacity later on, and it will be of some interest at some future time to learn the result of the offer. At present it is possible to obtain the best brains and experience in the world for the purely technical side of the industry on paying suitably for them, but for the administrative side the best material, we are told, is represented by the British office boy. It is strange that before making an appeal to those of university education an effort has not been made to secure suitable candidates from the technical colleges and schools; or has sufficient experience already been obtained with the material turned out by these institutions? If so, is it hoped to be more successful with university men, who have been taught to regard business as undignified or as representing a fall in the social scale? There may, however, be exceptions, and the hope may be expressed that they will be discovered, so that the experiment may be afforded a practical test."

* * *

The latest statistics relating to the exports and imports of machine tools in Germany show that the exports increased from 59,100 metric tons in 1910 to 71,500 tons in 1911. Austria-Hungary and Italy imported more German machine tools than any other country, but France and Russia also proved themselves to be good customers. The imports amounted to 7400 tons of which 4500 tons was from the United States, and 960 tons from Great Britain. The total value of the machine tools exported in 1911 was in round numbers $19,000,000, while the total value of the imports was $2,300,000.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

MAY, 1912

PAID CIRCULATION FOR APRIL, 1912, 24,812 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

DOUBLE-CUTTING PLANERS

Many attempts have been made to design a planer that will cut with equal efficiency on both the forward and return strokes. Recently a planer was brought out in Great Britain which is claimed to possess certain advantages in this respect; but while it is evident that the elimination of the idle strokes means a considerable advance in efficiency, the great difficulty to be overcome is to design a planer which will cut in both directions with equal efficiency and accuracy. It is apparent that the planer, as made today, is designed to take a maximum cut in one direction only, and a radical change must be made in its design before a really satisfactory machine can be produced which will take heavy cuts in both directions. The tool-head is clamped to the face of the cross-rail, which, in turn, is clamped to the face of the housings, and the stresses produced in these parts when a cut is taken in one direction are quite different from those when the cut is taken in the other direction. In one case there is a tendency to compress all of these parts solidly, giving a firm support to the cutting tool; in the other the tendency is to pull all joints apart, thus depriving the cutting tool of the firmness of its support and creating a tendency to chatter. It appears that if planers are to be made double-cutting, the successful design must be arranged on lines quite different from those of present planers, so that equal support is given to the tool when cutting in both directions.

* * *

PANTOGRAPH PRINCIPLE IN INTERCHANGEABLE MANUFACTURING

When a new machine is developed consisting of many small parts which must be accurately shaped and cheaply produced, preparation for manufacturing ordinarily involves heavy expenditures for presses, punches, dies, jigs, reamers, boring cutters and other tools common to interchangeable manufacturing. When the future of the machine is reasonably sure, there can be no question as to the wisdom of providing the best and most efficient tools that skilled designers and toolmakers produce; but when the outcome of the venture is in doubt because of the practical impossibility of testing the commercial conditions in any other way than by putting the machines on the market, the problem may be sorely perplexing.

Generally, it will not do to put out handmade machines, as the slowness of production, inevitable inaccuracies and high cost make that procedure impracticable. The common practice in that event is to make expensive form milling cutters, dies and jigs for producing the vital parts and to make the auxiliary parts by hand and by ordinary machine tools.

The possibilities of the profiling machine in manufacturing parts of considerable size which do not require the highest accuracy of form have been known and widely applied for many years, but the pantograph principle applied to profilers, of which certain engraving machines are good examples, has not in our opinion been developed as much as its merits deserve.

Take the case of an adding machine which has been developed in the handmade form to a practical success. The matter of making parts from flat stock in hundred lots with pantograph profilers would consist first of making the "copy," say, five times scale, correcting errors by trial, and then actually producing the parts from flat stock cut into strips and held for the operations by suitable quick-action chucks. The pantograph profiler, unlike the form milling cutter on the Lincoln milling machine, is not confined to the production of contours from flat stock only, but can be designed to work in three directions, thus becoming universal in scope. If heavily designed, these machines could be made to function automatically, and produce work of widely varying forms at costs higher than punch and die work, it is true, but so low that the product could probably be placed on the market advantageously under the conditions set forth in the beginning.

* * *

APPRENTICES TEACHING APPRENTICES

In shops employing numbers of apprentices directly subject to the foreman, the common plan of instruction on the operation of machines is to delegate the boy about to give up a machine to instruct the next apprentice in its construction and operation. This method has the advantage of relieving the foreman of the duty of instructing the boys in machine operation—for which he usually has little time and which, in many cases, he could not effectually carry out—and of making each boy as he "graduates," review his knowledge by showing his successor how and what to do. This method also has disadvantages of a serious nature. Not many boys are capable of running a machine at its highest productive capacity, and they are not expected to. They are likely to gradually sink in the scale of efficiency through lack of comprehension or competent instruction until a very low state is reached. Not only may the functions of a machine be but partly understood and used, but improper instruction in oiling bearings and caring for tools, belts, etc., may lead to rapid deterioration of the machine and its product.

When the foreman wakes up to the situation, there is a grand "raking over the coals" and "jacking up all around." Boys genuinely ignorant of their duties are blamed, perhaps, for what they could hardly be expected to know, and the result is dissatisfaction all around. The foreman thinks that apprentices are nuisances generally, and the boys are sorry they started to learn the trade. Unfortunately, few foremen are qualified to act as apprentice instructors. If they are good foremen they are likely to be poor teachers, and, *vice versa*, good teachers are likely to be indifferent foremen. The ability to impart knowledge is a rare gift, fully developed only after years of training.

Conditions like those set forth are less likely to develop when the boys are in charge of an overseer who devotes himself exclusively to their instruction and to instilling those ideals which are necessary for the making of good mechanics. The plan of letting a boy instruct his successor may then work out; that is, when the boy acting as teacher has had careful training and is able to produce good work in reasonable time, and to take proper care of his machine. But unless he has been and is under competent supervision, it is likely to lead to inbreeding of vicious methods and principles.

HELPING A MAN TO FIND HIS PLACE

One of the valuable features of the new systems of management, generally known as "scientific," is that when properly conducted they aid the individual in finding that place in an organization where he can do his best work, receive the most compensation, and in general develop his latent powers so as to produce the greatest benefit to himself and his employer.

In factories organized on the task basis it is often found, for example, that a man working on a lathe cannot possibly fulfil the task that has been found to be easy for the average man. In such a case, this man is not kept at his machine, but is shifted around to other machines or work better suited to his capacity. In nearly all instances, a certain machine or work can be found in the shop whereon this man will be able to perform the set task with ease.

Under the old methods of management such a man would have been retained year after year at work for which he was not fitted. He would have been poorly paid, and at that would have been a poor investment for his employer. He would have been dissatisfied, and helpless to better his condition. Under the new system he finds his proper place, earns good wages, is satisfied and returns a much greater profit to his employer. Of course, all so-called scientifically-managed shops have not applied this important principle of management, and to the extent that they have not they have been unsuccessful with the new methods.

Scientific management is not a mere stop-watch system; it requires constant and intelligent attention. It is not a system which once installed will run itself, nor is it a system that can be run successfully by a man whose views on the relation between employe and employer are too narrow. Scientific management is a broad scheme with far-reaching purposes, and it requires a broad-gage man to handle it.

CASEHARDENING PROCESSES AND RESULTS

The common process of treating wrought iron with a carbonaceous compound to give it surface hardness is probably the oldest method employed to convert iron into steel. The surface hardness of "case" results from the infusion of carbon which penetrates the iron to depths depending on the nature of the pack and the time of heating. The converted iron (steel) hardens when heated and quenched in cold water. The ease and cheapness of the process by which common iron can be changed to steel of considerable endurance has made possible the use of the casehardening process for a multitude of purposes requiring a cheap, strong, and tough material with hardened surface. Fifty years ago, before the advent of Bessemer steel, some of the railway companies in England treated wrought-iron rails to harden the rail heads and thus increase their durability. The later development of the iron-clad and armored battleship led to the development of casehardening processes for steel armor plate of extraordinary efficiency, producing extreme hardness to a depth of several inches and leaving the remainder of the plate soft and very tough.

In machine shops the casehardening process has been used to some advantage in the making of tools, especially large milling cutters, taps, etc. Varied success has attended these efforts, and hardly any two men having experience in different shops will agree on the value of such products. One shop may obtain uniformly satisfactory work, when another can never be sure of the quality of casehardening work produced.

The reasons for these varied results are several, the chief, of course, being the nature of the pack and heat treatment. One common error is to quench the work in the bath as it is dumped out of the boxes. For all work requiring the best quality of casehardening the treated parts should be allowed to cool slowly when dumped, and then heated to the hardening temperature so as to harden on a "rising heat."

But with the best packing materials and approved heat treatment, the product will vary, and sometimes be unsatisfactory if the chemical composition of the mild steel commonly used includes impurities known to be deleterious to tool steel. Sulphur, manganese and phosphorus must be present in minimum percentages only, if the casehardened product is to have those qualities which give it reliability and durability. The salesman who offers a casehardening compound with the claim that qualities will be produced in the product which make it equal to tool steel, is not honest and sincere if he does not state that the steel used must have certain specified chemical components to start with. Another fact which should be kept in mind by the user of casehardening compounds is that the difference in cost of mild steel and tool steel is materially reduced by the cost of the compounds and the heat treatment. Not infrequently the saving may be reduced to a negligible amount.

THE MOVING PICTURE AS AN AID TO MECHANICAL INSTRUCTION*

By CHESTER L. LUCAS†

A few weeks ago, at one of the popular moving picture theatres in New York City, a film was shown to illustrate the way in which "photo-plays" are originated. Among other views, were several intended to convey an idea of the work incident to the making of the moving picture machine itself. One of these mechanical views showed the drilling of the frames of the machines, and as it was a close-range view of the work and table of the drilling machine, every detail of the operation being performed could be plainly observed. The drill could be seen entering the bushing of the jig; chips curled out from the drill with credit to the man who sharpened it, and the drill "broke through" in the most natural manner possible. Any mechanic in the audience must have felt a responsive thrill as he viewed that part of the film. Another view showed the making of the film-spool on an automatic turret lathe. The bar stock could be seen as it was fed forward; the turning tools and turret came up to the work just as a few hours before they might have been seen to do in many shops; the drills and forming tools could be plainly seen, and even the cutting-off tool was visible as it fed slowly into the work. There were several other views of a like nature, the whole comprising a most graphic illustration of some of the phases of machine shop practice.

There seems to be every reason to believe that the moving picture should be of great value in imparting mechanical instruction. While the operations shown in this case were necessarily elementary, in order to appeal to the general public, there should be no trouble in making films that would show the working of complex mechanism. If the mechanism was very small, it could easily be enlarged in showing the film, and therefore be even more clearly grasped than from observing the work itself. Again, if the parts moved with great rapidity, as in adding machine mechanism, the film could be "slowed down" until the operation was easily understood. With the addition of a lecturer, to explain difficult parts of the operations shown, such exhibitions would be highly instructive to apprentice, mechanic or engineer.

Undoubtedly the greatest stumbling-block in the path of this method of instruction at the present time is the cost of the film. It is said that the average film costs about one thousand dollars to produce, and except for the fact that each new film is copied from twelve to fifty times, there would be little profit in making films. In the case of films for illustrating mechanical operations, correct shop practice and similar subjects, no expensive company of actors would be required, which, of course, would lessen the expense of making the film.

Within a few years' time a moving picture machine will undoubtedly be just as necessary a part of the equipment of a college as a microscope is to-day. It would even now seem feasible for a large number of trade schools or educational classes to confer as to what phases of their work could best be illustrated and taught in this way, after which several films could be made, distributing the expense. These films, together with a machine for showing them, could be sent from one school to another for exhibition; thus all would derive full benefit at a minimum cost.

* For previous suggestions and comments on this subject see "Moving Pictures as an Aid to Teaching Trades," January, 1909; "Moving Picture Show as an Educator," page 527, engineering edition, March, 1909; and "Moving Picture Shows as an Incentive to Crime," page 604, engineering edition, April, 1909.

† Associate Editor of MACHINERY.

NOTES AND COMMENT

Monel metal, which has been termed a "natural" alloy, is regarded as a successful substitute for steel and bronze in steamship propellers. It has recently been cast in pieces weighing as much as 25,000 pounds. Several castings for propellers have been furnished to the United States government.

The question of standard colors for piping systems has been taken up by several German engineering societies, and the following color scheme has been agreed upon: Green is to indicate water; yellow, gas; blue, air; white, steam; black, tar; pink, lyes; pink with a red ring, acid; brown, oils; and grey, vacuum. A black ring or band indicates impurity; a red ring, danger; thus a green pipe with a black ring carries refuse water; a white pipe with a red ring carries superheated steam, etc.

The trackless trolley systems which, during the past year, have been inaugurated in a number of places in Europe, appear to have a considerable future on account of the very decided saving in the initial investment. As an illustration it may be mentioned that Mr. H. Jackson, in presenting a paper before the Birmingham branch of the Institute of Civil Engineers, showed that routes of trolley systems 27 miles long, in the suburbs of Birmingham, could be established complete for a service of fifteen minutes intervals for about $375,000, while the same system along the conventional electric trolley line construction would cost about $1,650,000.

It appears from a recent Blue Book published by the British government, that the United States is practically the only country of any consequence in which there is no law for the compulsory working of patents. All other industrial countries have enacted laws—some long ago—which require the patentee to manufacture the patented article within a certain number of years, or to license somebody else to manufacture it. If the patented article is not manufactured to what is termed "an adequate extent" within the specified number of years, the patent becomes invalid. Great Britain makes this time four years, but most other nations do not permit so long a period before the patent must be actually exploited.

It is stated in the *Brass World* by Roy C. Davidson of Fort Blackmore, Va., that copper may be welded in the following manner: The pieces to be welded are placed in a fire and heated to a black heat, after which they are coated with borax. The two pieces are then removed and hammered. They are again returned to the fire and this process is repeated twice, after which the joint is covered with ferrous sulphate. The pieces are now placed in the fire again and heated as hot as the copper will stand without melting, and the joint hammered together. It will be found, it is stated, that a sound and homogeneous joint will then result.

According to *Engineering*, copper deposits of great importance have been found in the Katanga district in Congo, between the Zambesi and Congo rivers. It has been estimated that the Katanga district has copper deposits of sufficient extent to fill the world's demand for copper for the next hundred years. Besides the copper deposits, gold, platinum, silver and zinc are abundantly found in this district. While the enormous mineral wealth of this province has been a matter of knowledge in financial circles for some time, comparatively little has as yet been done with relation to mining enterprises, on account of the great transportation difficulties presented.

The import of machine tools to Great Britain is steadily increasing, and some concern is felt by the British mechanical journals on this account. It is stated that the import of machine tools in 1911 was three times that in 1910, and over two and one-half times that in 1909. On the other hand the export of machine tools from Great Britain in 1911 was less in tonnage, although greater in value, than in 1910, and considerably less than the export in 1909. The Machine Tool Association formed during the past year has now a membership of eighty firms and it is expected that the activities of this organization will make it possible to place the British machine tool building business on a more satisfactory basis.

Dr. J. W. Richards, in a recent lecture before the Engineers' Society of Western Pennsylvania, gave a review of the progress made in Sweden during the past year in the production of iron and steel by electrical processes. Dr. Richards has visited Sweden every summer for several years, and is well informed on the research and experimental work done by the Swedish Iron and Steel Institute (Jernkontoret), at Trollhättan. He asserted that there was no longer any doubt but that, under the latest Swedish practice, pig iron smelted from ore in the electric furnace will shortly displace the old charcoal iron that has made the Swedish iron industry famous. In fact, some steel makers maintain that the electrically smelted iron is superior to the charcoal iron.

To find the melting points of metals which fuse only at the very highest temperatures has been found to be extremely difficult, and until recently experiments have given widely varying results. By means of electric vacuum furnaces, however, some experiments giving accurate results have been undertaken in Germany by Otto Goecke, who places the melting points of the following metals as below:

Gold	1960 degrees F.
Manganese	2277 degrees F.
Chromium	2757 degrees F.
Platinum	3182 degrees F.
Iridium	4035 degrees F.
Vanadium Carbide (Va_4C_3)	4982 degrees F.

It is stated in the *Mechanical World* that the crankshaft for a 50-horsepower engine for a certain British type of aeroplane weighs only eighteen pounds. It consists of a tubular shell made of chrome-vanadium steel, the shell being ⅛-inch in thickness. It is stated that in the tests it has proved to have a margin of safety of 38 per cent over that necessary for the 50-horsepower engine. It would seem that the aviator runs a decided risk in employing an engine where the factor of safety of one of the most vital parts is as small as this. The frightful toll paid by the lives of aviators, it seems, could be diminished to a considerable extent if such perils were avoided as are introduced by employing machinery which is worked so near the danger limit.

A mechanic, in the *Mechanical World*, calls attention to the fact that there seems to be no standard for the squares or flats on taps and reamers. He states that many firms reduce the shanks too much, and in this way not only weaken the tap or reamer, but also produce a square which is not of a standard size. Some firms make the squares with sharp corners, while others merely mill four flats, so that the end of the tap looks more like an octagon than anything else. Standardization of this detail, though of comparative unimportance, is no doubt well worth while. If taps and reamers were made with squares of standard sizes, they would be more durable, the wrenches would last longer and their number would be reduced considerably.

The first locomotive in America, built for the Camden & Amboy Railroad in 1831, is still intact in the National Museum at Washington. It is interesting to make a comparison between this engine and the locomotive recently adopted by the Pennsylvania Railroad for its heavy passenger service. The weight of the old locomotive mentioned—called "John Bull"—is 24,625 pounds, while the Pennsylvania engine with tender weighs 430,000 pounds. The two driving wheels of "John Bull" are 54 inches in diameter, while the six driving wheels of the modern engine are 80 inches in diameter. The tubes of the "John Bull" are 7½ feet long and the tube heating-surface, 213 square feet. In the modern engine, the tubes are nearly 21 feet long, and the heating surface is 4420 square feet.

THE DESIGN OF CONICAL HELICAL SPRINGS*†

By E. R. MORRISON‡

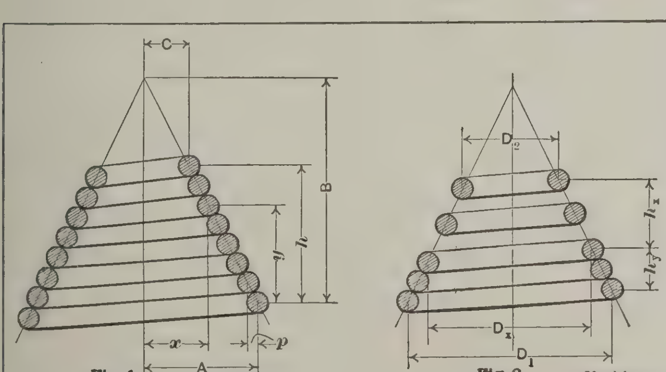
On account of their physical characteristics, conical helical springs divide themselves into two distinct classes, according to their use. The formulas applicable to a spring of this type used as a compression spring are not at all applicable if the spring is to be used as an extension spring. This is more obvious if we note that the safe load which an extension spring will carry is governed by the capacity of the largest or weakest coil, which condition is reversed in the compression state, where the spring retains its flexibility until the load becomes great enough to close up the smallest or strongest coil. It is the object of this article to develop the formulas applicable to the various types of conical helical springs. Round bar coils only will be considered.

Notation—Dimensions in Inches, Weights in Pounds

S = stress,
G = modulus of torsional elasticity,
f = deflection,
f_x = deflection under load P_x
H = free height,
h = solid height, assumed to equal $d \times N$,
y = solid height at any convenient coil,
P = capacity of spring,
P_x = any load not exceeding P,
P_1 = capacity of largest coil,
P_2 = capacity of smallest coil,
D_1 = mean diameter of largest coil,
D_2 = mean diameter of smallest coil,
d = diameter of bar from which coil is made,
A = mean radius of largest coil,
B = apex height of cone,
C = mean radius of smallest coil,
N = number of coils,
p = average horizontal pitch of coils,
w = weight of one cubic inch of steel,
l = length of bar in spring,
W = weight of spring,
x = mean radius of any convenient coil.

Deflection and Capacity of Extension Spring

It is obvious that P_x in this case must be understood to be not greater than the capacity of the weakest coil, inasmuch



Figs. 1 and 2. Diagrams for the Derivation of Spring Formulas

as a greater value of P_x would distort the spring beyond the realm of rational formulas. A conical spring is composed of an infinite number of elementary cylindrical coils, each element being in itself a uniform diameter helical spring, and each element differing from its neighbor in the one respect that each successive element has a mean diameter infinitesimally less than its first neighbor, and likewise infinitesimally greater than its neighbor on the other side. These increments of change in the mean diameter result in corresponding increments of change in the deflection of the successive elements, and being all governed by the one general expression for deflection of cylindrical helical springs, may be added together by resorting to calculus. Since the increments of change in the mean diameter are in this case in proportion to the increments of change in the solid height, it follows that the increments of change in the deflection also follow those of the solid height, and that we may expect to arrive at the summation of the deflection through a summation of the increments of change in the varying solid height, which for successive elementary cylindrical coils increases from 0 to its maximum h.

Now the expression for deflection in cylindrical coil springs is:

$$f = \frac{\pi S}{G}\left(\frac{D}{d}\right)^2 h$$

and for capacity:

$$P = \frac{\pi S d^3}{8 D}$$

The value of D is here, however, the variable, represented by $2x$. Therefore, in each elementary cylinder:

$$\frac{f_x}{f} = \frac{P_x}{P}, \text{ or } f_x = \frac{8 P_x (2x)^3 h}{G d^5} = \frac{64 P_x x^3 h}{G d^5}$$

Further,

$$\delta f_x = \frac{64 P_x}{G d^5} x^3 \delta y$$

$$f_x = \int_0^h \frac{64 P_x}{G d^5} x^3 \delta y = \frac{64 P_x}{G d^5} \int_0^h x^3 \delta y.$$

But, as shown in Fig. 1, $\frac{B}{y} = \frac{A}{A - x}$; whence $x = A - \frac{A y}{B}$

$$\text{Hence } x^3 = A^3 \left(1 - \frac{3y}{B} + \frac{3y^2}{B^2} - \frac{y^3}{B^3}\right)$$

Hence,

$$f_x = \frac{64 P_x A^3}{G d^5} \int_0^h \left(1 - \frac{3y}{B} + \frac{3y^2}{B^2} - \frac{y^3}{B^3}\right) \delta y$$

$$f_x = \frac{64 P_x A^3}{G d^5} \left(h - \frac{3h^2}{2B} + \frac{h^3}{B^2} - \frac{h^4}{4B^3}\right)$$

Also, from Fig. 1, we have: $B = \frac{A h}{A - C}$, whence:

$$f_x = \frac{64 P_x A^3}{G d^5} \left(h - \frac{3h^2 (A - C)}{2 A h} + \frac{h^3 (A - C)^2}{A^2 h^2} - \frac{h^4 (A - C)^3}{4 A^3 h^3}\right)$$

But $A = \frac{D_1}{2}$ and $C = \frac{D_2}{2}$. Hence,

$$f_x = \frac{8 P_x D_1^3 h}{G d^5} \left(1 - \frac{3(D_1 - D_2)}{2 D_1} + \frac{(D_1 - D_2)^2}{D_1^2} - \frac{(D_1 - D_2)^3}{4 D_1^3}\right)$$

$$= \frac{8 P_x D_1^3 h}{G d^5} \left(\frac{D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3}{4 D_1^3}\right)$$

$$= \frac{2 P_x h}{G d^5} (D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3) = \frac{2 P_x h (D_1^4 - D_2^4)}{G d^5 (D_1 - D_2)}$$

$$= \frac{P_x (D_1^4 - D_2^4)}{G d^4 \frac{(D_1 - D_2) d}{2h}}$$

Observe now that the expression in the denominator is the average horizontal pitch p (see Fig. 1) of the coils:

$$p = \frac{\frac{D_1 - D_2}{2}}{N}; \text{ but } N = \frac{h}{d}; \text{ hence, } p = \frac{(D_1 - D_2) d}{2h}$$

Therefore,

$$f_x = \frac{P_x (D_1^4 - D_2^4)}{G p d^4}$$

This then is the formula for the deflection of any extension type conical helical spring under load P_x, the value P_x not exceeding the capacity of the weakest coil, equivalent to the

‡ Address: Sharon, Pa.

capacity of a cylindrical helical spring of a mean diameter equal to D_1 and bar diameter equal to d.

If the value of P_x equals the capacity P of this spring, we have:

$$P = P_x = \frac{\pi S d^3}{8 D_1}$$

Substituting this value of P_x, we have the total deflection:

$$f = \frac{\pi S (D_1^4 - D_2^4)}{8 G p d D_1}$$

which is the final formula for the total deflection of the extension conical helical spring.

It will be noticed that the previous discussion is based on the assumption that the solid height of the spring is equal to the diameter of the bar times the number of coils in the conical spring. However, as one coil seats within the other, the solid height is really less than that assumed; the solid height becomes less as the taper of the coil becomes greater, until for a true spiral spring the solid height is reduced to the diameter of the bar. The actual deflection is dependent on the "slant height" of the conical coil which is equal to $d \times N$, as assumed for the solid height, rather than upon the actual vertical height. Due to this assumption, the changing of the angle of the cone formed by the spring does not change the actual deflection so long as the value of the slant height itself is not changed. Inasmuch as the above discussion is based on the slant height, the actual solid height of the spring and also the free height of the spring should be corrected by deducting from the value of these heights the difference between the slant height and the solid height. Stated briefly, the assumption that the solid height is equal to $d \times N$ is necessary in order to obtain the correct value of the deflection; but after this deflection has been obtained, correction should be made for this assumption.

Deflection and Capacity of Compression Spring

The deflection of a compression spring of this type is a fundamental problem of the same type. In this case, however, the summation is not the summation of increments of deflection under a uniform load and varying stresses, but the summation of increments of deflection when each elementary spring is stressed to a maximum, and hence under uniform stress.

In this case $f = \dfrac{\pi S}{G}\left(\dfrac{D}{d}\right)^2 h$, becomes $f = \dfrac{\pi S}{G}\left(\dfrac{2x}{d}\right) h$

$$\delta f = \frac{\pi S}{G}\left(\frac{2x}{d}\right)^2 \delta y \text{ and } f = \int_0^h \frac{\pi S}{G}\left(\frac{2x}{d}\right)^2 \delta y$$

But $x = A - \dfrac{A y}{B}$. Hence:

$$f = \frac{4 \pi S A^2}{G d^2} \int_0^h \left(1 - \frac{2y}{B} + \frac{y^2}{B^2}\right) \delta y$$

$$= \frac{4 \pi S A^2}{G d^2} \left(h - \frac{h^2}{B} + \frac{h^3}{3 B^2}\right)$$

But $B = \dfrac{A h}{A - C}$, and $A = \dfrac{D_1}{2}$, and $C = \dfrac{D_2}{2}$. Hence the expression above can be transformed to:

$$f = \frac{\pi S h}{3 G d^2} (D_1^2 + D_1 D_2 + D_2^2)$$

$$f = \frac{\pi S h (D_1^3 - D_2^3)}{3 G d^2 (D_1 - D_2)}, \text{ and since } p = \frac{(D_1 - D_2) d}{2 h}$$

$$f = \frac{\pi S (D_1^3 - D_2^3)}{6 G p d}$$

which expresses the total compression for a conical helical compression spring.

The capacity, solid, equals that of the smallest coil, or:

$$P = \frac{\pi S d^3}{8 D_2}$$

Deflection of Compression Spring for Given Loads

If the given load is less than P_1, the entire spring remains flexible, and the formula for deflection is the same as that derived for an extension spring, the condition of varying stress still being present.

If, however, the load exceeds P_1, then a portion of the spring will become solid. The division point may be found, for $P_x = \dfrac{\pi S d^3}{8 D_x}$, and since the load in cylindrical coils varies inversely as D:

$$\frac{D_x}{D_2} = \frac{P_2}{P_x}, \text{ whence } D_x = \frac{D_2 P_2}{P_x}$$

The deflection of the two portions of the spring should now be considered separately and added, using the two final formulas just developed.

Fig. 2 shows a graphical illustration of the divided spring. Let p_x be the average horizontal pitch of the unclosed portion, above D_x. Let p_y be the average horizontal pitch of the solid portion, below D_x.

The total deflection is then:

$$f = \frac{\pi S (D_1^3 - D_x^3)}{6 G d p_y} + \frac{\pi S (D_x^4 - D_2^4)}{8 G d D_x p_x}$$

In Fig. 2, h_y is the height, solid, of the solid portion of the spring. Its value is derived thus:

$$\frac{h_y}{h} = \frac{D_1 - D_x}{D_1 - D_2}, \text{ whence } h_y = h \frac{D_1 - D_x}{D_1 - D_2}$$

Bar Length for Conical Spring

Fundamentally, $l = \pi \left(\dfrac{D}{d}\right) h$, so that we have in a conical spring

$$l = \delta \pi \left(\frac{2x}{d}\right) \delta y, \text{ or}$$

$$l = \frac{2\pi}{d} \int_0^h x \, \delta y = \frac{2 A \pi}{d} \int_0^h \left(1 - \frac{y}{B}\right) \delta y = \frac{2 A \pi}{d} \left(h - \frac{h^2}{2B}\right)$$

And since $B = \dfrac{A h}{A - C}$, and $A = \dfrac{D_1}{2}$, and $C = \dfrac{D_2}{2}$, we get:

$$l = \frac{\pi h}{d} \left(\frac{D_1 + D_2}{2}\right)$$

Weight of Conical Spring

Fundamentally, $W = \dfrac{l \pi d^2 w}{4}$. Hence

$$W = \frac{\pi^2 d h w}{8} (D_1 + D_2)$$

Summary of Formulas

Summarizing and substituting for S a value of 80,000 pounds per square inch, and for G a value of 12,600,000 we have:

Extension Conical Spring Formulas

$$f = 0.002493 \frac{D_1^4 - D_2^4}{p d D_1}$$

$$P = 31{,}416 \frac{d^3}{D_1}$$

Compression Conical Spring Formulas

$$f = 0.003324 \frac{D_1^3 - D_2^3}{p d}$$

$$P = 31{,}416 \frac{d^3}{D_2}$$

Weight in each case, $W = 0.35 \, dh \, (D_1 + D_2)$.

Bar length in each case, $l = 1.571 \dfrac{h}{d} (D_1 + D_2)$

Numerical Examples

Example: Compression spring, $D_1 = 4\ 9/16$ inches; $D_2 = 3\ 9/16$ inches; $d = 1\ 1/16$ inch; $h = 7\ 1/16$ inches.

Then $N = \frac{h}{d} = 6.65$; $\frac{D_1 - D_2}{2} = 0.5$; $p = \frac{D_1 - D_2}{2N} = 0.075$.

$$f = 0.003324 \frac{(4\tfrac{9}{16})^3 - (3\tfrac{9}{16})^3}{0.075 \times 1\tfrac{1}{16}} = 2\tfrac{1}{16} \text{ approximately.}$$

See the accompanying Data Sheet Supplement for table of cubes, and also for other powers of numbers required in conical spring calculations.

$$H = 7\ 1/16 + 2\ 1/16 = 9\ 1/8 \text{ inches.}$$

Example: Same spring in extension.

$$f = 0.002493 \frac{(4\tfrac{9}{16})^4 - (3\tfrac{9}{16})^4}{0.075 \times 1\tfrac{1}{16} \times 4\tfrac{9}{16}} = 1\tfrac{7}{8} \text{ approximately.}$$

$$H \text{ (extended height)} = 7\tfrac{1}{16} + 1\tfrac{7}{8} = 8\tfrac{15}{16} \text{ inches.}$$

As might have been expected, the free height for the compression type is greater than the possible extended length for the extension type. This is because sufficient load to fully stress the smaller or stronger coils cannot be applied without distorting the extension spring, whereas the coils may all be stressed to maximum stress in the compression type, the closing of the coils solidly together protecting the spring from over-stress.

Reversion to Cylindrical Helical Springs

It will be noted that in each of our final formulas we have introduced the factor $(D_1 - D_2)$ and the value of $p = \left(\frac{D_1 - D_2}{2h}\right) d$. This has been done to leave the formulas in as simple a form as possible. Note, however, that if D_1 and D_2 each be taken as equal to D_1 or to each other, the formulas in each case revert to the fundamental cylindrical helical spring formulas, as should be expected.

Substituting $D_1 = D_2 = D$ in the extension formula

$$f_x = \frac{2 P_x h}{G d^5} (D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3), \text{ we have}$$

$$f_x = \frac{8 P_x D^3 h}{G d^5}$$

This is the fundamental formula for the deflection of an extension helical cylindrical spring under any load P_x, derived directly from the formula for load:

$$P = \frac{\pi S d^3}{8 D}$$

in which S has been replaced by its value in the formula

$$f = \frac{\pi S}{G} \left(\frac{D}{d}\right)^2 h \text{ giving } P = \frac{G f d^5}{8 h D^3}$$

from which $f = \frac{8 P D^3}{G d^5} h$

Substitute, again, $D_1 = D_2 = D$ in the compression formula:

$$f = \frac{\pi S h}{3 G d^2} (D_1^2 + D_1 D_2 + D_2^2), \text{ and we have}$$

$$f = \frac{\pi S}{G} \left(\frac{D}{d}\right)^2 h$$

the fundamental formula for the deflection of a compression helical cylindrical spring.

The reason for this comparison between the formulas for cylindrical helical springs and conical springs, is particularly, to bring out the fact that, while each of the conical formulas are thus shown to revert to the same form when $D_1 = D_2$, yet the conical spring formulas themselves, for extension and compression springs, are different. As already mentioned, one is an expression for deflection under a given load, regardless of stress, while the other is the expression for deflection under a uniform maximum stress. The former condition is that of the conical extension spring, while the latter is that of the compression type.

Auxiliary Formulas

The expressions for deflection and capacity are the main formulas for all helical springs; from these are developed such other formulas as may be desired. In this particular case, care must be taken in making such further developments, if using the expressions $D_1^4 - D_2^4$ and $D_1^3 - D_2^3$, to note that resulting formulas will not revert to simple cylindrical helical formulas, because of the fact that a zero quantity has been introduced when D_1 becomes equal to D_2.

Therefore, further formulas are based on the longer but primary formulas which we have arrived at before the introduction of the quantity $D_1 - D_2$.

The Ratio between Free and Solid Heights

Since $H = f + h$, we have, for compression springs:

$$H = \frac{\pi S h}{3 G d^2} (D_1^2 + D_1 D_2 + D_2^2) + h$$

$$= h \left[1 + \frac{\pi S}{G} \left(\frac{D_1^2 + D_1 D_2 + D_2^2}{3 d^2}\right)\right]$$

$$= h \left[1 + \frac{\pi S}{G} \left(\frac{D_1^3 - D_2^3}{3 d^2 (D_1 - D_2)}\right)\right]$$

In a similar way, for extension springs:

$$H = h \left[1 + \frac{2 P_x}{G} \left(\frac{D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3}{d^5}\right)\right]$$

$$= h \left[1 + \frac{2 P_x}{G} \left(\frac{D_1^4 - D_2^4}{d^5 (D_1 - D_2)}\right)\right]$$

By introducing the factor $(D_1 - D_2)$ the formulas are thus simplified as before, so that they may be readily solved with a table of cubes and fourth powers.

Deflection when only Free Height is Given

Considering first the compression type, we substitute the value of h as found from the formulas in the last paragraph, in the general formula for f. Hence:

$$f = \frac{H}{1 + \frac{G}{\pi S} \left(\frac{3 d^3}{D_1^2 + D_1 D_2 + D_2^2}\right)} = \frac{H}{1 + \frac{G}{\pi S} \left(\frac{3 d^2 (D_1 - D_2)}{D_1^3 - D_2^3}\right)}$$

In a similar way, for extension coils:

$$f = \frac{H}{1 + \frac{G}{2 P_x} \left(\frac{d^5}{D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3}\right)}$$

$$= \frac{H}{1 + \frac{G}{2 P_x} \left(\frac{d^5 (D_1 - D_2)}{D_1^4 - D_2^4}\right)}$$

General Considerations

In the compression type it is sometimes desirable to fix the heights, both free and solid, and afterwards ascertain the resulting capacity. If the heights so fixed exceed the allowable deflection by the compression formula, the spring will not return to its original free height. In other words, it will have taken a set. If the difference in heights is less than that of the compression formula, it cannot be assumed that there will be a uniform stress throughout the spring when solid, as there would have been, had the spring been built to the highest free height possible, and the capacity will not then be in proportion to the deflection. If the deflection, for instance, is one-half of the formula deflection, the capacity will not necessarily be one-half that of the strongest coil, instead of equal to that of the strongest coil. This type then appears indeterminable for capacity, the difficulty being to so pitch the coils as to assure uniform stress when the spring is solid. This difficulty does not present itself in cylindrical coils as we have a uniform stress at solid height.

Uniform stress at solid height in a conical spring requires a pitch of coils in proportion to the deflection of same at maximum stress, or, which is the same thing, in proportion to the diameters of the various elements. As the diametrical increase per unit of bar length is not a straight line formula, the pitch of coils necessary to gain uniform stress when solid would have to follow the law of a definite curve. While it may be possible to develop a machine which will so pitch these elementary coils, yet the demand does not seem to have developed such a machine.

Where the deflection is made originally greater than the

maximum stress will allow, the first compressions of the hardened spring will reduce the deflection to the maximum which the steel will stand. Thus, in such a case there is an assurance of uniform stress.

The laws governing the action of grouped cylindrical helical springs apply likewise to grouped conical springs. Briefly, the design should maintain the same free and solid heights throughout, which means that for all coils in the group the $\frac{D_1}{d}$ ratio should be the same, and the $\frac{D_2}{d}$ ratio should likewise be the same for all coils.

THE CUTLER-HAMMER MFG. CO.'S STUDENT COURSE

The Cutler-Hammer Mfg. Co., Milwaukee, Wis., has a course for training engineering graduates which differs in some essentials from those offered by other companies. The course embraces from three to six months of shop work in the various departments, from two to six months of testing room work, with additional time not specifically determined by any hard or fast rules, in the engineering department in designing work. In all cases the student is given an opportunity to use his own initiative. An attractive feature, from the student's point of view, of this course is that he is paid a salary which enables him to support himself, and to thus raise his self-respect. He is paid $60 a month for the first six months; $75 a month for the second six months; and $90 a month at the end of the first year. Progress beyond that figure depends solely on each man's ability and energy.

The company expects to meet with a loss in the training of these students during the first year, but it is expected that during the second and third years there will be an opportunity for returns on the investment, it being hoped that the students will remain for that length of time, observing the implied obligation. It is interesting to note that the company considers a pleasant personality a qualification for entering this student course. A disagreeable personality, it is stated, diverts the attention of the fellow workers from business, and hence involves a distinct loss.

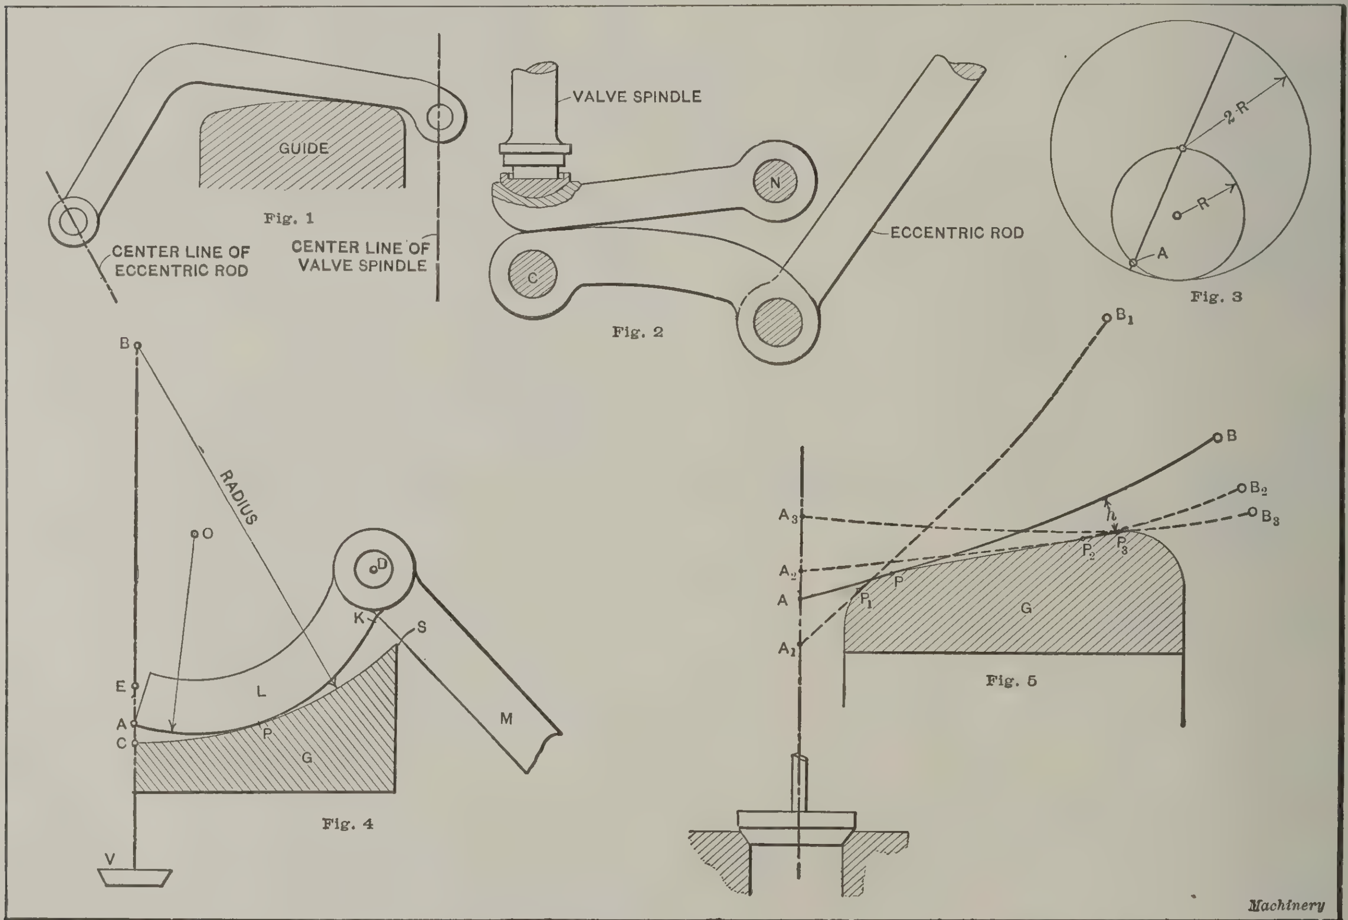
ROLLING LEVERS

By H. L. NACHMAN*

Rolling levers are commonly employed to actuate the valves of large gas engines as well as the poppet-type valves of steam engines, which are extensively used in Europe. These levers may be divided into two classes—the single-lever type shown in Fig. 1, and the double-lever type shown in Fig. 2. In the first case the lever rolls on a fixed guide, and has thus a continuously moving fulcrum, which travels from one end of the guide to the other. In the second case the levers are fulcrumed at fixed points, as at C and N, Fig. 2, and roll upon each other.

The levers should have a pure rolling motion in order to insure a minimum of wear. The valves should be opened quickly and should close with a constantly decreasing velocity, so as to seat quietly and without shock. It is not practicable to construct a mechanism that would fulfill these requirements with theoretical exactitude, but it may be of some interest to show how a simple pair of rolling levers that will approximately satisfy the requirements, may be designed. If a circle of radius R rolls inside of another circle, the radius of which is 2 R, as shown in Fig. 3, any point A in the small circle will travel along a straight line passing through the center of the large circle, as shown. In Fig. 4 the method of applying this principle to a valve motion is indicated. Here G is the fixed guide with a cylindrical surface of radius BC. The rolling lever L is actuated by a rod M. As the point of contact, P, travels from C to S, the point A will move from C to E along line CB. The valve stem is assumed to be attached at point A.

The example shown is a case of pure rolling motion. The point P is the instantaneous fulcrum of the rolling lever; therefore, the velocity of any point is proportional to its distance from this fulcrum. At the beginning of the motion the contact point is at C; hence the velocity of A is then zero. At the end of the motion the fulcrum is at S, and the velocity of A is to that of point D as AK is to DK. If M is actuated by an eccentric, as is usually the case, the valve will start to move slowly, its velocity being gradually increased to a maximum value, and will then again become zero at the end of the upward motion. The same action in reverse order takes place



Figs. 1 to 5. The Principles of Rolling Levers

* Address: 5309 Calumet Ave., Chicago, Ill.

on the downward stroke. The constructional difficulties of this mechanism, however, are such that it is not used in practice, and it must be modified to some extent. In its modified state, while there is not a pure rolling action, excellent results are nevertheless obtained.

In both the single and double lever type it is usual to make one of the two elements straight, and find the proper curve of the other element, to give the desired motion to the valve. In the single-lever type it is necessary to continue the guide to the center line of the valve spindle in order to start the valve at a velocity of zero. This would require the guide to be forked, which, however, is not generally done, and, therefore, the lever will strike the spindle at the moment that the valve opens with a perceptible shock. The velocity at the end of the stroke, however, may be kept quite low by a suitable form of lever.

In Fig. 5 let P be the point of contact of the lever and guide at the moment when the valve starts to open. The velocity ratio of the lifting point A to the driving point B (assuming pure rolling motion) is as AP to BP. It is evident that this ratio increases rapidly as the contact point travels toward the right. The rate at which the velocity increases depends on the radius of curvature of the lever, and therefore on the distance h between the guide and the lever. The larger this distance is, the more slowly will the valve open. It is customary to make h from 1/16 to 3/8 inch. Near B the radius of curvature should increase, thus reducing the velocity of the valve as it comes near to its top position. This decreases the stresses in the mechanism due to inertia. For pure rolling action, point A and contact point P should always be in one straight line perpendicular to the path of point A. The distance of point P from this perpendicular is a measure of the amount of sliding. To eliminate side pressure on the valve spindle, the center line of the eccentric rod and of the valve spindle, and the common normal to the curves at the contact point must all meet in a common point.

The two rolling levers in Fig. 2 are used for operating the exhaust valve of a large gas engine. The condition of pure rolling is that the point of contact must always lie on a line joining the two fixed centers C and N, at which the levers are fulcrumed. Generally one of the levers is simply made straight, while the other is made of such curvature as to give the desired motion to the valve.

SOME DISADVANTAGES OF SPECIALIZATION

In an address on "Comparison between Industrial Conditions in the United States and Europe," read by Mr. A. L. Valentine of Hartford, Conn., before the American Society of Swedish Engineers, the disadvantages that sometimes are incident to a too highly developed system of specialization, were referred to. With relation to the training and experience of the men in charge of shops and departments, Mr. Valentine said:

"The superintendents and foremen in America are usually experts in their respective lines, which is evidently an advantage, although at times this special knowledge and skill is gained only at the expense of a more general understanding of shop work and mechanical matters. If special skill is gained in such manner, it may prove a disadvantage. No matter how efficient a man may be in doing a certain line of operations, it is evident that his usefulness would be increased if his knowledge were not confined entirely to the kind of work he is doing. In this particular respect it may not be out of the way to mention that in Europe the apprenticeship system is very much more developed than here, and that a man can hardly ever expect to hold as responsible a position as that of shop foreman, for example, who has not served an apprenticeship, and thus gained a general knowledge of mechanical matters. In this country, on the other hand, it is not unusual that a man who has operated but one kind of machine or machines will eventually take charge of a department of such machines. However great an importance there may be attached to special training, the general training will always be of supreme value."

Haste may make waste in tool grinding as well as in tool using.

ACTUAL AND CONSTRUCTIVE PATENT INFRINGEMENT—2

By E. D. SEWALL*

The deductions made in the previous installment of this article are not, it appears to the writer, wholly in accord with a number of recent decisions of the circuit courts and circuit courts of appeal, about to be referred to. The original doctrine of contributory infringement which has already been briefly set forth, in a narrow sense imposes restrictions on the public beyond the terms of the patent claims, although in a broader sense it does not, but deems the contributor to join with another in infringing the complete combination claimed. The cases about to be referred to, however, hold as contributory infringers persons who have not conspired with another to make or use, without authority, the patented thing.

A Dangerous View of Contributory Infringement

The first of these cases, decided in 1896, is the celebrated Heaton-Peninsular Button Fastener Company *vs.* Eureka Specialty Company, 77 F. R., 288, reversing the circuit court. Complainant was the owner of a patent for a machine for fastening buttons by stapling them to a shoe. It sold machines, made in accordance with the patent, having attached thereto a plate on which were delineated the following words: "This machine is sold and purchased to use only with fasteners made by the Peninsular Novelty Co., to whom the title to said machine immediately reverts upon the violation of this contract of sale." The fasteners were ordinary unpatented and unpatentable staples, adapted to be fed from a magazine on the machine. They had to be of a size to fit the magazine and were not claimed as a part of the combination patented. Defendant sold such staples to one of the purchasers of a patented machine. No demand for the return of the machine was made thereafter. The court was satisfied that defendant had knowledge of the contract of sale and held him as a contributory infringer, on the theory that although the machine had been sold to the purchaser the use had been restricted, and defendant had conspired with the purchaser to violate the use, the right to impose restrictions upon the use being a portion of the patentee's monopoly.

Another similar case is Cortelyou *vs.* Johnson, 145 F. R., 932, reversing the circuit court. In this case the patentee of a copying machine known as the "rotary neostyle" sold the machines under a restriction requiring the paraffined paper and the ink used with the machine, both unpatented, and forming no part of the machine claimed, to be purchased from the makers of the patented machine. Defendant was proven to have sold ink to a purchaser of the machine. The circuit court held him as an infringer of the patent, but the circuit court of appeals reversed the court below on the ground that it was not affirmatively shown that defendant had knowledge of the conditions, and the U. S. Supreme Court affirmed the court of appeals.

The Court's Statement of the Conditions

The circuit court of appeals in this case stated its intention to follow the Heaton Peninsular case when the facts were the same, even though "as an original question" they might have ruled differently. The court then points out the embarrassments likely to follow the application of this decision:

"When confined to articles, whether patented or not, which are made for the express purpose of inducing infringement and are not intended for any legitimate use, the doctrine of contributory infringement is logical, just and salutory. But we doubt the wisdom of extending it to the ordinary commodities of life, used in connection with a patented machine, because the patentee sells or licenses the machine upon the condition that he alone is to furnish those commodities. Care should be taken that the courts in their efforts to protect rights of patentees do not invade the just rights of others engaged in legitimate occupations, by creating new monopolies not covered by patents and by placing unwarrantable restrictions upon trade. We think it is clear that the doctrine may be carried far enough to produce such results. For instance, should the patentee of a fountain pen, by such a notice as we have under consideration, be permitted to hold as an infringer one who sells ink to the owner of the pen even though he knows the restrictions? To compel the dealer to make

* Address: 2106 F St., N. W., Washington, D. C.

inquiries and take the precautions necessary to save himself from being sued as an infringer would place intolerable burdens upon business. . . . If the doctrine be driven to its ultimate conclusion, the merchant and the consumer may find themselves enmeshed in a network of monopolies embracing all the necessaries of life. No one may safely sell coffee to the consumer but the patentee of his coffee mill, no one can furnish him flour but the patentee of his baking pans, and he may yet be compelled to buy milk from the patentee of his milk can and soap from the patentee of his bath tub."

The Indefinite Meaning of the Law

This is a very forceful statement of the evils of the doctrine; but it alleges no definite legal ground whereby these evils may be checked, and leaves the question to be decided on a consideration of the mere degree of the restraint imposed, or the particular things with respect to which the restraint applies. If the restraint applies to the sale of soap and flour perhaps it may not be sustained; but if it applies to ink or wire perhaps it may be sustained.

In Dick *vs.* Milwaukee Specialty Co., 168 F. R., 930, defendant was held guilty of infringement for selling, with knowledge of a restriction, unpatented ink to be used with a patented copying machine known as a mimeograph. In Crown Cork & Seal Co. *vs.* Standard Brewery, and same *vs.* Greenberger, 174 F. R., 252, the Brewery Co. was held to be an infringer of a patented machine purchased by it under a restriction that only crown seals (not patented) made and sold by the patentee of the machine should be used with it, because it used seals made and sold by another. Here the court said defendant was liable "*even though he buys and pays for the machine and is vested with the legal title thereto*, and its use by him in violation of such restriction is an infringement of the patent." Greenberger, who furnished the crowns, was held guilty of contributory infringement. In Commercial Acetylene Co. *vs.* Autolux Co., already referred to, the defendant company was held for contributory infringement not only because it aided in reconstructing the patented package, but on the further ground that it had aided in violating a license agreement set forth on a plate secured to the receptacle.

These last cited cases, it will be seen, hold that under the patent laws, although one has bought a machine and paid the full price for it and obtained the legal title to it, he may not use it except in accordance with the wishes of the patentee, if any be expressed, and that the patentee may restrain trade in unpatented supplies used with a patented machine. There are many other cases to the same effect, all based on the decision rendered in 1896 in the case of Heaton-Peninsular Co. *vs.* Eureka Supply Co.

In view of the doctrine of the Heaton-Peninsular case, it has also been held that where a patented machine has been leased on condition that unpatented supplies therefor be purchased from the patentees, it is contributory infringement for a third party to furnish such supplies to the licensee with knowledge of the conditions of use. In Tubular Rivet Co. *vs.* O'Brien (93 F. R., 200), defendant was held liable under the patent laws for supplying to a licensee of a patented machine tubular rivets of a well-known kind in common use, because the license agreement required the licensee to purchase such rivets only from the licensor. Similarly, in Rupp, *et al.*, *vs.* Elliott, (131 F. R., 730), one who supplied ordinary wire to be used by a licensee in a patented machine was held to be an infringer.

The Right to Fix Resale Prices on Patented Articles

Another form of ultra-claim infringement, by judicial interpretation, consists in the resale, by a purchaser, of a patented device at a price less than that fixed by the patentee as the resale or retail price. This interpretation of the law is also ostensibly based upon the opinion in the Heaton-Peninsular case. In Victor Talking Machine Co. *vs.* The Fair (123 F. R., 424), one of the leading cases on this point, patented talking machines were sold to a department store subject to a condition appearing on a plate fixed on each machine that they should not be resold at a price less than $25. The department store offered them for sale at $18 each, and on appeal to the circuit court of appeals was held to be guilty of infringement of the patent and enjoined from making any further sales at cut prices. In Automatic Pencil Sharpener Co. *vs.* Goldsmith Bros. (190 F. R., 205), the rule was stated as follows: "The owner of a patent may sell the patented article under restrictions as to the price at which it shall be resold, and is entitled to an injunction to restrain a violation of such restrictions, by one having full knowledge of them, as an infringement of the patent."

In the case of Edison *vs.* Smith Mercantile Co. (188 F. R., 925), the facts, as appears from the decision, were substantially as follows: Patented talking machine records were made and sold by the patentee subject to a restriction on the price at which they were to be resold. The stock of Edison records in the store of an authorized dealer became damaged by fire. Some cartons containing the records were smoked, others blackened, and others more seriously injured. The stock was abandoned to an insurance company which took it over. The insurance company sold the stock to a salvage company and the latter sold the records in question in the case to the defendant who sold them at retail at less than the resale price fixed by the complainant, the patentee. Defendant was held to be an infringer of the patent for the record. The court remarked with reference to the language of the resale restriction imprinted on the records and the cartons containing them: "Whether the language in question effectively operates in this way after the article has once reached the ultimate user, and has been used, is a question not presented by this record, and which may not be in all material respects the same question as the present one."

There are other cases on the same point decided in the same way; but in the District of Columbia, in an application by the patentees of a medicine known as "sanatogen," for an order restraining a druggist from selling sanatogen at a cut price as an infringement of the patent, the order was denied by the Supreme Court of the District of Columbia without comment. (Bauer Chemical Co. *vs.* O'Donnell, August 4, 1911.)

Review of the Present Conditions

The class of cases of which Dick *vs.* Milwaukee Specialty Co. is a representative, holds that the patent law may be used to restrain trade in unpatented materials to be used with a patented machine which has been sold by the patentee, and legal title to which has passed from the patentee. This ruling nullifies with respect to patented articles the general rule of common law that the owner of a chattel is entitled to the free and innocent use thereof, and appears to nullify the common law, and the state and federal statutes against contracts in restraint of trade, which are, in the language of Mr. Justice Holmes, "contracts with a stranger to the contractor's business (although in some cases carrying on a similar one) which wholly or partially restrict the freedom of the contractor in carrying on that business as he otherwise would." (Northern Securities Co. *vs.* U. S., 193 U. S., 197.)

The class of cases of which Rupp *et al.*, *vs.* Elliott is a representative, holds that the patent law may be invoked to restrain trade in unpatentable materials to be used with a patented machine which has been leased, and likewise appears to nullify to a like extent the laws against contracts in restraint of trade.

The class of cases of which Victor Talking Machine Co. *vs.* The Fair is an example, holds that the patent law may be used to prevent a purchaser and holder of the legal title to a patented article from selling it at a price lower than that dictated by the patentee, thus nullifying to that extent the general rule of law against restrictions on alienation. "If a man be possessed of a horse or any other chattel, real or personal, and give his whole interest or property therein, upon condition that the donee or vendee shall not alien the same, the same is void, because his whole interest and property is out of him, so as he hath no possibility of reverter, and it is against trade and traffic and bargaining and contracting between man and man." (Hughes, J., quoting from Coke on Littleton in Dr. Miles Medical Co. *vs.* Park & Sons, 220 U. S., 373.)

In the case of Dr. Miles Medical Co. *vs.* Park & Sons, the U. S. Supreme Court held that such a contract with respect to an unpatented proprietary medicine was a contract in restraint of trade, and void so far as it affected interstate commerce. The same court has held that a like contract with respect to the price at which copyrighted books should be re-

sold, is not sustainable as a right conferred by copyright, saying: "To add to the right of exclusive sale the authority to control all future retail sales by a notice that such sales must be made at a fixed sum, would give a right not included in the terms of the statute, and, in our view, extend its operation by construction beyond its meaning." (Bobbs-Merrill Co. *vs.* Strauss, 210 U. S., 339, Day, J.)

In all three classes of cases above, the injury to the patentee was breach of contract, a wrong which the state courts and general law and equity are capable of dealing with, and was not an infraction of a patentee's right to exclude others from making, using or selling the invention, and there was no need therefore to resort to the patent law, and no remedy in the patent law appropriate to the wrong.

What Can be Done to Change the Present Situation?

Ordinary citizens, unlearned in the law, and accustomed to believe that the people, in consenting to the grant of a patent, have consented only to refrain from making, using and selling without permission from the patentee that which is defined in the claims of the patent, evince surprise and resentment when they learn that they may also be restrained by the law from making, using and dealing in ordinary unpatented articles of commerce; from deriving the protection of the general laws against restraint of trade when patented articles are involved; from selling at any price they see fit patented articles that they have bought. They begin to ask themselves whether they are not paying too high a price for the benefits derivable from public encouragement of invention. The people forced the annulment of the registration law of 1793 because of the abuses that grew up under it, and the enactment of the present law in its place in 1836. Since that time industrial conditions have changed. Trusts and corporations established for the purpose of monopolizing trade and manufacture prevail everywhere, and if the patent laws are to be construed to aid restraints of trade beyond those which the people consented to submit to by the grant of patents, the people are likely to demand, finally, their amendment or abolition.

Action in Great Britain

Already the English people have declared their intolerance of any interpretation that shall enable a patentee to monopolize more than the patent grants, urged thereto by practices of American corporations upheld by American courts. The British patent act of 1907 thus declares:

"Sec. 38. (1). It shall not be lawful in any contract made after the passing of this Act in relation to the sale or lease, or license to work, any article or process protected by a patent, to insert a condition the effect of which will be

(*a*) to prohibit or restrict the purchaser, lessee, or licensee from using any article or class of articles, whether patented or not, or any patented process, supplied or owned by any person other than the seller, lessor, or licensor, or his nominee; or

(*b*) to require the purchaser, lessee, or licensee to acquire from the seller, lessor, or licensor, or his nominees, any article or class of articles not protected by the patent;

and any such condition shall be null and void, as being in restraint of trade and contrary to public policy."

Action in the United States

The people of the United States, by their representatives in Congress, are showing their dissatisfaction with ultra-claim restraints enforced under the cloak of patents, as appears from proceedings in the last session of Congress. On May 8, 1911, a concurrent resolution was submitted in Congress resolving: "That a joint committee of both Houses of Congress is hereby created . . . empowered and directed . . . to ascertain the methods of sale, leasing, disposing and control of patented articles in the United States; to ascertain whether patents are used or misused in the establishment of industrial trusts or monopolies; and to investigate all other matters material or pertinent to the purposes of this resolution, and to report their findings to Congress with recommendations as to any needful legislation to protect the public interest and to promote the general welfare."

Among other bills to amend the patent laws introduced in Congress is Senate Bill 2158, "To protect trade and commerce against unlawful restraints and monopolies," providing (Section 8) "that every person engaged in any business, any portion or all of which constitutes a violation of tnis Act, shall forfeit by reason of such violation any and all rights which such person may have to protection under or right to damages for infringement upon any patent right held or owned by such persons, whether directly from the United States or under purchase, assignment or otherwise; and the right to the free manufacture and use of any and all articles, devices, or machines so held under right of patent by the person who shall have violated any of the provisions of this Act, shall thenceforth be open to all."

House Bill 2930 provides "that whenever any letters patent issued by the United States, or any article, commodity, compound, device, mechanical appliance, or machine protected by patent . . . is owned, leased, used, or controlled by any individual, firm, association, syndicate, corporation, or combination which is engaged in any vocation, business, or enterprise in violation of any law of Congress or of any state, prohibiting, restraining or regulating trusts, monopolies, or combinations in restraint of trade, the right to any protection under the patent laws of the United States shall cease and terminate."

House Bill 8661 reads as follows: "That no owner, proprietor, or beneficiary of any letters patent of the United States covering any tool, implement, appliance, or machinery shall, directly or indirectly, by any means or device whatsoever, make it a condition or provision, expressed or implied, of any sale or lease of, or license to use, any such tool, implement, appliance, or machinery, that the purchaser, lessee, or licensee thereof shall not buy, lease, or use, whether in connection with the operation or use of such tool, implement, appliance, or machinery, or otherwise, machinery, tools, implements, appliances, material, or merchandise of any person, firm, corporation, or association, other than such vendor, lessor, or licensor; nor shall any such owner, proprietor, or beneficiary of any such letters patent, directly or indirectly, by any means or device whatsoever, revoke any such sale, lease, or license made by any such owner, proprietor, or beneficiary, on account of the purchase, lease, or use by any such purchaser, lessee, or licensee, of machinery, tools, implements, appliances, material, or merchandise of any person firm, corporation, or association, other than such vendor, lessor, or licensor: Provided, that nothing in this Act shall be construed to prohibit the appointment of agents or sole agents to sell or lease machinery, tools, implements, or appliances.

"Sec. 2. That any such owner, proprietor, or beneficiary of any such letters patent who shall violate the provisions of this Act, and any other person, whether or not an agent of such owner, proprietor, or beneficiary, who shall wilfully assist in, or become a party to, any such violation, shall be punished for each offense by a fine not exceeding five thousand dollars."

Conclusion

Those who attain to power from the exercise of special privileges are very apt to reach for more. Corporations that have become wealthy through the monopoly of patents have grasped for further monopolies of things not protected by patents, and of things which though patented have been sold, returned their profits, and passed without the monopoly. And in this they have been sustained by U. S. courts, but not yet by the Supreme Court.

If the patent statutes do accord this ultra-claim privilege to a patentee, it is apparent that the people are going to change the statutes. Whether they do accord this privilege or not cannot be deemed settled until the Supreme Court shall have passed upon it. "A question arising in regard to the construction of a statute of the United States concerning patents for inventions cannot be regarded as judicially settled when it has not been so settled by the highest judicial authority which can pass upon the question." (Andrews *vs.* Hovey, 124 U. S., 694, Blatchford, J.)

The question may therefore be regarded as still open to discussion. If the patent statutes do not sustain the patentee's right to put a restraining hand on trade beyond the right to exclude others from making, using and selling the thing claimed in his patent, it would be inadvisable to complicate the statutes by the addition of declaratory sections, and by the possible imposition of drastic qualifications out of sympathy with the spirit of patent law.

A good law by inaccuracy or laxity of administration and interpretation may prove as injurious to the community as a bad law accurately applied. If some things that are done and permitted in the name of patent law are warranted by it, the law ought to be amended, or perhaps even abolished. But if such things are unwarranted by it, the remedy lies in more accurate administration and more careful application. The writer thinks the United States patent law, accurately applied, is, as it was expected to be by its framers, promotive of public welfare. Possibly it may be advantageously amended in minor particulars, but as a body of statutes it is believed to have no superior in its particular field. It would be unfortunate if the greed of those who have been granted special privileges by the patent law, in grasping for further privileges under the cloak of that law, should arouse such resentment in the people as to force hasty and drastic legislation where none is needed. The warning words of Professor Robinson are worthy of heed by all friends of the patent privilege: "Continued concessions to the patentee are as unjust, and ultimately as disastrous, as continued restrictions of his powers; for they constantly give rise to new grounds of litigation and are sure to produce, at some time, a reaction in public sentiment under whose impulse the entire system of exclusive privileges may disappear." (Robinson on Patents, Vol. 1, section 23.)

* * *

An automobile fire engine in Newark, N. J., was recently disabled when responding to a fire call by a fireman's coat, that had carelessly been thrown over a rear wheel becoming jammed between the driving chain and sprocket. The chain was broken and other damage done that put the machine out of use for several days. The accident is but another illustration of the folly of building motor trucks with unprotected chains and sprockets.

DIAGRAM FOR FINDING HORSEPOWER TRANSMITTED BY WORM-GEARING

By F. A. G.

A great many manufacturers of worm-gear drives in Europe build and guarantee drives for a given horsepower at a given speed. The accompanying diagram is one which has been used to determine the necessary factors in this connection in the designing-room of a large gear factory. The diagram makes it very simple to find the pitch of the gearing, if the speed of the worm and the horsepower are given. The most important rule for worm drives is to keep the diameter of the worm as small as possible. The diagram, therefore, gives for each pitch and each horsepower and speed the largest allowable pitch diameter of the worm. Under no circumstances is it advisable to make the pitch diameter of the worm larger than allowed by the diagram, as the gearing may then run hot and start to cut. On the other hand, there is no objection to making the pitch diameter smaller. The larger the lead of the worm the greater is the efficiency. In order to obtain the best results, double or triple threads should be used for the worm.

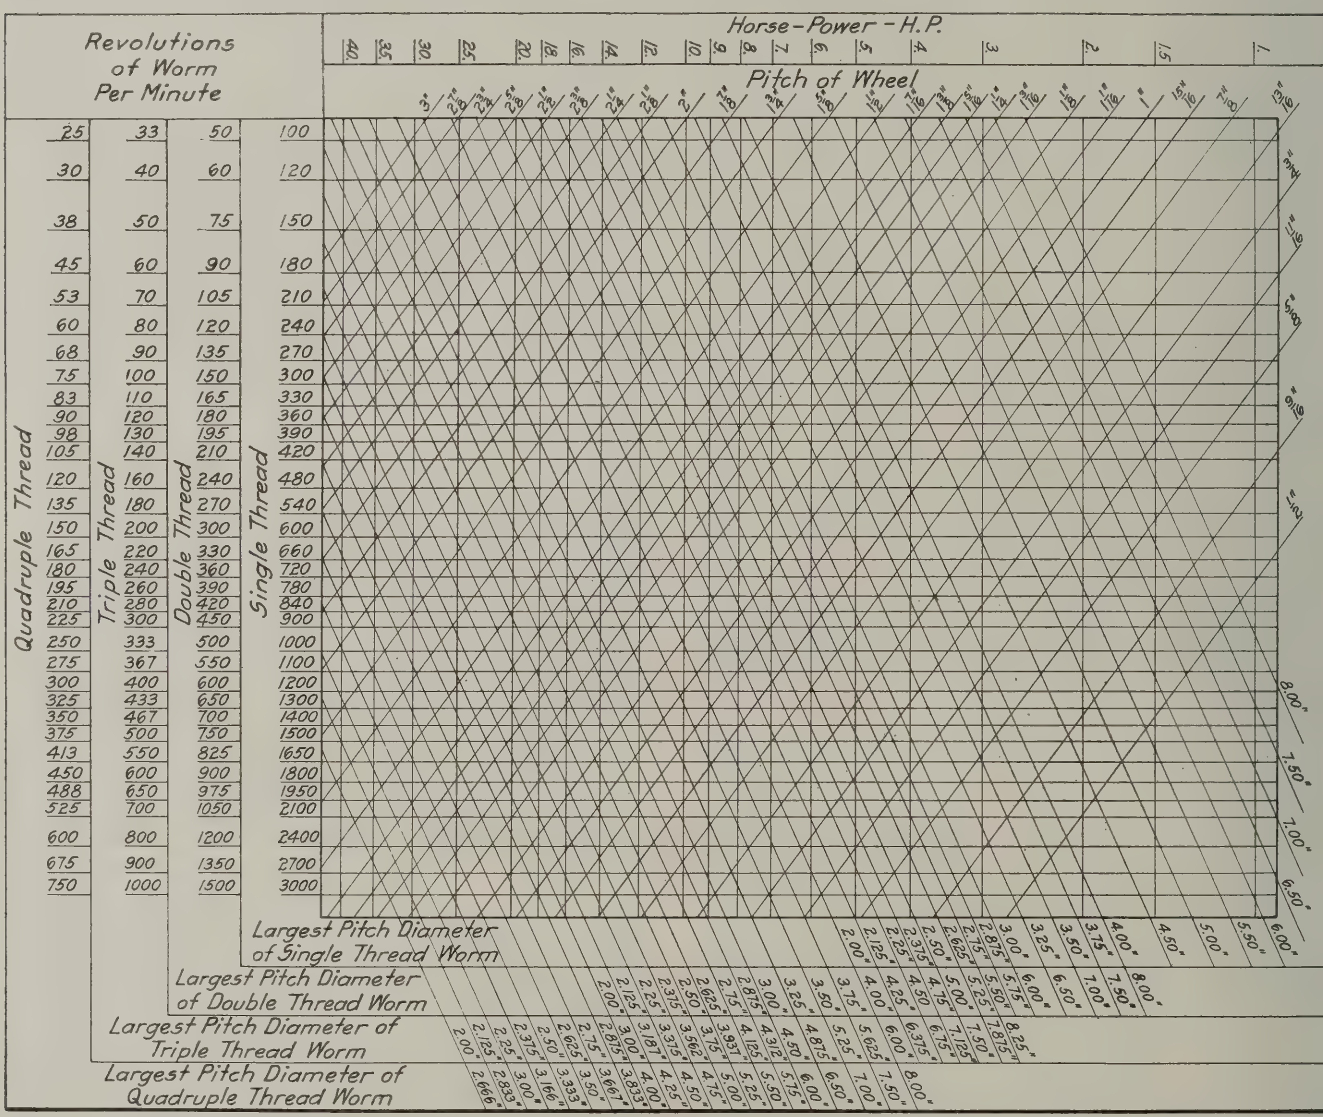

Fig. 1. Diagram of Relation between Horsepower, Pitch and Revolutions per Minute of Worm Gearing; Gear, Phosphor-bronze; Worm, Hardened Steel

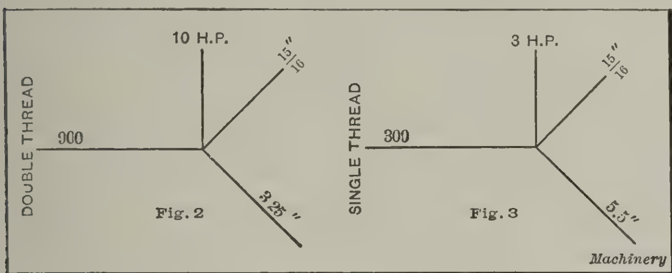
For cast-iron worm-wheels and worms with unfinished teeth, the pitch should be 1.33 times greater than that obtained from the diagram, as this is prepared for worm drives with cut teeth, made from any suitable materials. In the case of unfinished teeth, the pitch diameter of the worm should be only 0.8 times that given in the diagram.

The best material for worm gearing is hard phosphor-bronze

* The following articles on this and kindred subjects have previously been published in MACHINERY: "Table for Calculating the Outside Diameter of Worm-wheels," April, 1911; "Allowable Load, and Efficiency of Worm Gearing," September, 1910, engineering edition. See also the previously published information referred to in connection with the last-mentioned article.

for the worm-wheel and hardened steel for the worm. The next best materials are cast iron for the worm-wheel and hardened steel or cast iron for the worm. Steel or steel castings for both the worm-wheel and worm are only allowable for slow speeds. The teeth in the worm-wheel and the thread on the worm should always be cut, whenever the gearing is to be used steadily or at a reasonably high speed.

As an example of the use of the diagram, assume that an electric motor making 900 R.P.M. is to transmit 10 horsepower by means of worm gearing, the ratio of which is to be 1 to 30. By entering the diagram as indicated in Fig. 2, we find that for single thread, the pitch should be about 1⅛ inch. This would make the pitch diameter too small, and therefore the use of a double thread is necessary. In that case



Figs. 2 and 3. Diagrams indicating Use of Diagram in Fig. 1

the pitch will be about 15/16 inch, and the maximum pitch diameter of the worm somewhere about 3¼ inches. These factors having been found, the diameter of the worm-wheel, the center distance, and other necessary dimensions are determined as usual.

A lathe requiring 3 horsepower is to be driven through a cast-iron worm-wheel. The worm makes 300 R.P.M., and the speed ratio is to be 1 to 90. By entering the diagram as indicated in Fig. 3, we find that a pitch of 15/16 inch would be satisfactory for a phosphor-bronze worm-wheel, but for a cast-iron worm-wheel the pitch should be 1.33 times larger or equal to about 1¼ inch. The pitch diameter of the worm-wheel is found in the usual manner, the worm being assumed to have a single thread.

* * *

The American Society of Automobile Engineers has undertaken the standardization of motor trucks. At a recent meeting of a committee of the society it was decided tentatively that a motor truck should be capable of rendering normal or continuous service under its tonnage rating, and should have an overload capacity, for temporary or emergency service, of 25 per cent above its normal capacity. It was recommended that the desirable speed of trucks of various capacities should be as follows:

For 1-ton trucks	15 miles per hour
For 2-ton trucks	12 miles per hour
For 3-ton trucks	10 miles per hour
For 4-ton trucks	9 miles per hour
For 5-ton trucks	8 miles per hour

It is reported by Consul-General John E. Jones, of Winnipeg, Manitoba, that an industrial exhibition will be held this year in Winnipeg which will be the largest and most important ever held in Western Canada. The exhibition will be opened on July 10. The secretary and treasurer of the exhibition is Dr. A. W. Bell, Chamber of Commerce, Winnipeg.

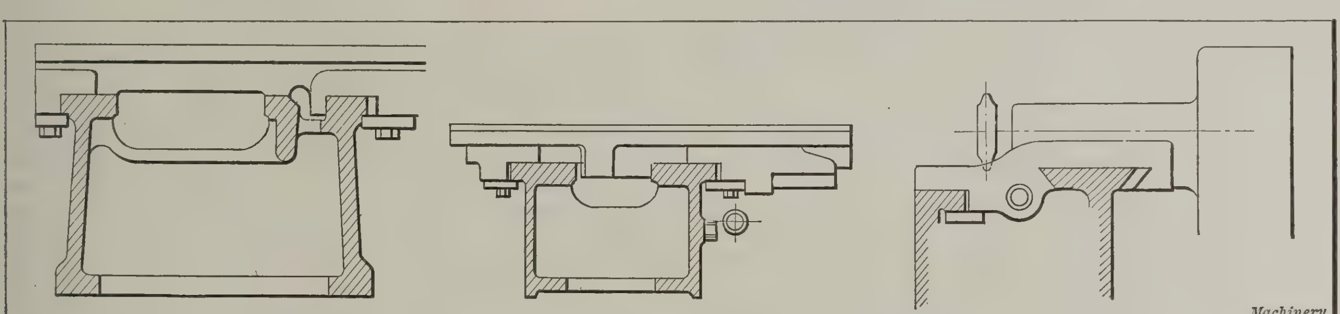
THE ADVANTAGE OF THE "NARROW GUIDE"*

By H. T. MILLAR†

The analytical faculty is very necessary in designing, for although it is the constructive ability which is brought into play when planning a structure or mechanism, this latter should also be analyzed for agreement with mechanical laws. It seems unfortunate that there is not more of critical analysis published in the technical press, since the contributors often have special facilities for it. These remarks are especially prompted by the article by Mr. J. G. Horner on "The Forms of Lathe Beds" in the February number of MACHINERY. In discussing the "narrow guide" lathe bed, Mr. Horner states that in the last five or six years it has effected a revolution in lathe construction. There is no analysis, however, of the claims made for it, and it is, therefore, the purpose of the writer to analyze the conditions of guiding surfaces, and the narrow guide in particular.

The question of the advantage of the narrow guide does not enter a great deal into American lathe design. If there has been any tendency to alter American designs, it has been away from the principles of the narrow guide, since the inverted V is perhaps the most highly developed instance of the principle, and the tendency has been to increase its included angle on account of the vertical pressure. The question arises, however, in American designs of other machines.

The accompanying illustrations Figs. 1 and 2 are taken from Mr. Horner's article and illustrate lathe carriages made by J. Lang & Sons, Johnstone, and J. Stirk & Sons, Halifax, respectively. Fig. 3 shows an example of American practice as embodied in a Brown & Sharpe gear cutting machine. Referring to Figs. 1 and 2, Mr. Horner says: "It is possible with these designs to obtain a length of guide of as much as ten times the width between the guiding surfaces, which has the effect of producing a steady motion with a greater amount of freedom from twisting than is the case when the saddle fits on the front and rear outer edges of the shears."



Figs. 1 to 3. Different Designs embodying the Narrow Guide

In other words, according to this, the amount of cross-wind is a function of the ratio of the length of a slide to its width, and hence the narrower a slide is made in proportion to its length, the less would be the cross-wind for a given amount of clearance between the strip and the slide. This is accepted almost as an axiom by many machine-tool designers. It can easily be shown, however, that this is not so, and that for a given length of slide and a certain clearance between the strip and the slide, the amount of cross-wind is unaffected by the width between the guiding surfaces. This was shown by a contributor in the April number of MACHINERY, and, in order to make the present analysis of conditions complete, it will be briefly reviewed here. Fig. 4 illustrates in diagrammatic form two slides superimposed. They are similar in every respect, except that one has a narrow guide and the other fits on the front and rear edges of the shears. Let w be the width of the narrow guide and W the width of the ordinary guide; let K be the clearance between the slide and the strip, and ϕ and ϕ_1 be the respective angles of cross-wind, which in this case may be regarded as infinitesimal. Then triangle ACE is similar to triangle APO; hence AE is proportional to

* See MACHINERY, April, 1912, "Narrow vs. Wide Guides for Machine Tools," and January, 1912, "The Introduction of the Narrow Guide on Machine Tools."

† Address: 150 Waterloo Road, Manchester, England.

OA, and triangle $A_1C_1E_1$ is similar to triangle A_1PO; hence A_1E_1 is proportional to OA_1.

The angle of cross-wind for width W (in radians) $= \dfrac{AE}{OA}$

and for width $w = \dfrac{A_1E_1}{OA_1}$.

Therefore, for a given length of slide and clearance K the amount of cross-wind is independent of the widths W and w.

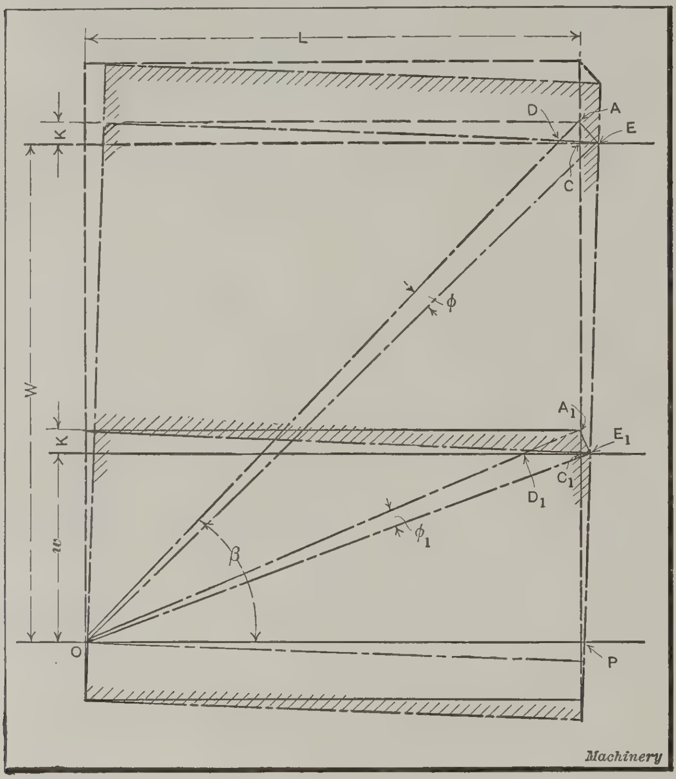


Fig. 4. Analysis of Cross-winding Action

The fact that the angle of cross-wind is a function of the strip clearance K and the length of the slide does not seem to have suggested itself to most writers on the narrow guide, but it will be easily seen that this is so.

The backlash or clearance K is equal to AC. Then,

$$AE = \frac{AC}{\cos\beta};\quad OA = \frac{OP}{\cos\beta}.$$

$$\text{Cross-wind} = \frac{AE}{OA} = \frac{AC}{OP} = \frac{\text{clearance}}{\text{length of slide}}$$

From this it is apparent that the narrowing of the width between the guiding surfaces does not directly affect the angle of cross-wind. When a generally held reason for an accepted practice is disposed of by mathematical considerations, it is wise to look around for another reason. It is not safe to dismiss a point too quickly which has been accepted and in practice for a considerable time. In this case, the narrowing of the distance between the guiding faces may have advantages, although it does not affect the angle of cross-wind. One advantage is that the chance of closing in the bed by setting up the strip too tightly is avoided. This, however, is probably not a very important point. Mr. Horner, elsewhere in his article, suggests what appears to the writer to be the chief advantage of the narrow guide. He says: "In conjunction with this, it is also the practice to bring the lead-screw as close as is practicable to the guide ways, and the twisting tendency and friction caused by the old-style construction is minimized. Thus the force is applied at the correct place near the guide ways."

It is in the resultant improvement in the relative positions of the feeding force, the resistance, and the guides, that the advantage of the narrow guide lies. In the case of the lathe, the narrow guide in front is near to the resistance due to the cut and the feeding force of the rack or lead-screw. If we take a general case of a slide moved forward by a force eccentric to the guides, and neglect for the moment any resistance due to the cut and friction on the top of the bed, we shall see that there is a limiting case for the proportion which the eccentricity of the force bears to the length of the guides. In Fig. 5 is a diagrammatic view of the slide, where T is the propelling force with the eccentricity r; P is the resultant pressure on the guides. Let μ be the coefficient of friction; then $T \times r = P \times L$, or $T = \dfrac{P \times L}{r}$. The resistance to motion (excepting the cut, friction on top of bed, etc.) equals $2\mu P$, and is assumed to act midway between the guides. Hence,

$$2\,\mu\,P = T = \frac{P \times L}{r},\ \text{and}\ \frac{L}{r} = 2\,\mu$$

Hence, if the ratio of the length of a slide to the eccentricity of the propelling force is not at least as great as the ratio of 2μ to unity, it is impossible to move the slide. Since the coefficient of friction is not likely in this case to exceed 0.1, and will probably be less, the limiting case for movement under these conditions would be when $L = 1/5r$, or, in other words, when the eccentricity of the feeding force is five times the length of the slide. The conditions in practice, of course, never reach this minimum.

In practice, however, the case is complicated by the addition of other resistances—resistance due to the cut, the friction on the top of the bed, and the sliding friction of the shaft bearings. Since the shaft generally revolves, this latter friction is very small. The effect of the friction on the top surface of the bed varies a great deal in different cases. The resist-

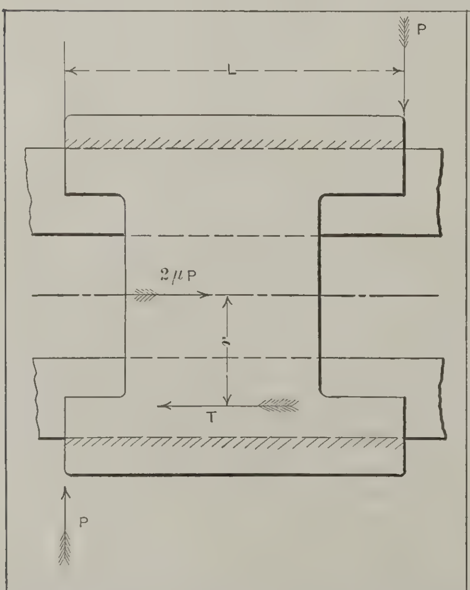

Fig. 5. Analysis of Frictional Resistance and Leverage

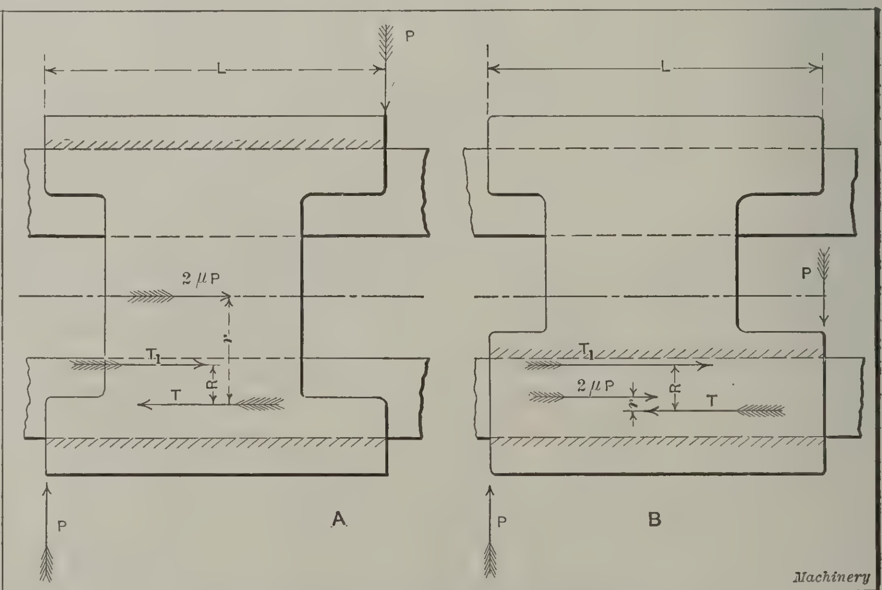

Fig. 6. Comparison between Wide and Narrow Guide

ance due to the cut is the greatest, and in the case of lathes varies in position, and consequently the moment varies. The conditions which obtain due to the cutting resistance are illustrated in Fig. 6, where, at A, is shown the ordinary construction with a wide space between the guide surfaces, and at B the conditions obtaining in a lathe with narrow guide. Let T_1 be the resistance due to the cut; T, the feeding force, and P the pressure on the guide as before. We see then that $2\mu P + T_1$ must not exceed T if movement is to take place.

$$PL = Tr - T_1(r - R) = Tr - T_1r + T_1R \qquad (1)$$

$$2\mu P = T - T_1 \qquad (2)$$

From (1) we get

$$T - T_1 = \frac{PL - T_1R}{r}$$

$$2\mu P = \frac{PL - T_1R}{r}$$

$$2\mu = \frac{L}{r} - \frac{T_1R}{Pr}, \text{ or } \frac{L}{r} = 2\mu + \frac{T_1R}{Pr}$$

In the limiting case, then, the minimum proportion for the length of the slide to the eccentricity of the feeding force is, of course, greater by the amount $\frac{T_1R}{Pr}$, than in the former case.

We can now see the reasons for the advantages of the narrow guide. The frictional resistance of the guiding surfaces may be assumed to act midway between them. If the position of the guide is such that this resistance has a small moment the conditions are improved. Comparison of the conditions in A and B, Fig. 6, illustrates the advantage of the narrow guide. It is evident that if the direction of the feeding force and the direction of other resistances were in the same straight line, the width between the guiding surfaces would be immaterial; in fact, no guides would be necessary. This is, of course, a condition impossible to attain in practice.

Conclusions

In conclusion it may be stated:

1.—That the width between the guiding surfaces does not affect the angle of cross-wind, but that this is a function of the length of the slide and the clearance between the strip and the bed.

2.—That the narrow guide has advantages, but that these advantages are dependent mainly upon its correct location: It must be placed close to the resistance and the feeding force; a narrow guide strip at the back of the carriage would probably be more detrimental than the ordinary wide guide. For the same reason, in American tool construction only one V and one flat way are used. The V must be nearer to the feeding force and the resistance.

3.—That when the narrow guide is placed near to the feeding force, its advantage lies in the reduction of the moment of the frictional resistance and the required feeding force.

4.—That some advantage is derived from the better mechanical construction possible with the narrow guide, since the guiding surfaces cannot be closed in, and most makers fit a taper strip in place of the common angle-strip set up with the points of screws acting against it.

* * *

On March 7, Henri Selmet, a Frenchman, flew in an aeroplane from London to Paris, a distance of 222 miles, in 2 hours and 57 minutes, without alighting anywhere on the way. This is the most remarkable record ever made in fast flying, the average speed for three consecutive hours being 75 miles an hour. The flight was made in a storm accompanied by very high wind, and most of the time in a drenching rain. While this weather, of course, increased the dangers of the flight, the speed made could probably not have been accomplished if it had not been that the aviator was riding on a favoring gale, the same as do birds of migration. Even if the aeroplane should become actually useful in the future as a means of transportation under certain conditions, it is very likely that it will be necessary to make a close study of wind conditions, and to arrange flights so as to take advantage of favorable air currents.

* * *

It should no longer be a question of whether or not you need or desire safeguards around machinery. The only question for debate now is, which kind.—*The Wood-Worker.*

DETERMINATION OF HELIX ANGLES*†

By GEORGE W. BURLEY‡

When calculating the angles of helices or spirals (as they are usually, though wrongly, called) for setting the tables of universal milling machines, the heads of twist-drill flute milling machines, etc., it is necessary to employ the formula:

$$\tan \alpha = \frac{\pi D}{L}$$

in which

α = the helix or spiral angle required,
D = the diameter of the work,
L = the lead of the helix or spiral.

Having calculated the value of $\pi D \div L$ for any particular case, the next step in the process is the consultation of a table of natural tangents for the determination of the value of α from tan α. To do away with calculations and consultation of a trigonometrical table, the table in the accompanying Data Sheet Supplement has been prepared, this table giving the values of the helix or spiral angles for a large number of values of the ratio of L to D. For the determination of the helix or spiral angle for any value of $L \div D$ not included in the table, the "simple proportion" method will give a result sufficiently exact, owing to the slight differences between consecutive helix-angle values in the table.

As an illustration, let us suppose that we wish to determine the value of the helix or spiral angle for a case when $L \div D = 3.75$. Consulting the accompanying table we find that when $L \div D = 3.70$, $\alpha = 40$ deg. 21 min., and when $L \div D = 3.80$, $\alpha = 39$ deg. 35 min. Therefore, when

$$\frac{L}{D} = 3.75,\ \alpha = \frac{40^\circ\, 21' + 39^\circ\, 35'}{2} = 39^\circ\, 58'.$$

This is the same value that would be obtained if the formula above were used, there being no difference between the exact value and the approximately calculated value of the angle. This is a very close result, but in no case is the difference between the two values greater than 7 minutes, and this only where the angle is in the neighborhood of 90 degrees, so that the percentage of error is very slight, and, therefore, negligible.

PROPOSED INSTITUTION OF MACHINE TOOL ENGINEERS

A society, known as the Institution of Machine Tool Engineers, is proposed by the *Practical Engineer*, London. This journal points out that the Institution of Mechanical Engineers in England is not giving the subject of machine tools a great deal of attention, and that, in many cases, not only the quantity but the quality of papers on machine tool design, presented before this society, has been rather unsatisfactory. In most cases, the only thing that has been done has been to discuss finished machines in a way similar to that in which a salesman discusses his own and his competitors' products. The designer's side of the subject of machine tool design has, in nearly all cases, been left severely alone. There is also need for standardization, which a society of machine tool designers would be able to accomplish in a more satisfactory manner than the larger societies. Some of the opinions stated by the *Practical Engineer* in drawing a picture of British conditions are true of conditions in this country. Our engineering societies have done little to gather and distribute information dealing with the design of machine tools, notwithstanding the fact that the machine tool industry is, so to speak, the basis of all machine building industries.

* * *

It is claimed that soap water used instead of ordinary water in mixing concrete makes it waterproof. A grain elevator, at times exposed to inundation, was built in Germany from reinforced concrete made with soap water, and this building was successful in withstanding the effect of the water, while another building of the same material, but having been made without soap water, failed to completely keep out the water.

THE USE OF ENGRAVING MACHINERY*

By C. H. COPPACK†

Having seen some articles in MACHINERY on special work done on the Gorton engraving machine, the writer thought that a description of the uses to which the machine made by Taylor, Taylor & Hobson, Ltd., of Leicester and London, can be put, would be of interest. This machine was originally made for engraving photographic mounts with the maker's name, which formerly had to be done by rolling before lacquering. With this machine, the work can be done after all surfaces are lacquered, as no burr is raised by the engraving process. The machine was so much in demand that it was re-designed after a few years, making it available for a wider range of work.

The principle of operation is that of the pantograph with sliding adjustments for varying the size of the letters or designs made from the copies. The copies must be at least three times the size of the work to be produced, and are in one plane only. The varying depths are obtained by a hand feed through a screw. The variety of work which has been done on this machine is very great. Letters may be cut varying in height from 0.002 inch to 3 inches. Twenty letters have been cut on the head of an ordinary brass pin in one line. The machine has also proved useful in making models. Enlarged copies of the parts are made on a drawing, say ten times the actual size, and then transparent celluloid about 0.020 inch thick is placed over the drawing and the outline scribed on this. The celluloid is then cut out, both a male and female model being thus obtained. This is especially useful when making press tools. Numerous punches and dies have been made on this type of machine. The dies and punches are left with about 0.005 inch of metal for hand finishing.

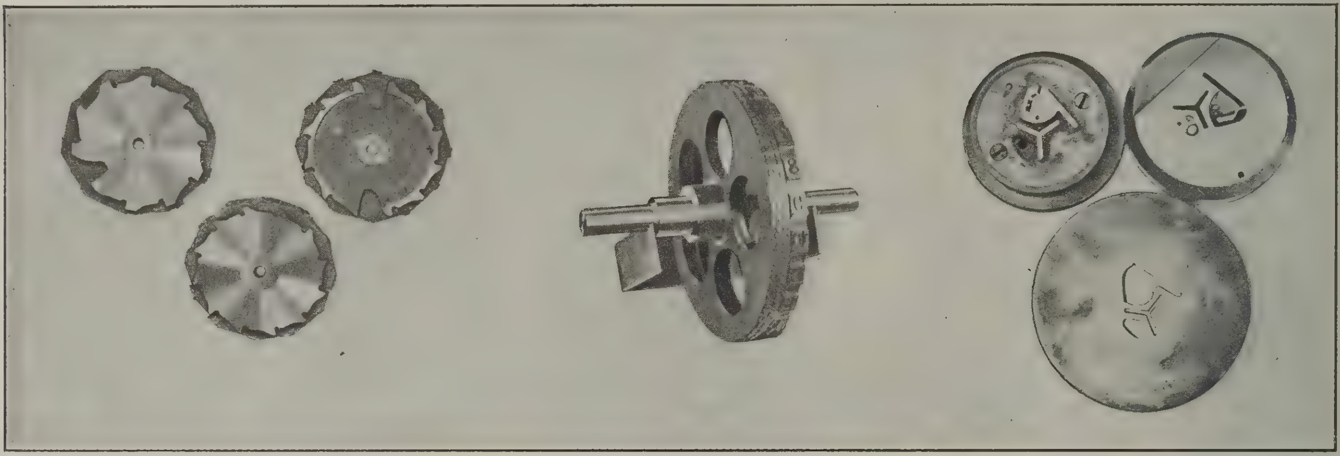

Fig. 1. Steel Wheels, with both Ratchet Teeth and Figures on Rim, cut in Engraving Machine Fig. 2. Time Recorder Wheels cut by Engraving Machine in Four and One-half Hours Fig. 3. Punch, Die and Stripper cut in Engraving Machine

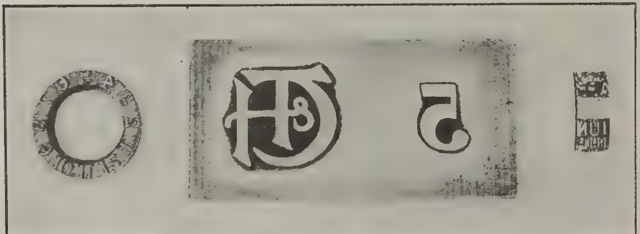

Fig. 4. Additional Examples of Work done in Engraving Machine

In instrument work, when about one hundred pieces are sometimes required, it would not pay to make press tools, especially if the piece were at all irregular. In this case the machine proves especially advantageous, as the pieces may be turned out at a cost of perhaps only one-half that of the press tools. One example of work done by this machine is that of the type wheels used in time recorders, where one wheel has twelve numbers and another sixty. Of course by means of die-casting processes, these wheels can be made cheaper in quantities, although the dies are expensive, but the metal of die-castings does not stand a great deal of wear; even brass types wear considerably in the course of time, and the best results are obtained with machine steel, casehardened. The cost of cutting the pair of wheels for the time recorder shown in Fig. 2 is about 84 cents, the time required being four and one-half hours, and the work being done by a girl.

Another interesting piece of work done on this machine is the cutting of sets of steel wheels as shown in Fig. 1, having ratchet teeth on the sides and figures on the rims. The ratchets are cut solid with the wheel. The ratchet spaces are recessed as indicated, so that a square-ended pawl can be used. The teeth are cut within a limit of 0.001 inch, and opposite teeth are tried across the center with a special gage. The figures are cut in exact relation to the ratchet teeth so that when a dozen of these wheels are put together, they will print a row of figures in a perfectly straight line. This would have been a very difficult matter to accomplish if the ratchet had been riveted to the rim, as it would then have been difficult to obtain the same accuracy.

In Fig. 3 is shown an example of punch and die work done on the engraving machine, the illustration showing a punch, die, and stripper. The punch is cut to a depth of 0.300 inch with a cutter of 0.050 inch diameter. The die is cut to a depth of 0.200 inch with the same cutter, leaving in each case 0.003 inch for finishing. Both punch and die are made of tool steel. The stripper is made of cast iron, 1/4 inch thick, and is finished complete on the engraving machine.

In Fig. 4 (center) is shown an embossing punch, cut 1/8 inch deep, the corners being finished with a cutter 0.005 inch in diameter. At the left in the same illustration is shown a small wheel with figures, which was cut in fourteen minutes in lots of two hundred.

* * *

A new industrial school, combining, it appears, certain features of the trade school and high school in one, has recently been opened in Vienna, Austria. The school is claimed to be the largest educational structure in the world, and practically all trades are taught. The building has a capacity for 5200 students, simultaneously instructed, and 337 separate study-rooms are provided, making the average number of pupils per room and teacher not more than between fifteen and sixteen. The building has five complete stories besides basement, and is built so as to entirely enclose a court yard. The total length of the building is about 425 feet, and the total width about 250 feet. In addition to the square building surrounding the court-yard, two buildings connect the long side wings, thereby forming three separate courts. Besides the study-rooms for the education in the trades, considerable space is set aside for gymnasiums, recreation rooms, a restaurant where the students can obtain meals at cost, etc.

* * *

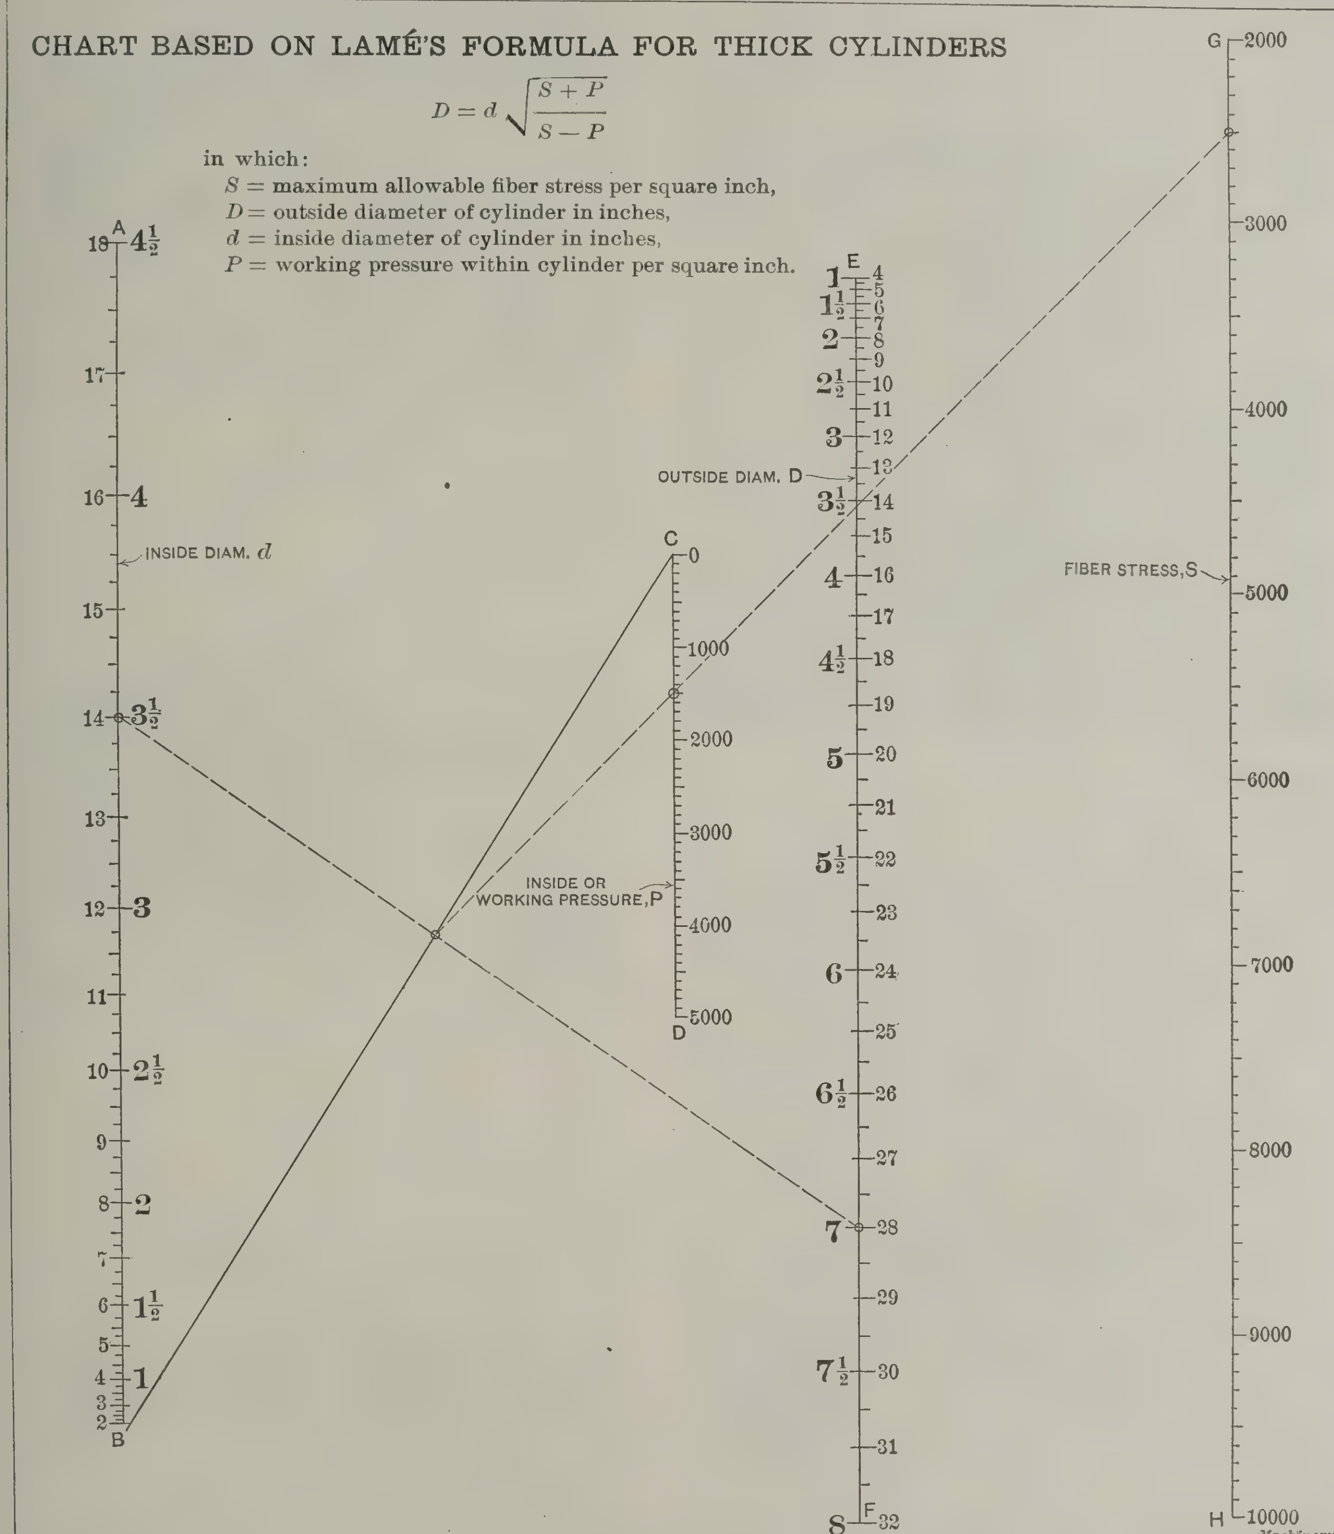
The famous 1400-H. P. Corliss engine which operated the machinery at the Philadelphia Centennial in 1876 and which subsequently was used to operate the plant of the Pullman Palace Car Co., in Chicago, was recently dismantled and sold for scrap iron.

CHART FOR THICK CYLINDERS*

By JOHN B. PEDDLE†

The accompanying chart for the rapid determination of the dimensions of thick cylinders is based on Lamé's well-known formula. This chart makes it possible to find the outside diameter of the cylinder very quickly when the fiber stress, the working pressure, and the inside diameter are known. Of course, the chart can also be used to find any other of the four quantities when three of them are known. The method of using the chart is as follows:

Locate the fiber stress on line *GH* and the working pressure within the cylinder on line *CD;* draw a line through the two points thus located, and extend this line until it intersects the auxiliary line or axis *BC;* through the point of intersection with this line draw a line which passes through the dimension for the inside diameter of the cylinder as found on scale *AB*, extending this line until it intersects scale *EF*. The point of intersection with line *EF* gives the required outside diameter. It will be seen that the scales *AB* and *EF* are provided with a double set of figures. When using these scales, the heavy-faced figures on *AB* should be used in connection with the heavy-faced figures on *EF*, the same rule being followed with regard to the light-faced figures.



An example of the use of the chart is indicated by the dotted lines. Assume that the allowable fiber stress per square inch is 2500 pounds. The working pressure within the cylinder is 1500 pounds per square inch, and the inside diameter is 14 inches. By following the directions given, we find that the outside diameter should be 28 inches; or, if the inside diameter were 3½ inches, as given by the heavy-faced figures, then the outside diameter would be 7 inches.

* See MACHINERY, July, 1909, engineering edition, "Thick Cylinders," and the articles there referred to. See also MACHINERY'S Reference Book No. 17, "Strength of Cylinders," and MACHINERY'S Data Sheet Book No. 17, page 35, "Ratio of Outside Radius to Inside Radius of Thick Cylinders."

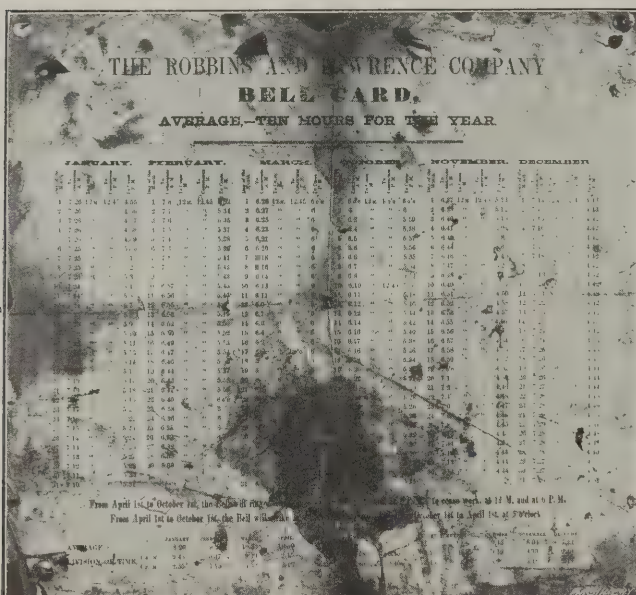
ANCIENT PISTOL AND SOME OLD TOOLS FROM A NEW ENGLAND SHOP

By F. R. HUMPHREY*

About 1850, one of the most progressive concerns in this country was the Robbins & Lawrence Co., of Windsor, Vt. This company had a good reputation and was well known everywhere, and a machinist who had served his apprenticeship there had no trouble in commanding the highest wages in any machine shop in the country. In many ways this company was far ahead of its competitors. An old gentleman who had served his apprenticeship in this shop claimed that the equipment of jigs and fixtures at that time was twenty years



THE ROBBINS AND LAWRENCE COMPANY

BELL CARD.

AVERAGE,—TEN HOURS FOR THE YEAR.

JANUARY. FEBRUARY. MARCH. OCTOBER. NOVEMBER. DECEMBER.

Fig. 1. A "Bell-card" of the Robb'ns & Lawrence Co., Windsor, Vt., in use about 1850

ahead of that of any firm manufacturing a similar line of work.

In Fig. 1 is shown a reproduction of the "bell card" which was used about 1850. The card from which the photograph was taken has apparently seen some hard usage; the dark stains covering it represent tobacco juice. This card gave the time when the factory bell—still in place on the old shop—would ring each day of the year. The time varied a few minutes each day, and was so arranged that the working hours of the shop averaged ten hours for the whole year, while at the same time the use of artificial light was avoided. During the month of December the average working time was only 7 hours and 54 minutes, while during the months of May, June, July and August, the men worked 11 hours a day.

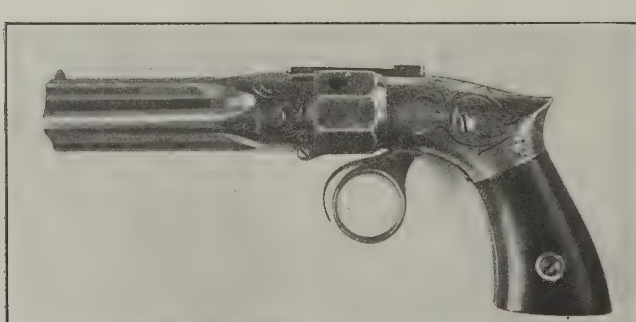


Fig. 2. An Old Pistol made by the Lawrence & Robbins Co., patented 1849

Fig. 2 illustrates a five-barreled "hammerless" revolver which was patented in 1849. This old weapon shows, in many of its details, indications of the skill of the mechanics working with the poor facilities of that time. The revolver is of 0.28 caliber. The forward part of the barrels, shown at *A* in Fig. 3, is rifled, and the rear part, shown at *B*, is chambered for the powder and ball. Percussion caps were used to cause the explosion of the powder. At *F* are shown the vents through which the gases and smoke from the caps escaped. At *C* is shown a part of the frame which is made from a steel casting, and evidently machined by the use of jigs and fixtures. The grips at *E* are made of fine selected black walnut. The chambers, the plate and the frame are ornamented with scroll design which was hand engraved.

The hammer shown at *A* in Fig. 4 struck each cap in succession. It was milled in such a manner that it would re-

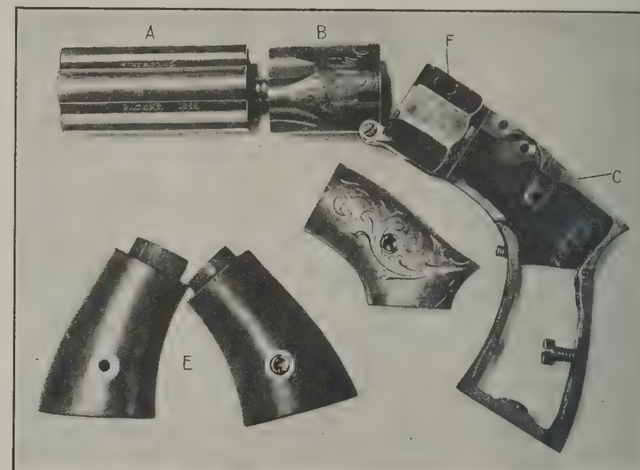

Fig. 3. Main Parts of Pistol in Fig. 2

volve one-fifth revolution while being drawn back or set, and it traveled straight ahead when released. It was milled with a combination of straight and spiral grooves, so as to be able to move in the manner indicated. The nut *H* fits on the hammer. The triggers, of which there are two, are shown at *B*. They are so arranged that by pulling back the ring *K* the hammer is set; then, by a slight pressure on the small trigger

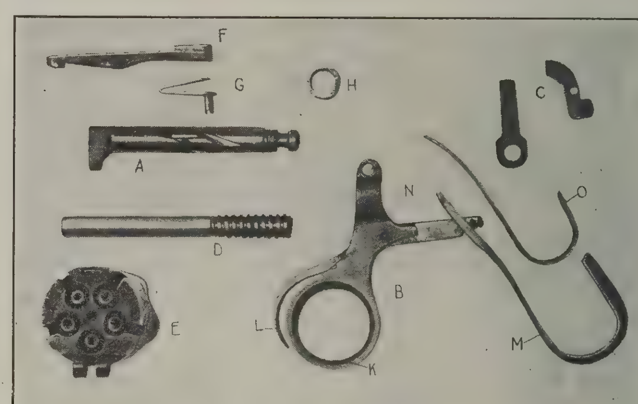

Fig. 4. Details of Pistol

L, the spring *M* is released, and the hammer is driven forward. The trip *N* is part of the trigger *L*. The button *C* is a release which acts the same as the trip *N*. The screw *D* serves to lock the barrel in place. Spring *O* returns the trigger after firing. At *E* is shown a rear view of the chambers. This view shows the nipples for the caps and the vents through which the gases escape. At the bottom is shown the

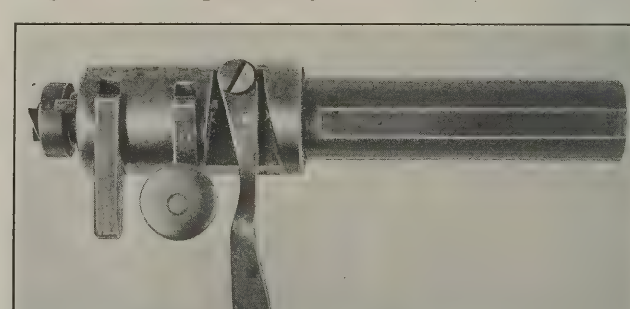

Fig. 5. An Old Hollow Mill and Threading Die with Holder

hinge. The latch *F* serves for a rear sight, and the spring at *G* holds the latch in place.

In Fig. 5 is shown a combination hollow mill and die. This unique tool was used on one of the early turret lathes. The details of the tool are shown in Fig. 6. The body *A* is made of soft steel in one piece; the hollow mill *H* is set into the

* Address: P. O. Box 585, Windsor, Vt.

spindle *B* and is threaded on the inside, thus forming the die. The lever *C* has a pin which engages in the slot *J* and thrusts spindle *B* forward in holder *A*. Parts *E* and *F* swivel on pin *D*. The thumb piece *E* travels in the cam slot *K* and forces the spindle forward; the lock *F* keeps the spindle from turning and catches in the notch *L*.

In Fig. 7 is shown a box-tool which was used on the same machine as the former tool; the details of this tool are shown in Fig. 8. The box *A* is machined from a forging; parts *B*, *C* and *D* are bushings which are used as back-rests; *C* and *D* are held in place by the nuts *E* and *F*. The tool is provided with two turning tools *G* and *H*, and a forming tool *K*. The tool *G* is held in place by clamp *J*, and the tools *H* and *K* are held by clamps *L* and *M*, and screws *O* and *P*. There are three screws *N* which are used for adjusting the tools relative to the center. These tools were used in the Windsor shops and happened to be left when the gun department was moved by the Winchester Arms Co. to New Haven, Conn.

A careless workman with a big monkey-wrench is expensive to have around where there are many small bolts or nuts to be tightened.

OCEAN LINERS WITH DIESEL ENGINES

It appears that the trials of the *Selandia*, a Diesel engine-driven liner, with a gross tonnage of 4900, marks a new departure in the driving of large ocean-going vessels. The East Asiatic Co., for which this vessel was built by Messrs. Burmeister & Wain, Copenhagen, Denmark, has three vessels of this type, and appears to be fully satisfied with their performance, as eight more motor-driven vessels have been ordered, two of 10,000 tons and six of 6000 tons capacity.

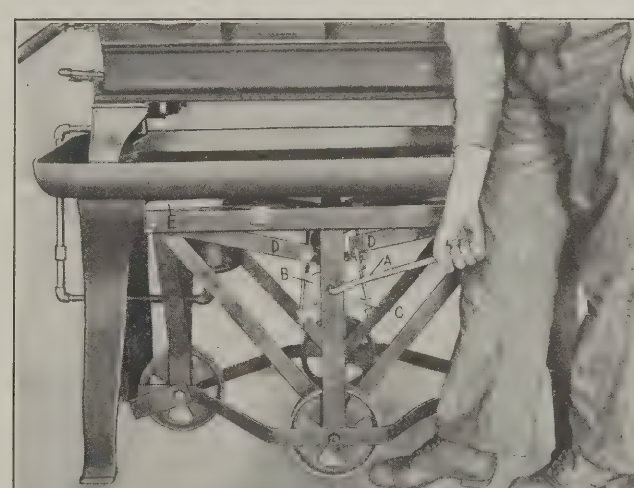
It is stated that, contrary to the expectations, there was a complete absence of vibration and noise during the trials of the vessel. In fact, even steamship engineers agreed that the machinery ran more quietly than steam-engines. The engines are under perfect control, as was proved during the trials, when the *Selandia* almost collided with another steamer, but was saved through the prompt reversing of her engines. Only fifteen to twenty seconds was necessary to change the direction of rotation from full-ahead to full-astern. On account of the absence of funnels, the vessel presents a peculiar appearance. The exhaust is led up through the hollow mizzen-mast, and the outlet is about 25 feet above the deck. The advantages gained in cargo-carrying capacity are considerable. The great bulk of the space usually given over to coal bunkers can be used for cargo. The main fuel tank of the vessel is provided for by her double bottom, which has a capacity for 900 tons of oil, sufficient to keep her main engines going during a voyage of twenty thousand miles under average condition.

The vessel is provided with twin-screws driven by two eight-cylinder engines, each developing 1250 brake horsepower (1500 indicated horsepower) at 140 R. P. M. The machinery cost about $50,000 more than steam engines, but it is expected to save some $40,000 a year by the use of the Diesel engines. This saving is accounted for partly by the saving on the fuel and partly by the fact that the vessel can carry 1000 tons of cargo more than a steam-driven vessel of the same capacity.

* * *

A HANDY TRUCK FOR MOVING MACHINES

The accompanying illustration shows a homemade truck, used in the shops of F. E. Wells & Son Co., Greenfield, Mass., that is extremely useful in moving or shifting the positions of partly erected machines. It is called the "back-saver" by the men, for it eliminates a great deal of lifting and pulling when moving a machine.



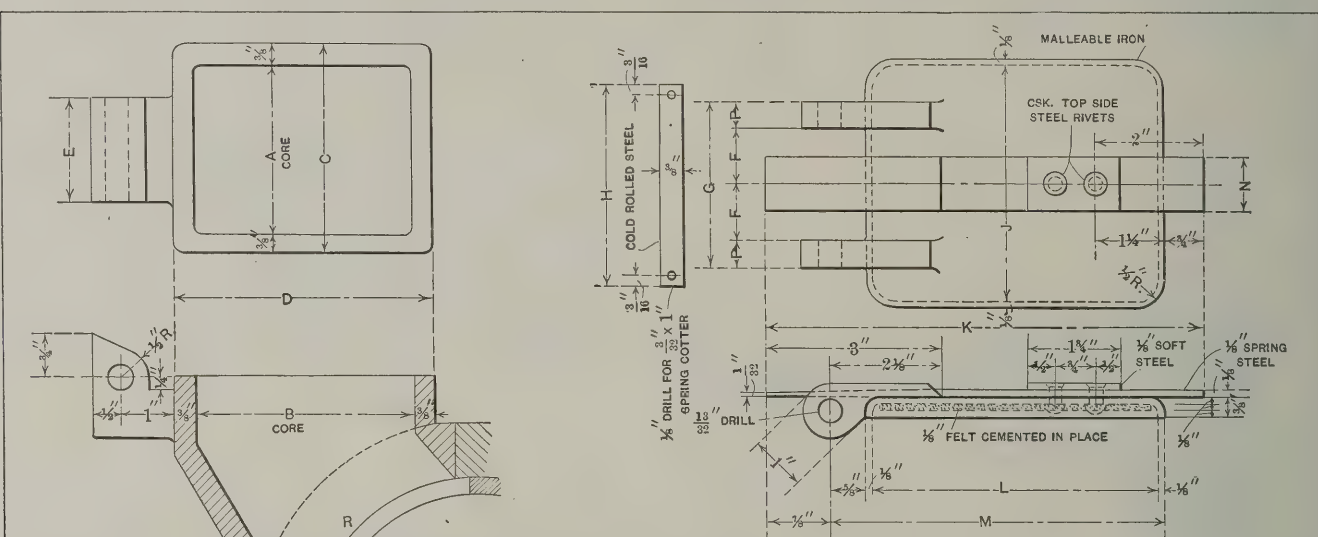
A Handy Truck for Moving Machines

The truck is run under the body of a machine, and handle *A* is pulled upward. This handle terminates in the cam *B*, which acts against bar *C* and forces the bar down. This bar is attached to the inner ends of the levers *D*, and the motion imparted to *C* raises the outer ends of these levers, throwing the lifting blocks, one of which is shown at *E*, against the body of the machine, and thereby raising the machine enough to clear the floor. In this position the machine may be readily wheeled to the new location, and by depressing the handle, the load is dropped. The high point on cam *B* is slightly flattened, so that the device will remain at that position until intentionally changed.

OIL-WELL DESIGN

By F. D. BUFFUM*

The accompanying illustration shows a design of oil-wells and covers that for several years has proved to be satisfactory and superior to grease- or oil-cups. It needs less frequent attention, is easy to fill, and the oil-well cannot be lost or stolen like an oil-cup. The design is inexpensive, the lubricant is in contact with a large part of the journal, and coats it with a film much better and more evenly than a cup, and without waste. It also feeds the lubricant automatically without any adjustment. The lid and hinge boss are made similar to the Master Car Builders Association's standard used in railway service. As long as the hinge boss and the other external parts of the oil-well mouth are made of standard dimensions, the lid design and the material can be varied considerably, just as in the case of the M. C. B. journal box. No part of the passage at *R* should be smaller than the entrance, and the bushing should be cored out at *S* to correspond with the dimension *A* in the table. The dimensions given are suitable for ordinary steel or iron castings. The oil-well should be located at the top of the bearing when practicable, and should be made deep and of large capacity, the dimensions shown at *A* and *B* being the minimum dimensions.



A	B	C	D	E	F	G	H	J	K	L	M	N	P	Size Rivet
4	5	4¾	5¾	1 15/16	1	3	3¾	5¼	8¾	6¼	7⅛	1	½	¼
3	4	3¾	4¾	1 7/16	¾	2½	3¼	4¼	7¾	5¼	6⅛	1	½	¼
2	3	2¾	3¾	13/16	7/16	1⅝	2⅜	3¼	6¾	4¼	5⅛	¾	⅜	⅛
1¼	3	2	3¾	9/16	5/16	1⅜	2	2¼	6¾	4¼	5⅛	½	⅜	⅛

Dimensions of Oil-well and Cover

These oil-wells are adapted to any kind of machinery especially heavy outdoor machines where cups are liable to be stolen, jar off or break, and also to plug up with dust in summer or freeze in winter. They can be used with either grease or oil, and, with the latter, are economical of the lubricant, because it is soaked up by the wool waste with which they should be packed when oil is used. This waste then feeds the oil to the journal by capillary action, evenly and continually, and without attention for long periods of time. There is nothing to regulate or adjust, and the journal is coated with a film of oil without spilling any. The main advantage, however, is in the saving of the operator's time in attending to the lubrication. To fill, all that is necessary is to hook open the cover, pour in the oil and slam the cover down again.

The easiest thing for the designer of any machine to do is to indicate a tapped hole and call for a grease- or oil-cup where lubrication is required, and, until a few years ago, when the writer went into the operating end of the business, he supposed that it was entirely satisfactory. However, he found that it didn't take much of a machine to require half an hour or more a day attending to cups. They have to be filled when they are empty and that is not always a convenient time. Labor occupied in filling and fixing them is an expense and a delay that has to be paid for, and a small sum daily amounts to a good deal in a year.

In looking for a more satisfactory substitute, the oil-well with spring-hinged cover, used on railway motor journals for mine locomotives and for their gear cases, appeared to be just the thing. These were made in a variety of designs, but the one that seemed to be the best and cheapest was adopted and improved in minor particulars. A few were used with great satisfaction to the machine operator, and their advantages were clearly demonstrated.

These oil-wells cost no more in the end than cups, if the outlet is large and is *cored* in the lining metal and not cut out afterwards. Valuing that metal at 30 cents per pound, the opening need not be so very big to save the cost of the well and cover, and the price of the cup which is saved helps out too.

The purpose of this article and of the table submitted in connection with it is to urge that manufacturers adopt *some* standard design and thus secure the advantages of interchangeability and low cost that the master car builders' standard obtained for the railroads. There is no advantage in having a lot of different designs and sizes, such as are now in use, when the adoption of standards would cut the cost down to no more than the 25 cents, at which the M. C. B. cover retails. To have a standard, all that is required is to retain the dimensions of the hinge boss and the outside of the oil-well. The cover design can be varied to suit the designer. He can make it thicker or thinner, with felt or without, and of cast iron or other material, and still have interchangeability. For larger covers, or for hand holes, the writer would suggest the regular M. C. B. standard.

* Address: Ellsworth, Pa.

INTERESTING TEST PIECES OF MONEL METAL

At the recent motor boat show in New York some interesting test pieces of monel metal were exhibited. This metal, which has the strength of steel, takes a finish like pure nickel, and is less corrodible than bronze, was shown in the form of a 1¼-inch diameter cold-drawn rod bent over flat, surface to surface, without fracture. Another ¾-inch rod, cold-drawn, was tied in a close knot with no fracture. Other test pieces of hot-rolled rods which had shown tensile strengths of 100,000 to 103,000 pounds per square inch, with yield points ranging from 76,000 to 81,000 pounds, were to be seen.

* * *

To produce a solder that will fuse at a low temperature, add six drops of mercury to each ounce of solder. With this, soft metals melting at a low temperature, can be soldered.

THE FACTOR OF THRUSTS IN MACHINE DESIGN

By WILL O. WYNNE

The successful and effective working of many mechanisms depends entirely upon the direction of the thrusts set up in them. The question of the direction of thrusts is a phase of the designer's work which is very often left to look after itself. Negligence in this respect sometimes results in the failure of a mechanism to produce satisfactorily the desired result. When designing a new movement, a thorough analysis of all of the strains and thrusts set up will sometimes reveal the possibility of counteracting the thrust of one member by that of another, thus producing a more self-contained arrangement, and possibly reducing, to an appreciable extent, the power required for driving the mechanism.

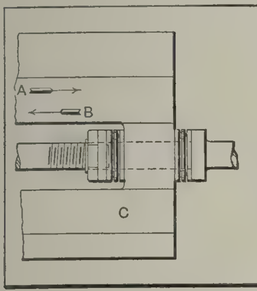

Fig. 1. Direction of Thrusts in Ordinary Carriage Construction

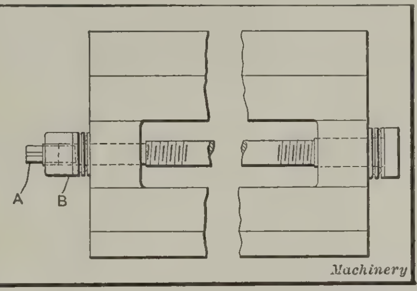

Fig. 2. Improved Design of Carriage Construction in which the Screw is always in Tension

Of course, there are many arrangements, theoretically incorrect, in which the thrust is not sufficient to affect the successful working of the mechanism. Such a condition of affairs is illustrated in Fig. 1. When the carriage on slide *C* is drawn, by means of the screw, in the direction of arrow *A*, the screw will be in tension, the thrust being taken by the collar on the outside of the slide *C*. When the direction is reversed, however, the carriage moving in the direction of arrow *B*, the thrust is taken on the ball washers on the inside of the slide. The screw is thus in compression. The disadvantage of this construction is not as apparent in small machines, but where heavy thrusts are set up, as in planers, it is obviously advantageous to arrange for the screw to be in tension irrespective of the direction of movement of the driven carriage. In addition to this, the construction as shown in Fig. 1 renders it rather difficult to introduce the usual form of lock-nut.

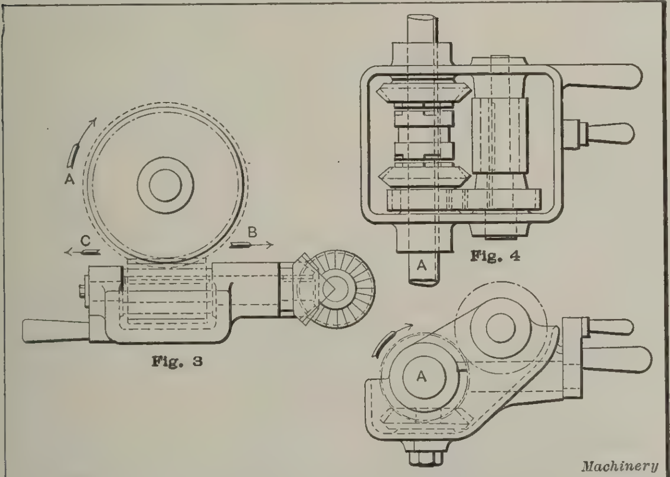

Fig. 3. Direction of Thrusts in Worm and Worm-wheel Design. Fig. 4. Worm-box with Reversing Mechanism

The arrangement by means of which the screw is always kept in tension is shown in Fig. 2, and is self-explanatory. This method allows the application of an exceedingly simple locking nut. The screw *A*, after the adjustment of the nut *B*, is forced against the end of the traversing screw; thus the thrust of the traversing screw, the adjustment of the nut *B*, and the locking of the nut by screw *A*, all act upon the same side of the thread of the traversing screw, forming a most effective lock.

In automatic trip motions, in which the feed is to be tripped while the machine is cutting, the question of direction of thrust is, in some cases, of paramount importance. This can be simply illustrated by a worm and wheel in which it is required that the box carrying the worm shall fall, throwing the worm out of gear with the worm-wheel, and thus disconnecting the feed. The worm-box, as commonly constructed, is shown in Fig. 3, and is usually pivoted at the apex of the bevel gears that impart motion to the worm-shaft. If the worm-wheel is arranged to rotate in the direction of arrow *A*, the thrust on the worm is in the direction of arrow *B*. This thrust acts on the pitch line of the worm, and the pitch line produced passes above the center of rotation of the worm-box; thus, the box is prevented from falling by the thrust of the worm. The greater the thrust on the worm, the greater also will be the tendency for the worm to be forced deeper into mesh with the wheel. If the direction of rotation is reversed, the thrust will be in the direction of arrow *C*, tending to throw the box downward, and the greater the thrust, the more effective the action when the support to the box is tripped.

An instance somewhat similar to the foregoing is that of a worm-box driven by spur-gearing, as is illustrated in Fig. 5. In this case, the box is hung on shaft *A*, which imparts motion to the worm-shaft and worm by means of spur gears *B*. If shaft *A* rotates in the direction of arrow *C*, the thrust of the spur gears on the box is in an upward direction, and this thrust will hold the box up when the support is tripped, thus necessitating some auxiliary motion to push the box out of gear. If the direction of rotation of the shaft *A* is reversed, the thrust tends to throw the box downward, and the mechanism has now all the elements of an effective automatic trip.

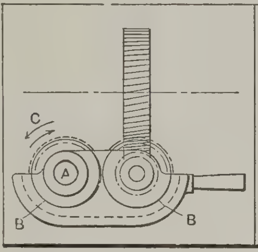

Fig. 5. Worm-box with Spur Gear Drive

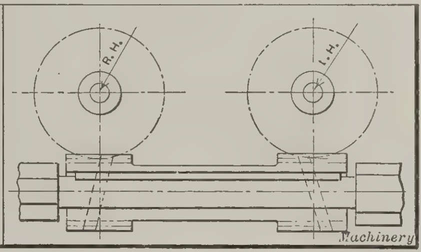

Fig. 6. Twin-screw Drive in which the Thrusts are Balanced

It is very often necessary to be able to trip the worm while feeding in either direction. In this case it is advisable, if possible, to mount the reversing mechanism in the worm-box, as shown in Fig. 4. As the rotation of shaft *A* is in the direction of the arrow, the driving pressure thus always tends to throw the worm-box downward.

The consideration of the automatic balancing of thrusts has led to the design of a planer drive, as outlined in Fig. 7. This arrangement has been used by the writer for some time. The drive, as shown, illustrates a large planer table driven by a double rack. It is generally known that with this style of drive, under ordinary conditions, it is practically impossible to equally distribute the drive between the two racks. This, however, is automatically accomplished with the drive arranged as shown.

The racks *A*, of ordinary straight tooth type, are bolted to the table; bull wheels *B* mesh with the racks and ride loosely upon a large stationary shaft fixed in the bed. In mesh with the bull wheels are separate rack pinions *C*, riding loosely on a long stationary shaft *D*, carried in brackets bolted to the under side of the bed. Keyed to these rack pinions are two separate helical gears *E*, with teeth cut at opposite angles. In mesh with these two wheels is a solid double helical pinion *F* keyed to the driving shaft *G*, but free to move endwise along the shaft. The shaft *G* is driven by the usual gearing, with which we are not concerned. When shaft *G* is rotated, the double helical pinion *F* drives the helical gears *E*, which, in turn, drive the rack pinions and the racks. The pinion *F*, due to its being of a double helical form, will continually be in a state of either compression or tension; thus, if at one instant the driving pressure on one rack became greater than on the other, the difference of pressure would immediately be transmitted to the pinion *F*, causing that pinion to move endwise, and to again equalize the pressures on the two racks.

Whereas, in the usual double rack drive, great care is necessary in mounting the gears on their respective shafts in order to try to obtain an even drive, this trouble is entirely eliminated and a perfect self-contained automatically balanced drive is obtained with the arrangement above described. It will also be seen that whereas the end thrust on the pinion, whether compressive or tensile, is all self-contained, the resulting thrusts on the single helical gears are taken on ball washers mounted between the pinions *C* and the brackets carrying the shaft *D*.

The same principle might be employed in the driving of a twin-screw planer, or, in fact, in any machine which is driven by two members, one member always receiving the thrust set up by the other. The application of this drive to a twin-screw planer is shown in Fig. 8. A short article bearing somewhat upon this subject appeared in MACHINERY, August,

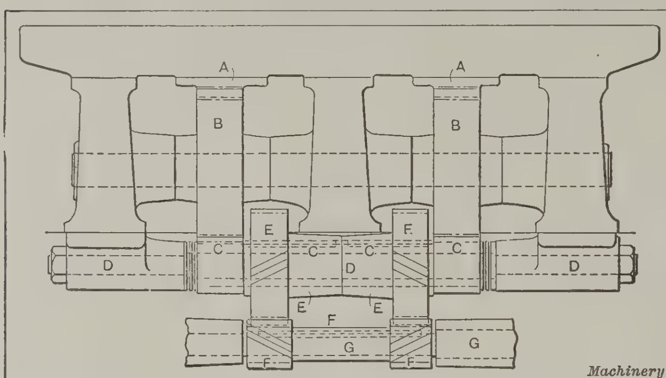

Fig. 7. Improved Form of Double Rack Planer Drive

1911, engineering edition, on page 943: "Points in the Design of a Power Elevating Cross-rail." While nothing whatever can be urged against the principle advocated in the raising and lowering of the cross-rail by means of which the thrusts are regularly balanced, using right- and left-hand screws, the construction, however, due to the possibility of automatic balancing, could be considerably improved in that the coupling for maintaining alignment could be eliminated.

After the alignment of the cross-rail has been obtained, the shaft carrying the worms can be rotated and moved endwise until the worms bear equally on both wheels, this position of the shaft then being fixed by means of a collar on each side of the central bracket, care being taken to have sufficient clearance between the worms and their brackets, as shown in the drawing. This construction, however, might fail to appeal to those who place little reliance upon a long shaft of small diameter under compression—among whom may be numbered

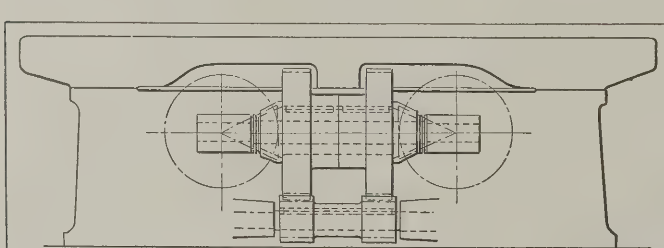

Fig. 8. Twin-screw Planer with Drive having Thrusts Equalized

the writer—although he is well aware that the shaft could be arranged to be in compression when lowering the slide.

This principle could be, and is, in fact, used advantageously under such conditions as shown in Fig. 6, in which the worms are solid with a tube that is free to move endwise along the driving shaft. This principle is the subject of several patents, but a little consideration will reveal the fact that this arrangement is by no means perfect. Similar examples could be cited and others will occur to all who are connected with machine designing, but enough has been said to illustrate the advisability of a little more consideration of a subject which is sometimes the sole basis of a satisfactory mechanism.

* * *

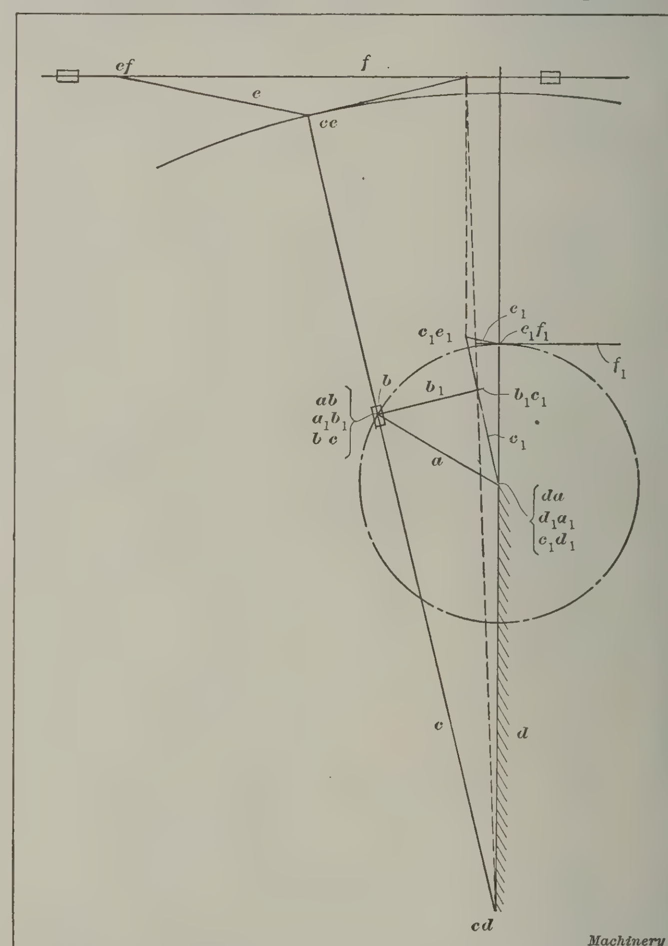
Saving a dollar in wages or in factory costs, and losing two in efficiency, is really not a money-making proposition, although lots of people seem to think it is.

THE PHOROGRAPH—A REJOINDER TO A CRITICISM

By FREDERICK H. MOODY*

In the criticism appearing in the February number, relative to the writer's article "The Phorograph," published last October, Mr. Sullivan is evidently laboring under a misapprehension of the possibilities of the phorograph system of analyzing mechanisms. Those who have used it are certain that if it had been given a fair trial on the drawing board, in comparison with the "instantaneous center" method, the criticisms offered would never have been made. The opinion of several users of the system is that there is no comparison in the simplification of the analytical work resulting from it.

In the original article, mention was made that the phorograph formed part of the instruction in the mechanical engineering course at the University of Toronto. In the early stages, the instantaneous center method is still employed, for it seems as if that method could not be improved upon from an instructional standpoint, as all the principles are presented



Quick-return Motion as analyzed by the Phorograph

in such a clear and logical manner that the relative movements of the parts are more readily understood by the student. However, this method has decided limitations in practice. For example, consider the difficulties of solving a problem by the instantaneous center method for a link attached at its ends to nearly parallel links; the instantaneous centers would be away off the board somewhere in space, making such a solution impracticable. It also requires a great deal more line drawing than the phorograph method. In the latter method, the area over which the operations are carried, so to speak, is kept within smaller compass. In consequence, while the fundamentals are taught by the instantaneous center method, that method is superseded by the phorograph in the later stages of the course.

Consider next some of the specific criticisms. The statement is made in the criticism that "the results are all correct except that in the quick-return motion illustrated, the velocity of the oscillating arm is represented by the line c_1d_1–c_1e_1, and it still remains to solve for the velocity of the ram in order to com-

* Address: 70 Bond St., Toronto, Canada.

plete the solution." To call this an omission rather than an error would have been more to the point. As the writer's article was merely explanatory of the phorograph, rather than an effort to thoroughly analyze specific mechanisms, it was not deemed necessary to carry the solution to a conclusion. The accompanying illustration shows the same mechanism with the addition of the ram f, joined to its connecting link at ef. Points ce and c_1e_1 have the same motion. As a point in link e, the image e_1f_1 of the point ef, must be somewhere along a line through c_1e_1 parallel to e. Likewise, as a point in ram f, which has a horizontal motion, the image must be in d produced, as only such points have a horizontal motion. Hence, the image is at the intersection of these two lines at the point e_1f_1. The ram velocity at that particular instant is thus the length c_1d_1–e_1f_1. With regard to the original statement calling the quick-return mechanism a Whitworth, the writer stands corrected.

Exception is taken by the critic to the statement that the image found by the solution outlined, is not *on* the constantly-revolving link itself, *i. e.*, in the simple four-link mechanism, the point b_1c_1 is not on a. Near the bottom of the second column of the original article, there is the following statement: "The link a is considered as a large member of sufficient size to include the images in all positions." The line shown representing the link a is only a skeleton line connecting centers, the actual link comparing as regards size to the disk-crank commonly found on large stationary engines. This, of course is only a constructional assumption. The scaling methods suggested by Mr. Sullivan are good, representing natural developments in any method of graphical solution.

The line of reasoning outlined by the critic in his second to last paragraph, and in the first sentence of the last paragraph, emphasizes his unfamiliarity with the subject he is criticizing. The conditions mentioned, while from a casual inspection presenting much the same appearance, are fundamentally different, and require an intelligent knowledge of the application of the phorograph to obtain the correct solution, for it will be noticed in the first instanced case that the block is sliding on the stationary link on which all points are the same, while in the second case, the block is sliding on a movable link on which all points have different relative motions. If the solution originally outlined be carefully analyzed, it will be found to be perfectly correct and logical, embodying in a simple manner the phorograph principle.

Near the end of the criticism, there is this statement: "In Fig. 4 of Mr. Moody's article, it will be found difficult to project b_1c_1–c_1d_1 to a tangent from ce accurately." If the original article be correctly read, it will be found that no such move is attempted. The construction that was outlined may be seen by referring to the accompanying illustration, which in this particular is the same as the one referred to. Quoting from the original article: "The distance between b_1c_1 and c_1d_1 corresponds to the distance between bc and cd; so in order to obtain the full image of the link c, we must join cd and b_1c_1, producing this line to meet a tangent from the point ce. From this point of intersection, drop a perpendicular to cut a line through c_1d_1 and b_1c_1 produced, in the point c_1e_1. The line between c_1d_1 and c_1e_1 is the image c_1 of the link c, obtained by simple proportion, this method of obtaining it being simply a constructional means of so doing." The tangent at ce is at right-angles to c—a simple construction. No difficulty should be experienced through graphical errors in the other points, as the locating points are all a good distance apart, minimizing the possibility of error.

In conclusion, the writer wishes again to emphasize the fact that if the phorograph be first properly understood, its application will lead to simplification in the solution of problems commonly solved by the method of instantaneous centers.

* * *

A small tube and bulb containing mercury and so arranged that the rise of the mercury due to its temperature closes an electric circuit and rings a bell, may be effectively used as an alarm for hot bearings. The apparatus is attached directly to the bearing, and when several bearings are connected, an ordinary electric bell indicator can be used to show which bearing is hot.

DATA ON ROPE-DRIVING

In a paper read by Mr. R. E. Hart before the Association of Engineers-in-Charge (England), the author stated in a concise manner the main requirements for a successful rope-drive. The main features of an ideal rope-drive are that the diameter of the pulleys shall not be less than thirty times the diameter of the rope used, and the driving and driven pulleys shall, if possible, be of equal diameter; but where this cannot be arranged, their ratios should not be greater than 5 to 1. The distance between the pulley faces should, if possible, be not less than 25 feet, and the drive should be horizontal, with the slack side of the rope on the top. The speed may be from 2000 feet to 4000 feet per minute. If the speed is too low the ropes are apt to slip, and if too high the action of centrifugal force affects the efficiency. There should be a distance of from 4 feet to 6 feet clearance under the ropes, and the ropes must, of course, not rub on anything. An allowance of 2 or 3 inches clearance between the bearing foundations and the sides of the pulleys must be made so as to leave room for the ropes to be put onto the pulley. The pulleys must also be accurately in line, well balanced, and the grooves exactly alike. All gears between the prime mover and the rope-drive should, if possible, be avoided; the ropes should be kept dry, properly lubricated, and not too tight. They should all be put on at one time, and the full load should be applied to them as soon as possible after they are in place. Carrier pulleys, rollers, and angular drives should be avoided as much as possible. Regarding the two types of rope generally used—namely, three-strand and four-strand—the former can be made more pliable than the latter, and it is also stronger; but these advantages are more than counterbalanced in the four-strand rope, because, compared with the three-strand, it stretches very much less, and it has a larger surface in contact with the pulley grooves; it is also capable of a stronger splice. A well-made four-strand rope is, moreover, nearly as strong as a three-strand, but it requires more skill to splice it. The general opinion now is that cotton is the best material to use for driving-ropes, and Egyptian cotton, though a little more expensive than American, is generally preferred.

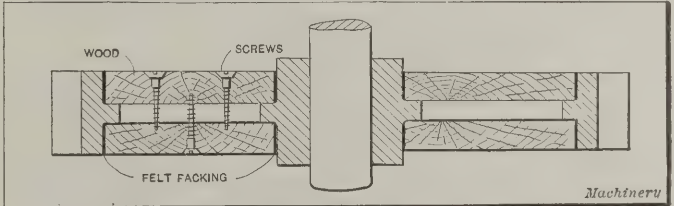
A CURE FOR NOISY GEARING

A little kink for eliminating the noise of gearing is given in the *Practical Engineer* (London). Trouble was experienced from the excessive noise made by the gearing of a crane placed in such a position that the noise was highly objectionable. Several methods were tried to eliminate it. Grease and oils of all kinds were used with but temporary success. Finally the following method was tried: The annular space between



A Method for Eliminating the Noise in Crane Gearing

the hub and the rim was packed with wood. This wood butted tightly up against felt pads as shown in the engraving. The pieces of wood were secured to each other by ordinary wood screws, care being taken not to have the heads project. Good hardwood should be used, and rubber might be used to advantage instead of felt, except for exposed outdoor work. This method eliminated the objectionable noise from the gearing.

* * *

In a report by the secretary of the French Aero Club, relating to aviation in France during 1911, the following figures indicating the development of aeronautics are given. In that country alone 13,000 flights were made across country, and in total 1,625,000 miles was covered; the total time that aeroplanes remained in the air was 30,000 hours. The English Channel has been crossed thirty-seven times. The accident record has decreased, and during the year 62,500 miles was flown for every fatal accident.

INDUSTRIAL EFFICIENCY*

The word "efficiency" has been used somewhat to excess for some time past. A great many people are writing and talking of efficiency who do not seem to have a clear conception of what that word means. It is the special business of the engineer to study efficiency, but the fact that a man styles himself an "efficiency engineer" is not necessarily a recommendation. Recently a man prominent in the industrial field stated that it seemed as if everyone who had failed at everything else was advertising himself as an efficiency engineer. Now, it is possible to be entirely in sympathy with *bona fide* efforts to increase efficiency without being in sympathy with all this talk about efficiency by people who do not know what the engineer means by this word. A society has recently been formed for the promotion of national efficiency which has spent some time trying to find a definition of the word efficiency. This being the case, there is apt to be a great deal of misunderstanding on this subject.

What we want to do is not necessarily to change our methods of work, but to do our work thoroughly, and this cannot be done by merely talking. The author's work has sometimes been criticised because it is said to have been done too thoroughly—he goes too much into detail, etc. However, any work which has anything to do with engineering must be done thoroughly.

Possibilities for Greater Industrial Efficiency

With regard to industrial efficiency, it does not seem to be necessary to present a great many ideas, but it is necessary that the fundamental ideas and causes be clear. Some time ago, the financiers of this country thought that they had solved the industrial problem by the great economies made possible by consolidation into huge combinations. Large trusts were formed, and it was believed that by eliminating competition it would be possible to manufacture and sell a great deal cheaper than had been possible in the past. These expectations, however, do not seem to have materialized, because the continually increasing cost of living in this country seems to indicate that we need something more than able financiering to round out our theory of industrial economy. This has been a growing conviction on the part of students of our economic conditions for several years, but the most critical were not prepared for the admission, before the Interstate Commerce Commission, in November, 1910, by some of the most noted railroad financiers of the country, apparently seconded by Mr. Morgan himself, that they had done everything possible to reduce the expense of operating railroads, and that from now on the public must accustom itself to increasing freight rates. These financiers thus admitted that in the branch of industry in which the financial man is, perhaps, more nearly supreme than in any other, and in which competition has been practically eliminated, rising costs forced them to ask the public to bear a portion of their burden.

The student of economics asks if there is not something lacking in our system of industrial economy that makes such requests necessary, or even possible. If it is a fact that in any branch of industry every possible economy has been effected, and that in the future costs will be higher, we are confronted with a very serious condition, the far-reaching effect of which it is hard to foresee. It has been our boast in the past that with our labor-saving machinery and our improved methods, we had so reduced costs as to make the luxuries of today the necessities of tomorrow. If, in any branch of industry, we are forced to acknowledge that costs will in the future be higher, are we not pointing to the time when these necessities will again be luxuries?

The statement, which happily few believe to be a fact, that in any industry the minimum cost has been reached, and that hereafter costs must be higher, is such a serious one, and fraught with such serious consequences to our industries at large, that many of us feel like asking the great financiers who are backing this statement to speak for themselves only, for there are many engineers who not only do not agree with them, but who believe there are means of increasing efficiencies and reducing costs that the financier has as yet no conception of. These methods have been applied in isolated cases, and to a greater or less degree to a great variety of industries, and they have produced a better and a cheaper product; and the workers are better paid and better satisfied.

In making this statement, it is not intended to disparage the work of the financier, but to remind him that the civilization of to-day has not been built up solely by his efforts. In this process, the engineer and his able assistant, the skilled mechanic, have been even more integral factors than the financier, and until they hold up their hands and say the end is reached, that modern combination of engineer and mechanic, the mechanical engineer, respectfully asks that they withhold their cry of despair, and allow him to present what Mr. Brandeis calls his "Gospel of Hope."

Present Tendencies in the Development of Industries

Until within a few years, all mechanical knowledge was empirical. It had been gathered by cut-and-try methods through centuries, and was handed down with no written record. Yet, it is wonderful what great progress had been made. The master workman of a century ago was justly proud of his work and of the apprentices that went forth from his shop. With the perfection of the steam engine, which is the foundation on which our civilization is built, and which was the invention of a mechanic whose work has had a greater influence on the world than that of all the financiers that ever lived—with the perfection of the steam engine, the master workman obtained cheap power, and was enabled to increase the size of his shop. The increase in size of the workman's shop gradually developed the factory system of today, in which the foreman and workmen have no interest other than their daily wage, and where they are too often laid off without cause and without notice, to suit the plans of the owner. Is it surprising that, under these conditions, their interest in the training of apprentices should lag, and that the foremen and workmen should take but little trouble to train men who will shortly become their competitors?

The Use of Records

But this is not all. The owner too often puts all responsibility for the promotion of efficiency upon his superintendent and foremen, yet limits them in the wages they are allowed to pay, or the records they are allowed to keep. The records, as a rule, are just sufficient for him to make criticisms by, but not enough detailed to enable the foreman or superintendent to know where the inefficiencies are, or which of his men are most valuable to him. In one concern a man who had complete charge of all the cost records frankly avowed that he was not keeping these records for the benefit of the superintendent; he was simply keeping them so that he would know what was being done; he did not care anything about the superintendent. In other words, he was there to criticise, not to help. He had a lot of clerks to help him do the work. Now, he did not say so, but this is what was in his mind: Those records were to keep somebody from stealing something. In fact, there are too many records to keep somebody from stealing something, and not enough to help the man who has to do the work to do it right. The difficulty of keeping people from stealing things is not great; we do not have any difficulty in that. The records of cost and material should be kept to enable people to do the work right.

Having no individual record of his men, the financial head too often orders that all men of a certain class shall be paid the same wage, and for a long time it has been extremely difficult for the capable man to rise much above his fellows, no matter how much more, or better, work he did. What has been the result? The capable man, failing to rise above his class, has devoted his energy to raising his class, and by means of his union has forced his employer to raise the class wage, regardless of the work that was done. But let us not blame the financier or the owner too much for that. When he allowed his foreman or, perhaps, his superintendent to raise wages, he found that very often the brother-in-law, or the nephew, or somebody like that, got the high wages and the efficient man did not, and that has happened too often. When he found that out he said, "Well, we will pay machinists all the same wage." But when he made that statement, he put the strongest possible weapon into the hands of the men who wanted a

* Abstract of an address by Mr. H. L. Gantt before the American Society of Swedish Engineers, Brooklyn, N. Y., March 23, 1912.

union. They then said, "If we cannot get increased wages for the efficient man individually, we will get higher wages for our whole class," and they then banded together to get the union wages, and you cannot blame them.

The employer now complains bitterly; but has he not combined with his fellow to get all he could for what he had to sell? Are the workmen not playing the same game he has played, and playing it better? By forcing the capable man to remain in his class, the employer has held back the individual, but greatly strengthened the class, until today the employer with his combination on one side, and the workman with his union on the other, stand facing each other as two great armies, each trying to get the better of each other, by manoeuvering, if possible, but by fighting, if necessary. Without considering who is to blame for this condition, let us ask if there is any remedy.

The Causes of Industrial Unrest

While arbitration has certainly averted strikes, it has not settled anything, or diminished the desire of either party to oppose the other, and can only be considered as a temporary expedient. Collective bargaining has certainly increased the wages of the workman, but cannot alone offer a final solution of the labor problem, for wages cannot be increased indefinitely. The railroad presidents claim that the increase of wages obtained by this means necessitates increased freight rates, which, if granted, must necessarily, in a measure at least, increase the cost of living. Thus, neither arbitration nor collective bargaining, on which we have placed so much confidence in the past, gives promise of any permanent solution of our difficulties, and the time seems rapidly approaching when the friction of conflicting interests will seriously hamper our further development. We, therefore, naturally, ask why these interests conflict. The answer is plain; neither party has been willing to consider the interest of the other. The employer has too often insisted on paying the lowest wage, regardless of the service rendered, while the employe, through his union, has demanded the highest wage, regardless of what he gave in return.

I heard something in the last two or three days that quite astonished me. I have heard the same thing from three or four persons, but the last time I heard it from a rather unexpected source. I have heard a number of men make the statement recently that the financier—the capitalist—was getting too large a percentage of the earnings of the increase in wealth. A man told me that a millionaire friend of his in Wall Street had made that statement to him. Now, there is not any question that within the last fifteen years there has been a much greater percentage of the increased wealth harvested by those who already had wealth. The worker, the engineer, the producer, did not get the same proportion of it that he had gotten previously, and that is one of our troubles today. The very serious unrest in this country, England and the countries of Europe, is due to the fact that the workmen have made up their minds that they are going to get a larger percentage. Now, we have got to face that condition and find out what is the proper thing to do, and try to do it as soon as we can, and prevent what seems to be the impending conflict, which is due to the fact that both employer and employe have disregarded the great principle of equity, which is the foundation of all harmony.

In the commercial world it has long been recognized that transactions which do most to promote prosperity are those which are beneficial alike to buyer and seller. Does not the same law hold good in the industrial world in the purchase of labor? With the operation of such a law, the interests of the employer and employe become identical, and we have laid the foundation for their harmonious cooperation. Having done this, we are ready for the next step, namely, the promotion of efficiency in the utilization of human effort. The progress so far made in this direction has in many cases been in spite of a lack of equity in the relations between the employers and employes. Consider how much faster progress could be made if all men were assured of an equitable return for their efforts.

As a matter of fact, real efficiency is impossible without equity, for no man will continue to put forth his best efforts without a proper reward. The idea of doing work efficiently is comparatively new to people in general. It is only within very modern times that the best educated people have given any thought at all to the subject of physical work. The only serious subject requiring manual skill that was considered worthy of their attention was that of fighting, or war. As a matter of fact, it was Sir Henry Bessemer's search for a stronger metal with which to make field guns that gave us Bessemer steel. Until within a few generations, it has been very much more important to defend the wealth you had than to acquire more than sufficed for your daily needs. Hence the importance of defence. The time has come, however, when a man no longer has to defend his property with his skill or life, and can devote his energies to acquiring a surplus for himself and family. The great majority of men are ambitious to secure such a surplus, and are willing to work efficiently and industriously if they can be assured of an equitable compensation. The precise method of compensation is comparatively immaterial, provided efficiency is rewarded and not penalized, as is too often the case.

What has become of the ingenious Yankee, of whom we heard so much forty years ago? Are Yankees less ingenious today? Not at all; but our factory system of today too often fails to reward either ingenuity or efficiency, and these men have turned their attention to getting their advancement through their labor union. How much better it would be for the community at large if these men could devote their labors to the promotion of efficiency, and thus get their reward. A system of industrial economy based on industrial warfare is so evidently wrong that few will undertake to defend it, for it necessarily groups employers and employes into two hostile camps. Under such conditions, cooperation within each class is to be expected, and the combination of employers on the one hand and the formation of labor unions on the other are the only natural results.

Now, it seems that these segregations of interest which are practically mutual in their nature, are the cause of a great deal of our industrial difficulties. It is not out of place to dwell so long on the industrial unrest, because the great problem before us today, industrially, is the very problem outlined in the foregoing paragraphs. It is necessary to utilize the human efficiency in such a way that all the reward of the increased efficiency does not go to one class. The man who works wants his share, and it is, therefore, necessary to devise ways and means to give him a larger proportion of the results of his labor. Any scheme for the utilization of the energies of the community for the benefit of one class of people only, would develop an oligarchy which would ultimately be overturned by a revolution. England presents an example of the conditions that follow improper economic relations. It is felt in England that even though the coal strike be settled, they have not passed their worst danger. There is an industrial unrest there of which the coal strike is merely a symptom, and the whole country is stirred up a great deal more than is indicated by that strike.

The Task Idea

In trying to find a means for uniting the interests of the employer and employe, the task idea was developed; that is, the idea of putting before each workman a certain task to be performed in a given time, assuring him his regular wages if he could not perform the given task, and promising him a suitable reward in case he was able to perform the given task in the given time.* One of the important points relative to this method, frequently called "scientific management," is that the reward or bonus must be great enough so that the workman will feel that he is fully compensated for the extra exertion required to do the task. The bonus is usually from 20 to 50 per cent of the regular day rate. Task work does not necessarily mean more severe work, but it means more continuous work, but at the same time, work under more favorable conditions.

Another important point that should always be noted is that having set a task, the responsibility for its performance does

* The subject of task work and the methods employed were dealt with in the December, 1911, number of MACHINERY, in an abstract of a paper entitled, "Task Work—The Basis of Proper Management" read by Mr. H. L. Gantt before the National Machine Tool Builders' Association.

not rest upon the workman alone. Every case of lost bonus must be investigated by the management, and the reason determined. It seems very difficult to get people to grasp that idea and to go to that trouble. If a man does not make the bonus, they seem perfectly willing and content to let him lose it and pay little attention to him, but this is a great mistake and tends to discredit the system. The man is discouraged—it may not have been his fault; the machinery may have been out of order or the appliances he has been working with may have been unsuitable; the material may have been inferior in quality. All these reasons may have prevented him from performing his task. Frequently imperfections and defects in material bought have been found simply by investigating why the workman has been unable to perform his task; yet, that material may have passed inspection, but the imperfections have been such that they could not be located in that manner, although they would show up when the workman got ready to perform his work.

If, again, when some workman is unable to accomplish his task, a capable man, in whom he has confidence, tries to find out what the reason is, he will feel satisfied and try to earn his bonus the next day. Therefore, in the task system, next to the subject of the proper task comes the necessity of investigating every case of lost bonus and of determining the reason. If a proper scheme of management is devised, by which all the available knowledge is used to plan the work, and if the tasks are set in accordance, and the workman liberally compensated for the performance of the task, there is no question but that marked economy can be produced by this new method of management.

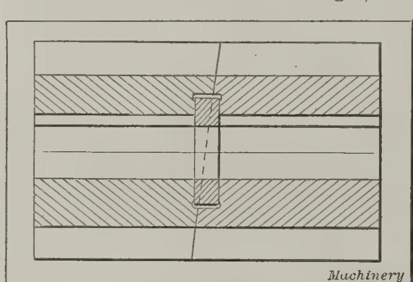
SIMPLE METHOD OF INTERLOCKING MILLING CUTTERS

The accompanying illustration shows a simple method for interlocking milling cutters. As indicated, the method consists simply in milling or planing off the ends of the two halves of the cutter at an angle, and providing recesses in the angular faces as indicated. The angular faces are not intended to bear tightly against each other, and, hence, do not need to be absolutely true, but the bearing is on a washer placed in the recess mentioned, as it is much easier to provide true bearing surfaces in that manner.



"Interlocking" Milling Cutters

The method was originated by the firm of J. A. Kühn of Frankfort a. M, Germany, and was recently described in the *Zeitschrift für Werkzeugmaschinen und Werkzeuge.* It seems that this method has certain advantages over the ordinary interlocking methods on account of its simplicity. It may not be exactly right to call the method an interlocking one, as it is rather a case of "overlapping" milling cutters. The object in view, however, with both the interlocking method generally used in this country and the method shown in the accompanying illustration, is the same.

* * *

According to *Power*, Sir Hiram Maxim recently made a statement regarding the superiority of American workmen. It was his experience that in England, for example, while there are plenty of men to be hired at a salary of about 30 shillings ($7.50) per week, it was difficult to find a man at £5 ($25) a week for a position requiring care and intelligence. In Canada and in the United States he believed a positively different state of affairs to exist. In 1877 to 1880 he had charge of an electrical works in which a considerable number of young men were employed, and today nearly every one of them is in a high position. Young American mechanics are found studying algebra and geometry, while in England the penny novel takes the place of scientific books.

A SMALL MACHINE VISE

By CHESTER L. LUCAS*

Fig. 1 shows a small vise or clamping fixture which has proved valuable for holding miscellaneous pieces in the toolroom, as pins, screws, or small flat blocks, upon which some slight machining operation such as drilling or milling must be performed. This vise is made from a Starrett toolmaker's clamp and consists essentially of a jaw *A* which is held to the inside face of the end of the clamp by a fillister-head screw *B*. The other jaw *C* is a counterpart of the first, and, in making, the two are clamped together and holes drilled for the two dowel pins *D* which are more clearly shown in the line engraving, Fig. 2. These dowel pins are made a driving fit in the holes in the movable jaw of the vise and a sliding fit in the holes in the stationary jaw. Small spiral springs placed behind these pins insure that the jaws will open when the pressure on the movable jaw is released. Two vertical V-grooves are cut in the centers of the jaws so that round or square pieces may be rigidly held in an upright position. By cutting a socket in the back side of jaw *C*, to receive the clamping screw, the flat tip shown on the screw may be dispensed with, but it works very satisfactorily as shown. The object of using the two dowel pins, which, by the way, is the important feature of the fixture, is to provide a means for holding work perfectly true, the tendency otherwise being for the inner jaw to lift the work when pressure is applied behind the jaw. With this method of guiding the jaws, no trouble is encountered from this source. For holding the clamp and jaws on the table of the milling machine, two holes may be drilled through the center of the bottom part of the clamp. These holes are countersunk from the top, and flat-head screws may be passed through and into T-nuts or blocks in the T-slot of the milling machine table. When the clamp is wanted for regular work, the fillister-head screw *B* and the jaws are removed.

The Supreme Court of the United States will not reopen the Dick mimeograph constructive patent infringement case, and the decision of March 11 stands, affirming the right of the makers of a patented machine to prescribe what supplies shall be used with it. The gravity of the situation is generally recognized and Congress should immediately pass such legislation as is required to relieve an intolerable condition. Legislation is also required that will give inventors better protection and prevent the buying up and shelving of patents by corporations seeking to monopolize any line of manufacture and selling.

At the factory of the Wells Bros. Co., Greenfield, Mass., the 300 employes who do not go home to their lunches are supplied by the firm with hot coffee, which is provided free of charge.

* Associate Editor of MACHINERY.

UNUSUAL HOBBING OPERATION

The shaft seen to the left in Fig. 1 is used in the construction of the Amplex motor cars (built by the Simplex Motor Car Co.), for advancing the spark or varying the points of ignition in the engine cylinders. As the illustration shows, this shaft has four equally spaced spiral grooves which are

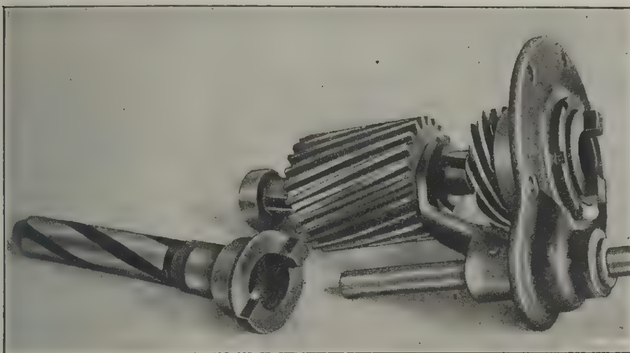

Fig. 1. Spark-advance Shaft having Helical Grooves which are cut by Hobbing—Shaft assembled with Shifting Fork and Timer Gear

¼ inch wide and ⅛ inch deep. When the shaft is assembled as shown in the view to the right, it is connected with the shifting fork and timer gear, and the right-hand end is equipped with a clutch which is coupled to the armature of the magneto. The four spiral grooves for giving this spark advance shaft a rotary movement, are cut by hobbing in a Lees-Bradner hobbing machine. The operation is both novel and interesting and presents some new features in the design and application of a hob.

The way the machine is arranged for this work is shown by the detail view, Fig. 2. The shaft is held at one end, by a draw-in collet inserted in the horizontal work-arbor, and the other end is supported by the regular tailstock center. The cutter-head containing the special hob is set at right angles to the axis of the work. This hob has four teeth, and the four helical grooves in the work are cut simultaneously. The four teeth are equally spaced and each tooth finishes its own groove. The hob and shaft rotate in unison, there being approximately one revolution of the cutter spindle for each revolution of the work spindle. In Fig. 2 is shown a shaft that has just been completed.

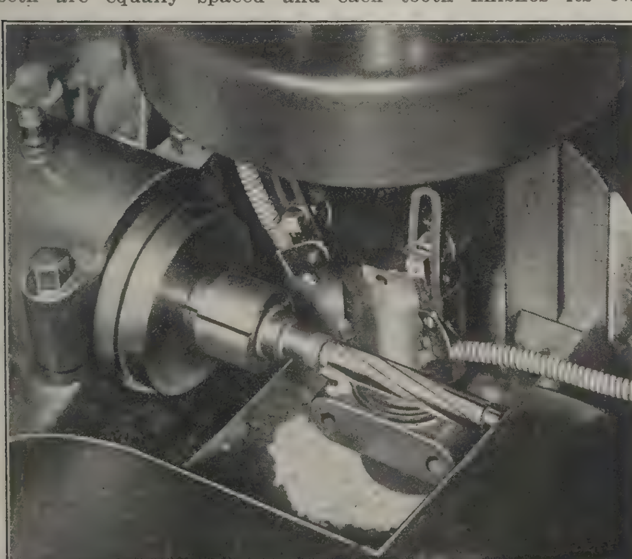

Fig. 2. Method of Hobbing Shaft in Lees-Bradner Hobbing Machine

The relative action of the work and hob, as well as the construction of the latter, are shown more clearly in the diagrammatical view, Fig. 3. As previously intimated, the hob is set in a perpendicular position, the four cutters and the axis of the work all being located in the same horizontal plane, as shown in the end view. The shaft to be splined rotates in the direction indicated by arrow w, and the hob, as shown by arrow h. In addition, the shaft has a longitudinal feeding movement to the left, and is geared to produce the angle of the helical groove that is required to be generated. The action of the hob and work is as follows: Cutter A cuts groove A_1 (see end view) and when the hob has rotated one-quarter revolution, thus bringing cutter B to the front, the work has also turned a corresponding amount (plus the rotation due to the geared movement), so that cutter B enters groove B_1. Another quarter turn brings cutter C into groove C_1 and in the same manner, tool D enters groove D_1. The geared movement previously referred to causes each cutter to follow a helical path on the work. When a cut is started at the end of the shaft, the gashes generated by the four cutters are at an angle owing to the rotation of the shaft, and in order to make the cutters follow the helical path thus started, as the work feeds longitudinally, it is necessary to have a correct movement; in other words, if a single gash were cut across the shaft, without the correct movement and with the cutter and work rotating uniformly, the angle of this gash would be zero, that is, the cut would be parallel to the axis.

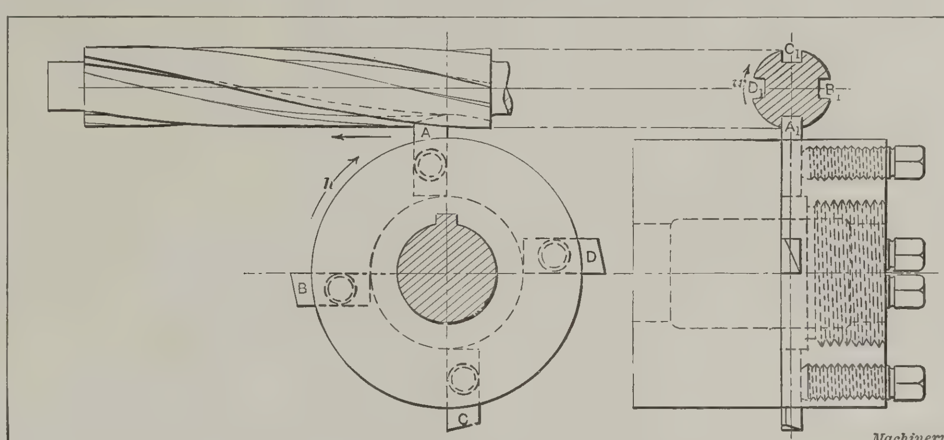

Fig. 3. Diagram showing Work and Four-toothed Hob used for Cutting the Helical Grooves

It will be seen that the hob is, practically, a four-tooth fly-cutter and each groove is milled to the proper depth by a single tool. The four grooves are finished in one passage of the work and the time required for hobbing a shaft is seven minutes. The length of the shaft is 7¾ inches, the diameter, ⅞ inch, and the material 0.020 carbon steel. The lead of the spiral is 11.568 inches and the spiral angle, 13 degrees 22 minutes. Each groove generated by this hob is similar to a

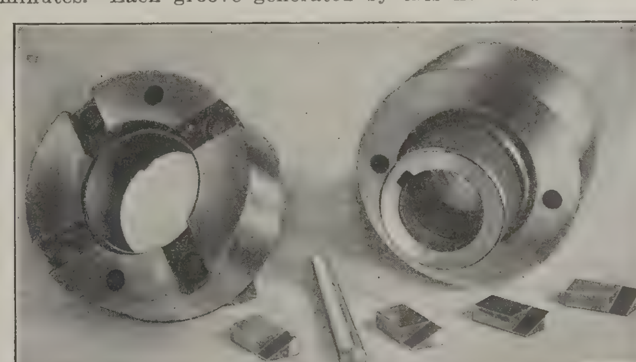

Fig. 4. The Component Parts of the Four-toothed Hob

helical keyway in that the sides on a cross-section taken at right-angles to the axis of the shaft are practically parallel to a radial line passing through the center of the groove. The groove differs in this respect from a theoretically correct thread groove, the sides of which are square on the longitudinal section.

The construction of the hob, as well as the form of the cutters, is shown in Fig. 4, which is a view of the hob before assembling. It consists of a body having a threaded hub over which is screwed the locking ring seen to the left. This ring

contains the tool slots which are ground to size and are accurately spaced equi-distant from each other, in order to secure uniform spacing of the spiral grooves on the shaft. It will be noted that these slots are offset so that the front or cutting face of each tool will be on a radial line. The cutters are made from high-speed steel and the cutter shanks are ground to fit the slots in the locking ring, so that they are interchangeable. The cutting edge is parallel to the axis of the hob and the under side of each cutter has a rather large clearance angle in order to clear the lower side of the groove. When a hob becomes dull, it is sharpened by simply grinding the tops of the teeth.

* * *

CUTTING SPEEDS AND FEEDS FOR TWIST DRILLS

The accompanying diagram originated by Messrs. E. G. Wrigley & Co., Ltd., of Birmingham, England, is published by the *Practical Engineer* (London). It gives speeds and feeds applicable to ordinary practice for high-speed and carbon steel twist drills, when drilling mild steel. As the values given

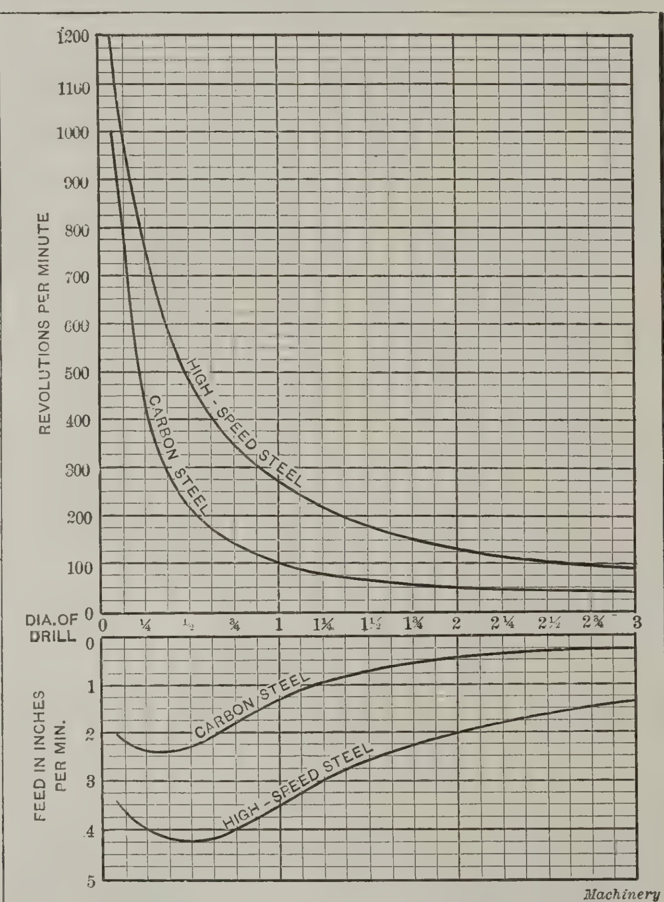

Diagram of Cutting Speeds and Feeds for Twist Drills

are not experimental or test rates, but intended for everyday practice, they may, of course, be exceeded under favorable conditions. It is, however, generally desirable to keep the cutting speed comparatively low, so as to avoid overheating of the drill point, and consequent waste of power.

* * *

The Kempsmith Milling Machine Co., Milwaukee, Wis., caseharden the gears used in the feed boxes of the Kempsmith milling machine. The gears are packed in cast-iron boxes about 12 inches long, 8 inches wide and 6 inches deep with a German casehardening compound. The boxes are provided with a cast-iron cover having a groove for sealing. The groove is filled with clay when the cover is applied and the cover is held in place by two keys engaging lugs at the ends. When the boxes are placed in the furnace they are turned upside down, the purpose being to hold the covers more securely and prevent the gases from escaping. The covers are provided with four lugs or feet at the corners, on which the box rests, and in the reversed position the cover is not likely to work out of shape. The practice works well.

EMPLOYER'S LIABILITY AND WORKMEN'S COMPENSATION*†

Under the common law and employers' liability statutes, employers are held for the consequences of accidents to employes, only provided the employer or his supervising agent is negligent; and not even in such case if the employe has been contributorily negligent or the injury has been due to the negligence of a fellow-servant or co-employe; or in case the hazard was of such a character that it belonged to the usual risks of the occupation which it is considered the employe assumes by accepting the employment. These three defenses are known respectively as the "contributory negligence," the "fellow-servant" and the "assumption of the risk" rules.

Purpose of Workmen's Compensation Acts

The purpose in workmen's compensation acts is to cause the employe, or his dependents in event of his death, to receive compensation on a reasonable basis, without regard to fault. The Court of Appeals of New York held a law making the employer directly liable for such compensation to be unconstitutional as "taking property without due process of law," that is, in this case without the employer having contracted to pay under such circumstances and without his having been guilty of a tort, that is, a wrong which would give the employe a right to recover.

The method of avoiding the effects of this decision, by offering to employers an opportunity to come under a workmen's compensation act voluntarily, it being made advantageous for them to do so, has taken several different forms, *viz.*:

In New York the option was given to employers to whom the compensation act did not directly apply, to avail themselves of its provisions by agreement with employes. There was no special inducement to do this, however, and the rates of premium to cover the risk under the compensation act were so much higher than rates charged by the same companies to cover the risk under the common law and the employers' liability act, that virtually no employers took advantage of the privilege.

In several states—California, Illinois, Kansas, New Hampshire, and Wisconsin—compensation acts have been passed of the usual type; that is, providing for payments of a definite percentage of the wages (usually with a minimum and a maximum for a certain number of weeks, and of a definite amount based upon the weeks in event of death) for all accidents occurring while at work, without regard to fault. Under these laws it was made optional with the employer either to come under the act or not to do so; but in case he did not do so, two of the usual defenses, *viz.*: the "fellow-servant" rule and the "assumption of the risk" rule were abrogated, and in most cases the "contributory negligence" applied only to reducing the damages. In some of these states, *viz.*, Illinois and Kansas, if the employes refuse to be under the compensation act, these defenses are available against him and his dependents.

In three states, Massachusetts, Ohio, and Michigan, laws have been passed offering to employers the election to insure their employes so as to provide compensation to them and their dependents for the consequences of all accidents occurring while at work, without regard to fault. In these states, also, in case the employer does not so elect, the defenses of the "fellow-servant" and "assumption of the risk" rules have been taken away, and also the defense of "contributory negligence," except that in Ohio and Michigan it may be used to reduce the amount of the verdict.

Respects in which Laws Differ

In other respects, the laws in regard to insurance in these three states differ very considerably. Thus in Ohio the insurance must be in a state insurance fund, charging premiums fixed by a board, with the privilege of assessing for more;

* Abstract of a paper read by Mr. Miles M. Dawson, attorney-at-law and consulting actuary, before the fourteenth annual convention of the National Metal Trades Association, New York City, April 11, 1912.

† For a list of articles on industrial accidents and employers' liability, which have previously been published in MACHINERY, see the note accompanying the article published in the November, 1911, number, entitled "The Prevention of Industrial Accidents."

and, of course, with the privilege of taking into account previous payments in fixing payments for future years. In Massachusetts, the insurance may either be in a mutual association of employers under state supervision or in any licensed mutual or stock insurance company. In Michigan the insurance may be in a state fund, in a licensed or stock insurance company, or by the employer himself satisfying the state board that by reason of his resources and the number of his employes, it will be safe to permit him to be the insurer.

In New Jersey, the law provides for the compensation of all accidents occurring while at work without regard to fault, and applies to all employers unless by written notice to a given state officer they elect to remain under the common law and the employers' liability act. If they do so elect, the "fellow servant" and "assumption of the risk" rules are abrogated, "the contributory negligence" rule can only be used to reduce the verdict, and the burden of proving "contributory negligence" is put upon the employer instead of, as previously, the burden resting upon the employe to prove that he was not contributorily negligent.

Under these different laws, elective in form, there have been very different results. Thus, as has been stated, exceedingly few employers accepted the provisions of the New York law.

In New Jersey, on the contrary, since it took an act upon the part of the employers to keep from going under the law, a very large proportion of them have accepted its provisions; but some large employers have refused to do so, among others the Standard Oil Company, while some other employers have obtained more advantageous rates by refusing to do so. There is no provision under the New Jersey law for mutual insurance. Consequently, a number of New Jersey employers have joined together to organize a stock company in which to insure themselves, hoping thereby to get lower rates.

In California, there is a good deal of complaint that the rates under the workmen's compensation act are materially higher than under the common law and employers' liability act, even with the defenses abrogated; and consequently many employers have not elected to come under the former. This complaint is also made in other states, notably Wisconsin, where, however, mutual companies are being organized under the encouragement of state authorities; and Ohio, where the stock insurance companies are making as strong a fight as possible to keep the business from going to the state insurance fund. The Michigan and Massachusetts acts have not yet taken effect.

In the state of Washington a compulsory insurance act took effect on October 1, 1911, requiring all employers to whom the act applies to insure with the state insurance fund. For the purpose of the fund they are divided into a good many classes, each of which must pay its own claims. In consequence, a few classes already show a deficit, but most of them show a surplus. The total premiums collected amount to about $500,000, the payments and reserves for sums payable hereafter on account of claims already arising amount to about 30 per cent, and expenses to about 15 per cent. The Washington law differs from the other laws in one other respect, *viz.*, that the amount payable in event of disability, *viz.*, from $20 to $35 per month during disability, and to the widow for herself and children, from $20 to $35 per month, varies not according to the wages, but according to the number of dependents.

In Montana, an act is in effect providing for certain rates of compensation to be paid to miners through the medium of compulsory insurance in a state fund, each employe, however, or the dependents of an employe killed by accident, having a right to elect, after the accident occurred, whether to accept this compensation or proceed under the common law or employers' liability law.

In the state of Nevada, notwithstanding the decision of the Court of Appeals of New York, an act was passed, requiring, subject to reduction of amount in event of "contributory negligence," all accidents occurring while at work which are not compensated under the common law or employers' liability law, to be compensated to the amount during disability of 60 per cent of the wages for a time until a maximum amount of $3000 is paid, and in event of death, a minimum of $2000 and a maximum of $3000.

Recommendations of Commissions

In addition to these plans, which have already gone into effect, bills have been introduced upon the recommendation of commissions, as follows:

In Congress a bill has been introduced to do away with liability at common law and under the employers' liability act, and to substitute a workmen's compensation act, calling for compensation for all accidents occurring while at work, without regard to fault. This will apply to railways only.

In Maryland a bill has been introduced by the commission which also seeks to repeal the common law, and employers' liability act, and to hold employers directly liable for compensation for all accidents occurring while at work, without regard to fault. This bill also makes provision for transferring the liability to mutual or stock insurance companies, and provides that if this is not done, all employers with less than $150,000 resources over and above all liabilities, or employing fewer than 1000 men, shall be required to insure in a state insurance fund. Provision is made for the compulsory insurance feature to apply to all employers in case the portion of the law, holding the employer directly liable, should be declared unconstitutional.

During the past year, the question of the constitutionality of some of these acts has been before the courts and decisions have been rendered as follows: In Massachusetts, the matter was submitted by the legislature before the act was passed, to the Supreme Judicial Court—which may be done in that state—and the proposed act was held to be constitutional. In Ohio the elective insurance act has been before the Supreme Court and has been held to be constitutional. In Washington, the compulsory state insurance act has been before the Supreme Court and has been held constitutional. In Wisconsin, the elective workmen's compensation act has been passed upon by the Supreme Court, and has also been held to be constitutional. In New Jersey, the lower court has passed upon the law and found it to be constitutional.

In Montana, the state insurance act, applying to coal miners, was upheld as constitutional in all respects but one, *viz.*, that it was discriminatory, and in violation of the rights of employers as depriving them of property without due process of law, in that, although an employer might have paid his premiums, his employes and their dependents might, at their own free will, sue him at common law and under the employers' liability act, and hold him responsible so that he would not receive any benefit from the insurance for which he had paid.

The benefits provided under these various acts vary as follows: Temporary disability, from 50 per cent of the weekly earnings, with a $4 per week minimum, and $10 per week maximum in Massachusetts, to 66 2/3 per cent of the weekly wages in Ohio, with a $5 minimum and $12 maximum. Six of the states fixed the percentage at 50 per cent, one at 60 per cent, two at 65 per cent and one at 66 2/3 per cent. The term of payment varies from 300 weeks in New Hampshire and New Jersey to the entire period of disability in Illinois (where the amount payable after eight years, however, is reduced), Ohio and Washington. The maximum amounts of total disability compensation when named in the laws, range in the neighborhood of $3000, except where compensation is payable throughout the disability, when no such limit applies.

In two states, New Jersey and Wisconsin, the employer, if under the workmen's compensation act, has no other liability. In other states his additional liability ranges from "intentional violation of a safety law" in Illinois, or "serious or willful misconduct of employer or his superintendent" in Massachusetts, to liability in all cases where the "employer is liable for damages under other liability laws" in Nevada. The employe is excluded from right to benefit on account of willful misconduct only in California, Illinois, Kansas (where it is limited to certain acts of misconduct), Massachusetts, Ohio and Wisconsin. In New Hampshire, intoxication also excludes, and in Nevada, wherever "contributory negligence" was solely responsible for the accident, that is, where it was wholly the fault of the employe injured.

In one state, Washington, where there is compulsory state

insurance, compensation is payable from the first day. In California, Illinois and Ohio the first week is excluded and in Wisconsin also unless disability lasts longer than four weeks, in which case the first week is also included. In Kansas, Massachusetts, New Hampshire and New Jersey, the first two weeks are excluded and in Nevada the first ten days, unless the disability last longer, in which case apparently the first ten days are also paid for. In all the states excepting New Hampshire, where to recover under the act calls for an action in equity (not requiring a jury) instead of an action at law, and New Jersey, where the court is directed to decide the matter "in a summary manner," an accident board is set up or a provision is made for arbitrators to make an award before the matter can be taken to the courts.

In the following states commissions have been appointed and are now at work upon bills to be introduced in the next legislatures, *viz.* Pennsylvania, Colorado, North Dakota, Missouri, Iowa, West Virginia, Nebraska, Connecticut, Rhode Island and Delaware. It is said that the Missouri commission has abandoned the task, no appropriation having been made. In Texas the governor was asked to appoint a commission to report to the legislature at its then session, but no appointment was made.

In Canada, all the provinces have now adopted workmen's compensation acts excepting New Brunswick and Ontario. In New Brunswick the employers' liability act was much extended in 1909 by modifying the defenses. The Canadian workmen's compensation acts hold the employer directly liable. In Ontario, the Chief Justice of the High Court has been appointed a sole commissioner to report a bill. The Canadian Association of Manufacturers and the representatives of workmen's associations have been before the commission and have joined in recommending a system of compulsory mutual insurance, through funds covering all sickness as well as accident during the early weeks, to which both employers and employes would contribute, and a fund covering death and disabilities beyond the first few weeks, due to occupation accidents only, to which employers will alone contribute. The Commissioner has just handed in a preliminary report, expressing favor for this plan.

European Laws Changed

In Switzerland, where for more than ten years past employers have been held directly liable for negligence, with the defenses abrogated, a compulsory insurance act has been passed, submitted to the people at a referendum and adopted by them. It provides for insurance against sickness as well as accident, covering the first few weeks, to which both employers and employes contribute, and for insurance covering death or disability beyond the first few weeks, due to occupation accident, to which employers only contribute. The state, however, makes contributions either directly or by meeting certain expenses in connection with each of these.

In Great Britain, no change has been made in the workmen's compensation act, which holds employers directly liable for the consequences of all accidents and some occupation diseases "arising out of and in the course of the employment;" but the principle of compulsory mutual insurance has been accepted with much favor, practically all the representatives in both houses of both the political parties voting for it, in the form of two laws, one requiring workmen to be insured against sickness and invalidity, and the other requiring them to be insured against unemployment. Toward these mutual insurances, the employers and employes both contribute, and the state also makes a contribution.

The main lines of the German system are as follows:

That accidents (during the early weeks of disability) should be compensated as well as all sickness, through sickness insurance societies to which employers and employes both contribute, and subject to their joint management.

That disabilities beyond the first thirteen weeks and all deaths due to accident while at work should be compensated through mutual associations of employers, to which employers only contribute and which are managed by them.

That as to both of these classes of associations, no more should be collected than is necessary to meet the requirements for the payments currently falling due, plus what is required for expenses, and a moderate amount in addition for the purpose of establishing a reserve, not intended to take care of future payments on account of claims already approved, but only to be called upon in event of a great and widespread disturbance of industry, so that many employes would be out of work and the payrolls of the employers low, in which case, if there were no such provision, obviously the rate of assessment might be very high.

The superiority of this system in economy of management, general efficiency, special efficiency in regard to prevention and the all-important respect of putting upon industry the smallest possible burden currently, was strongly supported both by representatives of employers and of employes, as well as by practically all who, from official or private viewpoint, have carefully investigated the matter.

It is proper here to say that none of the insurance plans so far introduced in the United States are of the same character. Thus the plan adopted in Washington, while dividing the employers into classes, leaves the management in the hands of a state commission. Moreover, the aim is to collect a sufficient amount to set up capitalized values for death claims and presumably, though not avowedly, also to hold sufficient reserves for payments thereafter to be made upon other claims. Certainly there is no indication that an "assessment" system, calling for no more money than is actually required for current payments, was in any sense intended.

The same is also true of the state insurance plan in Ohio. The law there does not require in definite terms the setting up of capitalized values, but from the nature of the system adopted, this is strongly implied. In Massachusetts, a distinct provision is made in the law for setting up capitalized value reserves and charging the state insurance fund with its unearned premium reserves, in the same general manner as would be applied to a private insurance company, whether mutual or stock. Under the state insurance laws of Montana and Maryland relating to coal miners, no special provision was made.

All of these appear to look for the plan to go into full effect from the outset, that is, the full burden falling upon industry from the beginning. Under the German plan, on the contrary, the idea was that the cost would be small at the outset, because only persons who were injured that year would be drawing money. It would be larger the second year, because then persons who were injured the first year and persons who were injured the second year would be drawing money, and in this way the cost would continue to increase for several years until an equilibrium was struck, which, if the risk remain precisely the same from year to year, would not be until from 25 to 50 years had passed.

This condition might be—and in many cases has been—very greatly modified by the introduction of excellent prevention, offsetting this natural increase by reducing the number of claims. A good illustration in steam railways, which started the first year at a cost of 0.39 per cent of the payroll, was 0.79 per cent the second year, 1.26 per cent the third year, and so on, reaching 1.80 per cent in the eighth year. This resulted in prevention so remarkable in character that there was an actual recession of the rate for several years, going down to as little as 1.26 per cent, notwithstanding that they were paying for persons who had been injured (and for the widows of those who had died) in every one of the twelve years previous. Since then, the rate has again increased, but for six or eight years past it has been about 1.80 per cent of the pay-roll—not higher than fifteen years before.

* * *

Calbraith P. Rodgers, the noted coast-to-coast aviator, was killed April 3 by a fall from his aeroplane, resulting from the attempt to perform a difficult spectacular evolution in the air over the beach at Los Angeles, Cal. Rodgers started for the Pacific Coast, September 17, 1911, from Sheepshead Bay, Long Island, and covered 3220 miles after many mishaps and accidents, but too late to win the $50,000 prize offered for the performance of the feat. Rodgers is the seventeenth victim of aviation this year, and the one-hundred and twenty-sixth since Lieut. Thomas E. Selfridge, the first, was killed near Washington, D. C., September 17, 1908.

DIES FOR RAISED LETTER NAME PLATES*

By CHESTER L. LUCAS†

Aside from the manufacture of the Sweetland chuck, for which the Hoggson & Pettis Mfg. Co., New Haven, Conn., is well-known, there is another line of work carried on in its factory that is of interest on account of the high degree of manual skill required to produce it. This work is the cutting of artistic steel stamps, a few impressions of which are shown in Fig. 1, and the making of dies for raised letter name plates, such as are shown in Fig. 3.

While it is the purpose of this article to treat especially of the methods used in the making of the name-plate dies, some

Fig. 1. Impressions of Artistic Stamps

of the stamp impressions shown are of considerable interest. It is difficult to illustrate such work to advantage. Of the impressions shown in Fig. 1, all of the script lettering is very difficult to cut in steel, for, of course, it must be cut "reverse," still maintaining its style. Monograms like some of those

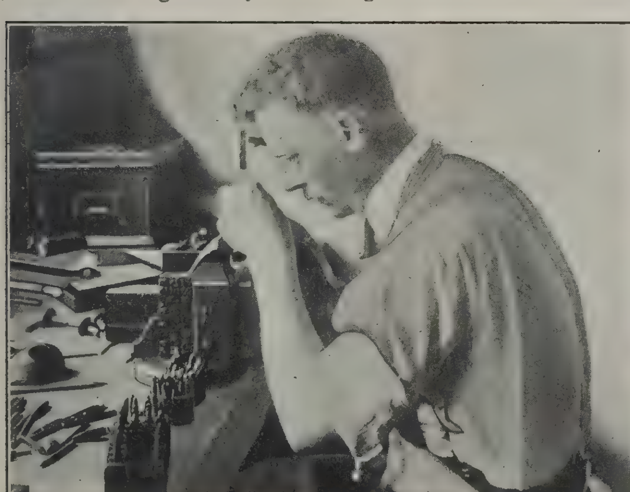

Fig. 2. Making Steel Stamps

shown present difficulties of their own, for the various lines must cross and re-cross without breaks or deflections from their true directions. The "Old English" style of lettering is also difficult to produce in steel, and when the letters of a stamp are minute, as well as of difficult shape, like the small "Tannewitz" stamp near the center of Fig. 1, the troubles of the workman are not imaginary. The illustrations of the stamp impressions shown are considerably larger than the originals. Fig. 2 shows a workman engaged in making one of these stamps.

The name plates or brass labels, as they are sometimes

Fig. 3. Specimens of Raised Letter Name Plates and Labels

called, are usually made of very thin brass or aluminum, approximately 0.005 inch thick. They are used as name plates for light machinery, such as graphophones, sewing-machines etc., and for fire extinguishers, tanks, etc., to which they may be soldered. Still another use is in connection with the mold-

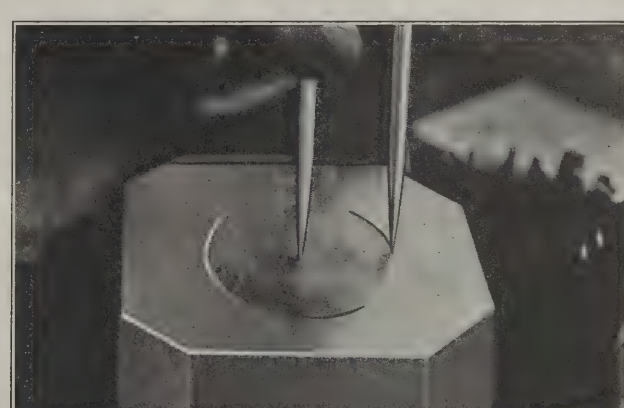

Fig. 4. Using the Cutting Dividers

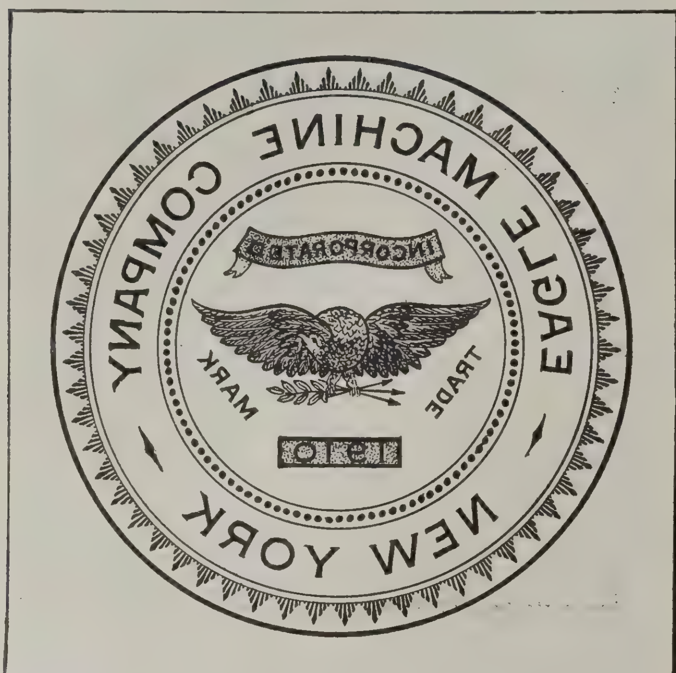
ing of rubber articles such as hot water bottles, when it is desirable to have lettering appear on the finished surfaces. As in other classes of die-work, the tools used for embossing these name plates comprise two parts, *viz.*: the die and the "force." In the majority of cases machine steel is employed for the dies, tool steel being used only for those dies which have a great deal of small detail or from which labels of thick material are to be made. If the die has been made from machine steel, the forcer, or force, as it is usually called, is made from soft white metal, but if the requirements of the work call for a hardened die, the force should be of brass or steel. Usually, however, machine steel dies and white metal forces is the combination employed. If the labels are to be used in mold-making, the reverse side of the plate must be

* For articles on kindred subjects, see MACHINERY, April, 1912, "Brass Engraving by Machinery"; January, 1912, "Steel Letter Stamping Dies"; and June, 1909, "Coin and Medal Dies."
† Associate Editor of MACHINERY.

just as good as the front side, for the letters are formed on the rubber by means of its contact with the reverse side of the label.

Making the Die

The steel block from which the die is made is first faced off carefully and its surface coppered or blued, so that the laying-out lines may be easily seen. Let us assume that we are two stamping units is to provide a means for properly spacing the impressions. After the first two impressions, but one impression is stamped at each blow, half of the punch being used as a spacer, after the manner of a spacing center-punch. As soon as the entire border of beads has been stamped in, a single beading tool is used to go over the impressions, leaving each bead perfectly shaped. After each of these two stamping



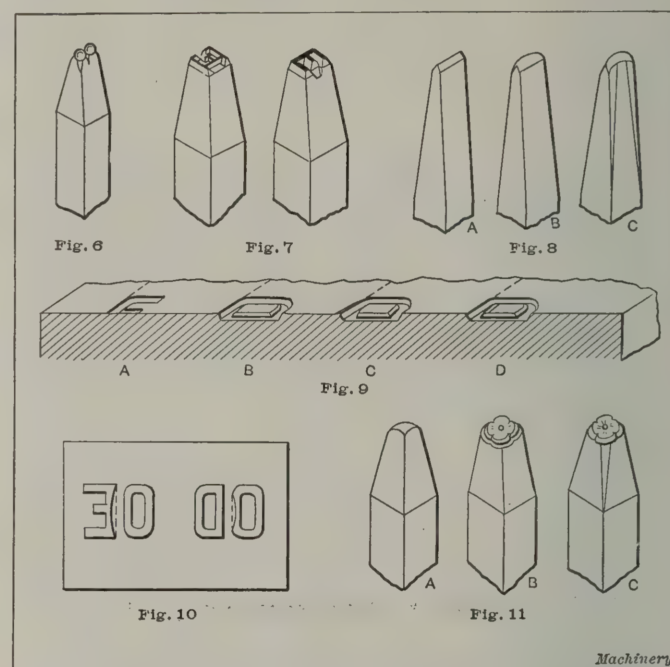


Fig. 5. The Face of a Name-plate Die. Fig. 6. A Double-bead Punch. Fig. 7. Comparison between a Die Letter and an Ordinary Stamping Letter. Fig. 8. Three Types of Lining Tools. Fig. 9. Illustrating Points in Stamping. Fig. 10. How Close Stamping displaces the Steel. Fig. 11. Three Steps in Making a Punch

to make a die for the design shown in Fig. 5. The reason for selecting this particular design is that it involves a number of the different methods of die-sinking that are not often employed on one design.

After the main lines of the design have been laid out on the die, faint circles are scribed with cutting dividers to guide the die-sinker in stamping the fancy border near the outer edge and the bead border between the lettering and the design. operations, the burr raised by stamping is faced off with a file.

Often the design is surrounded with a plain line-border. If the design is circular, such a border may be cut with the cutting dividers, but if rectangular or of other than circular shape it must be punched in with a lining tool or a straight-line punch in the manner shown in Fig. 12, the punch being moved ahead half its length after each imprint. Should it be necessary to have a wide flat border, it is best to chip out

Fig. 12. Stamping the Lines of a Design

Fig. 13. Making a Punch from a Master Block

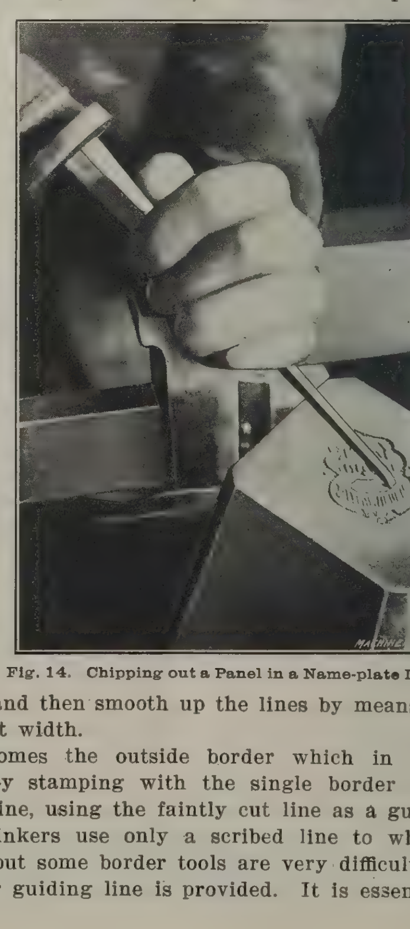

Fig. 14. Chipping out a Panel in a Name-plate Die

This operation is shown in Fig. 4. The cutting dividers are merely an old pair of dividers, one leg of which has been ground with a cutting lip. This tool is very convenient for cutting grooves. The plain line borders and other circles are not cut at this time.

In stamping a bead border like the inner border shown, a double punch is made use of. One of these double punches is illustrated in Fig. 6. The object in making the punch with most of the metal, and then smooth up the lines by means of a punch of the right width.

Next in order comes the outside border which in this instance is made by stamping with the single border tool around the border line, using the faintly cut line as a guide. A good many die-sinkers use only a scribed line to which to stamp a border, but some border tools are very difficult to use, unless a deeper guiding line is provided. It is essential

that the border shall "come out even," that is, that it shall be spaced uniformly at every part of the circle. It is customary to employ double punches only for bead or rope borders, because the units of other borders are so much larger that trouble would arise in spacing the last few units. Nine out of every ten borders of name plates are, however, either plain, beaded, or of rope pattern.

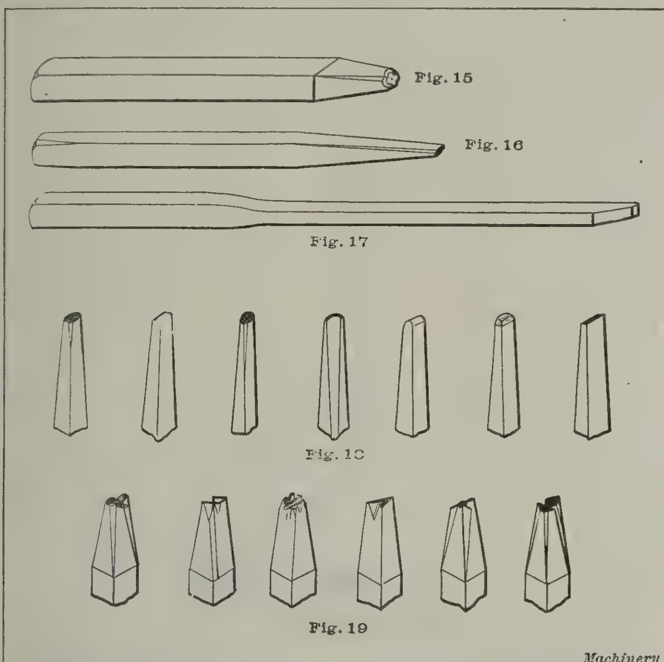

Fig. 15. Proportions of a Punch 3 1/2 inches Long. Fig. 16. Proportions of a Chasing Tool 4 inches Long. Fig. 17. Proportions of a Chisel 6 inches Long. Fig. 18. Various Styles of Chasing Tools. Fig. 19. Various Border Tools

Before stamping the last few units of a fancy border, the die-sinker usually measures the remaining space with his dividers and compares it with a section already stamped, to see if it will be necessary to space the remaining units differently in order to make them "come out even." Sometimes the last few units must be spaced either closer or farther apart

Fig. 20. Taking a Wax Impression to get the Effect of the Finished Work

Fig. 21. Working on the Design—Using a Chasing Tool

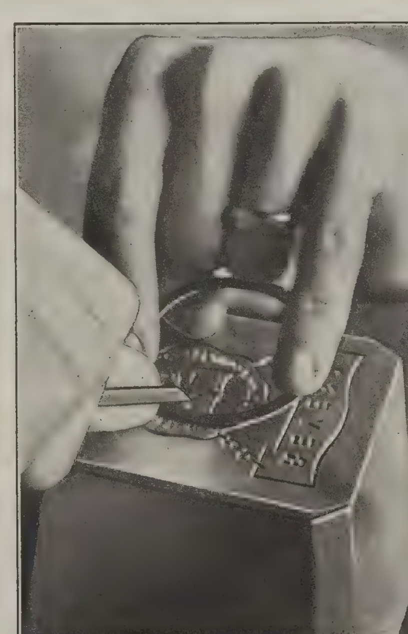

Fig. 22. Working on the Design—Using an Engraving Tool

to avoid having half a unit left over. This half-unit of blank space would be very noticeable if not distributed over several units. Referring to the design, Fig. 5, it will be noticed that the border has been spaced very evenly except between the points directly over the "L" in "Eagle," and the "H" in "Machine." Within this short distance the six units have been slightly spread to make up for the half unit that would otherwise have been left over. This slight discrepancy in spacing is not noticed by those not familiar with die-making. Samples of border tools are shown in Fig. 19.

Stamping in the Letters

The borders being successfully stamped in, attention is directed to the lettering. From the center point of the design, if circular, limiting circles for the letters are scribed. While great care is taken to make the limiting circles for the letters of correct dimensions, the letters themselves are only roughly spaced. If the lettering is different from any that the die-sinker has previously stamped, it is well to first stamp the letters lightly upon cardboard, although a very common way is to merely count the letters and spaces, and start the stamping with the central letter upon the central dividing line of the design, which in Fig. 5 runs through the "I" in "Machine."

In stamping in these letters, the eye is almost entirely depended upon for getting their positions right. The faces of the letters on the stamps are made different from ordinary stamping letters, in that they are not reversed and also that they are not sharp-faced, but have narrow flat faces. A comparison between steel stamping letters and die letters is shown in Fig. 7. In stamping, the stamp is held with the bottom half of the letter even with the line, being tipped slightly toward the stamper. After striking the stamp lightly in this position and having found it to be in the proper location relative to the line as illustrated at *A*, Fig. 9, it is refitted into the lightly stamped impression, tipped up straight and the other half of the letter struck in, the result appearing as at *B*, Fig. 9. If, however, the first impression is not in line or is crooked, it may be corrected by the stamp being moved slightly in the proper direction. Two of these corrected impressions appear at *C* and *D*, Fig. 9. The lighter that the preliminary stamping is done, the better. After all of the letters have been lightly stamped, they should all be driven in to a uniform depth of 1/64th inch, taking care to have all parts of the lettering of even depth.

All stamping of any kind displaces the stock immediately surrounding the letter stamped. Some of the metal rises above the surface of the die in the form of a burr, and some is crowded away at the sides, often distorting a letter that has been previously stamped. Especially is this true when the lettering is closely spaced. To overcome this trouble, it is best, after stamping a letter, to go back to the preceding letter and re-stamp it lightly. This will throw the displaced steel upward in a burr. If, however, the letters are very closely spaced, this re-stamping will simply push the metal back into the new impression, and to avoid this, the displaced steel should be cut away, as indicated by the dotted lines in Fig. 10, after which a tap with the stamp will finish the work.

As already mentioned, those lines which are not circular arcs must be stamped or traced with a straight-line punch or a lining tool. Lining tools are of three distinct varieties, shown in Fig. 8. *A* is for straight lines; *B*, for slightly curved lines; and *C*, for very sharp curves. If the faces of these lines must

be flat or curved, special lining tools may be made to suit the work. The panels in the central part of the design shown in Fig. 5, may be outlined and the two dashes at the ends of "New York" may also be stamped. Other parts like the arrows and the leaves may also be easily stamped by making one or two special punches, thus saving considerable time that would otherwise be spent in hand-engraving this part of the work.

Making Special Stamping Tools

Special stamping tools should be made of Jessop's steel, if possible, using square bar stock for all standard punches except those that are very large. Generally speaking, these stamping tools, exclusive of those for the die letters, may be divided into two classes: punches and chasing tools. The general proportions of these tools are shown in Figs. 15 and 16, and although every die-sinker has his own ideas, those shown will be found to be of about the average type. Moreover, while every die-sinker would like to have his tools of standard lengths, they are constantly subject to breakage, and if redressed are consequently shorter, until, if care is not taken, chasing tools and punches will be of "all lengths." The chisel in Fig. 17 is six inches long.

Chasing tools, a box of which is shown in Fig. 12, should be made about four inches long. They should be of various shapes, a few of which are shown in Fig. 18, and there should be several sizes of each shape. The sides are filed with very little bevel as they are made to do very little work, their chief use being in smoothing up the design in the die. These tools should be hardened and drawn to a dark straw color.

Punches should be made about three and one-half inches long and of much heavier steel than chasing tools, as they have to be driven into the die. While many designs must be originated, a good deal of time can be saved by using a master block like that shown in Fig. 13, to aid in making special tools. This block is hardened. A blank punch is filed so as to have its face

Fig. 23. Lettering a Mold for Rubber Heels

slightly convex as shown at *A* in Fig. 11; it is then driven into the proper impression which will form the design on the end, leaving it in the condition shown at *B*; and lastly, the steel around the design is filed away to the proper bevel and the punch, as shown at *C*, is ready to be hardened. After hardening, the temper should be drawn to a medium straw color, unless the design is deep, when it may be drawn still more.

Fig. 20 shows a die-sinker taking a wax impression of his work, in order to see how it is going to look on the finished name plate. The best and cheapest way to obtain this wax is to purchase a pound cake for thirty cents; a pound will last for years. Receipts for making this impression wax are given in MACHINERY'S "Shop Receipts and Formulas." The wax is used on the end of a short block of wood. The die-sinker cleans out the die, breathes on its face to form a film of moisture, and then drives the wax into the impression. Upon gently removing the block, the wax is removed and every detail of the work may be plainly seen. While stamping in the lettering, impressions are frequently taken to indicate those letters which are uneven in depth or crooked, so that they may be corrected.

After the stamping of the letters, borders and other parts has been finished, the next step is to cut any rings or grooves like those shown in the design in Fig. 5. If there are a large number of these rings, or if they are deep, it is best to set up the block in the lathe and turn them, but for dies that have only two or three such rings, they can be cut more easily with the cutting dividers. The reason for leaving the cutting of these rings until after the stamping has been finished, is to avoid distorting them by displacing the metal during the stamping.

Engraving the Design

The most difficult part of the making of a die of this character consists in engraving those parts that cannot be stamped. In the design shown in Fig. 5, this part is, of course, the eagle. The first step consists in facing off the surface of the steel very smoothly, after which the design is very carefully drawn. The outlines are then cut lightly with an engraving tool, and if the design is deep, chisels are employed for cutting out the bulk of the steel, as shown in Fig. 14. The general proportions of these chisels are shown in Fig. 17, and the shapes

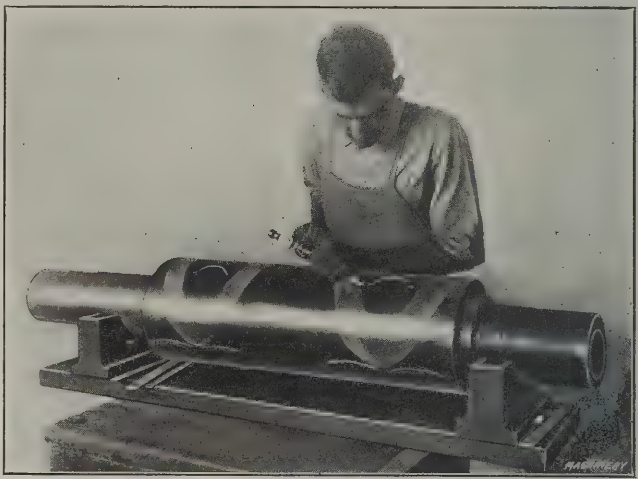

Fig. 24. Cutting the Pattern on a Calender Roll

most often used are the flat and half-round. The final finishing of the details is accomplished by means of chasing tools used as shown in Fig. 21, and by engraving tools as shown in Fig. 22.

Engraving tools of various shapes and sizes are employed for the different angles and curves of the design. The ring used in Fig. 22 protects the design from the under side of the tool, and is especially useful in sinking deep dies. Frequent wax impressions are taken to aid the die-sinker in perfecting the details of the design.

The very last step in the work consists in "matting" such places as the panels shown in the design in Fig. 5. Matting tools are varieties of chasing tools used in pebbling or matting parts of the die in order to form a contrast with the smooth parts. After matting, no filing can be done on the surface of the die, as this would injure the delicate finish left by the matting tools.

Specimen labels may be struck from the die before the top die, or force, has been made, by placing the die under a small drop press, or a screw press, laying the blank name plate upon the die, and placing either a piece of sheet lead, 1/8 inch thick, or a piece of leather belting, over it. By striking several blows upon this soft backing a good specimen of the work that will be produced by the die will be obtained.

Should the die require hardening, it should be done in the manner described in the article "Coin and Medal Dies" that appeared in MACHINERY for June, 1909.

Making the White Metal Force

While the most difficult part of the die is the engraving of the lower block, it is just as essential that the force which is used be fitted properly and that it fill the design in every detail, so that it will be possible to strike up labels or name plates that will be perfect on the reverse side as well as on the face side. This is important on dies of this character, because the metal from which the labels are made is very thin and will not be forced into the design unless it is backed up in every detail by the force.

White-metal forces are made by first fitting the face of the die with a temporary wall, usually made of pasteboard. Into this enclosure molten white metal is poured until it has reached the depth of approximately 3/8 inch. The white-metal force is then struck into the die under a drop or screw press, after which it is ready for use.

The labels themselves are struck up by holding the die in the screw press, the die block being held by screws in a bed-plate, and the white-metal force being held to a flat block in the ram of the press by means of the contact secured by a thin film of beeswax. The thin brass is cut into squares large enough to make the labels, and each of these squares is in turn laid upon the die and the ram of the press brought lightly down so as to force the brass into the design of the die.

If the work is of such a nature that the die must be hardened, the force should be of copper or steel, and as the making of such forces involves many different processes, this phase of the matter will be described in a later number of MACHINERY.

Figs. 23 and 24 illustrate phases of die-sinking operations in connection with rubber mold work. In Fig. 23 the workman is lettering a mold for rubber heels, the work being done in the same manner as the die work just described. Fig. 24 shows the way in which the outlines of rubber shoe patterns are cut on a calender roll with chisels. Afterwards the lines are smoothed with punches, and the surface of the roll filed smooth. Thus, when the plastic rubber is rolled under one of these calender rolls, the rubber sheet emerges from the other side of the roll with the patterns outlined on it, ready to be cut out and put together.

SPECIAL MEETING OF THE A. S. M. E.

A special meeting of the American Society of Mechanical Engineers was held in the auditorium of the Engineering Societies Bldg., New York, April 9 in honor of the commission of the German Museum of Masterpieces of Natural Sciences and Technical Arts, visiting America. An illustrated lecture prepared by Dr. Oscar Von Miller on the work of the commission, was read by Mr. Charles Whiting Baker. The lecture described the German Museum at Munich, Bavaria, its aims and methods. The method of the German Museum is to correlate and arrange machinery, apparatus, architecture, processes, industries, etc., in order of development and thus produce progressive historical presentations of the arts and sciences to date. This admirable conception has been carried out with characteristic German thoroughness, and the views illustrating the lecture, showed the arrangement of interesting mechanical groups, chemical apparatus, astronomical instruments, etc. Of special interest was the reference to means by which visitors can demonstrate the working of a machine or a chemical reaction by simply pressing a lever or knob.

The importance of preserving in convenient locations the progressive developments of the arts, can hardly be overestimated. The history of inventions thus shown in concrete form should serve in many cases to prevent inventors and manufacturers from making serious mistakes by developing old ideas over again and thus wasting time and effort needlessly. Museums developed on these lines become educational institutions of high order instead of show places for jumbled and unrelated things.

* * *

According to *Eastern Engineering*, screws are still made in India just as they were made hundreds of years ago, that is by winding two soft wires side by side around a mandrel. The wires are then carefully separated and one of them is soldered to the inside of a tube, which then will form the nut, while the other is soldered to a mandrel or rod. All the screws are left-handed, because they are wound over and over by the right hand.

* * *

Owing to the limited knowledge of many draftsmen as to the qualities of materials used in machine construction, there seems to be a tendency to specify better materials on drawings than are actually necessary for the part. Thus, frequently, tool steel is called for where machine steel, case-hardened, would serve the purpose equally as well—and sometimes better.

DIFFERENTIAL MECHANISM ON GEAR HOBBING MACHINES*

By WILLIAM NATISCH†

The writer has read many articles relative to gear cutting machines of different constructions, but has not seen any comparison made between a hobbing machine with differential mechanism and one without it. A great number of mechanics do not know how important it is to have a differential mechanism—or simply a "differential"—on gear hobbing machines. If we take time-saving and accuracy into consideration, a differential mechanism which combines the indexing and helical feeding movements of the table is absolutely necessary. We would not need this extra adjustment for the helical movement if there were no prime numbers between one and ten million.

When generating helical gears on hobbing machines without differential, the required ratio which combines index and feed gears must be calculated at least with 7 decimals, as otherwise a large error will result which will impair the accuracy of the gears. It frequently happens that the required ratio consists of prime numbers, especially when cutting right- and left-hand gears with one hob. To produce correct helical gears with their axes standing parallel to each other, the errors for the right- and left-hand spirals must be absolutely the same, otherwise there will not be a bearing on the whole length of the teeth. In fact, exactly the same conditions exist with helical gears as with spur gears. If, for instance, the teeth of one of two spur gears stood at an angle of only 5 seconds with its axis, the bearing would be at one end of the teeth only.

Furthermore, if the hobbing machine has a differential, it is not necessary to have a right- and left-hand hob when cutting any angle up to 30 degrees; on the contrary, a higher efficiency is obtained when using only one hob for both right- and left-hand spirals. The reason for this is very simple: if there is any distortion in hardening, the right-hand hob will be different from the left-hand.

It has been mentioned before that the ratio must be calculated to at least 7 decimals when cutting the gears on machines without differential. The belief of many mechanics that the ratios and errors obtained by formulas are alike for all hobbing machines, with or without differential mechanism, is entirely erroneous. There is a great difference between the two ratios. In the one case the ratio represents the value of the indexing and the helical movement, and the slightest change of the "driver," *viz.* numerator, will cause a great error if the "driven," *viz.* denominator, is not also changed in the same proportion. In the other case, *i. e.* with the differential, the ratio obtained refers to the angle or helical movement only, and adds or subtracts itself automatically to or from the ratio of the indexing gears. The indexing gears required for cutting helical gears are given on a chart and can be read off the same as for spur gears. This is impossible without the differential. The difference between the two ratios is explained in the following example.

Example:—Gear, 48 teeth; 10 pitch; 20 degrees; 1/16 inch feed per revolution of table.

Gear ratio of machine with differential for 20 degrees = 1.2052784.

If we deduct 1 from the third decimal which is 5, and omit the rest, we have 1.204 = ratio for 19 degrees 58 minutes 42 seconds; *i. e.*, 1 minute 18 seconds difference.

This shows how slight the error would be if we were to change the third decimal; in practice the change is made on the fifth decimal, and the error almost eliminated.

For the same pitch, number of teeth, angle and feed, the gear ratio for one of the machines without differential equals 1.2517385. If here we were to deduct 1 from the third decimal and omit the rest, the result would be that instead of generating teeth the material would simply be milled off from the blank. This is explained as follows: Gear ratio for 20 degrees is 1.2517385. When deducting 1 from the third decimal we obtain 1.250, which is the spur gear ratio.

* See MACHINERY, December, 1911, engineering edition: "Calculating Gears for Generating Spirals on Hobbing Machines."
† Address: Care of Schuchardt & Schütte, 90 West St., New York.

The Schuchardt & Schütte gear hobbing machines are provided with a differential which on the new type of machines is independent of the feed and indexing; in other words, when changing the number of teeth, or feed, or from right- to left-hand gear, no calculation is required. Thus the great advantage of the differential mechanism is that the helical movement is not disturbed whatever when the number of teeth is increased or decreased or the feed is changed. Suppose we intend to generate helical gears with 30, 40, 56 and 60 teeth, of which those having 40 and 60 teeth are left-hand, and those having 30 and 56 teeth are right-hand; the spiral angle is 15 degrees; the pitch is 10. The material is supposed to be cast iron; therefore, 1/16 inch feed per revolution of the table would be selected as the proper one. All the gears are to be cut with one right-hand 10-pitch hob. In calculating the change gears used when generating these gears on the Schuchardt & Schutte machine but a few minutes will be required, the following formula being used:

$$\frac{\text{Constant} \times \text{sine of angle} \times \text{pitch}}{1} = \text{ratio.}$$

$$\frac{0.3524 \times 0.25882 \times 10}{1} = \frac{912}{1000} = \frac{19 \times 48}{20 \times 50} = \frac{\text{driving gears}}{\text{driven gears}}$$

On machines not provided with a differential mechanism, every gear of the same pitch, with only a different number of teeth, must be calculated for separately, and the slightest change in the feed will require a separate calculation. A change in the formula must also be made, if right- and left-hand gears with the same number of teeth are cut with one hob.

The differential is also of great importance when cutting worm-gears with a taper hob. Worm-gears for worms with multiple threads ought to be generated with taper hobs if high efficiency is required. The writer believes that hobbing machines without differentials will disappear after the patent expires.

HANDLING A LARGE JOB OF MILLING ON A SMALL MILLING MACHINE

By CHESTER L. LUCAS*

The casting shown upon the table of the Van Norman duplex milling machine that appears in the accompanying illustration is the main casting for a wood screw threading machine, designed and built by H. P. Townsend, Hartford, Conn. The casting was first milled on the under side to provide seats

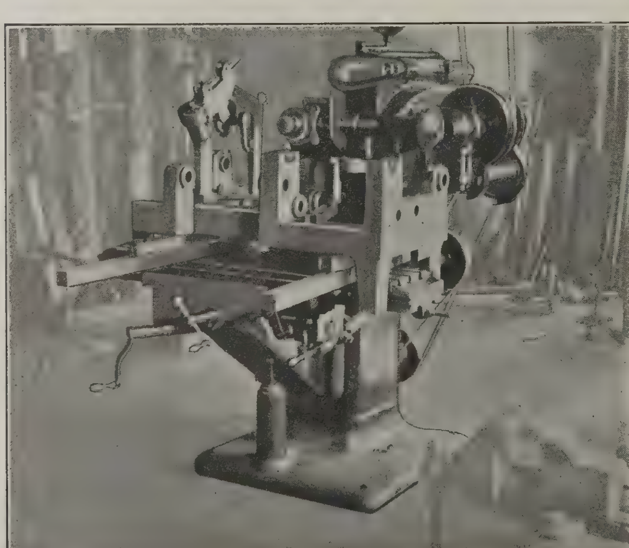

Fig. 1. The Work Set up for Milling the Tops of the Bearing Posts

to receive the parallels. The piece was then set up as shown, and by means of the vertical attachment the tops of the boxes and several bosses and raised panels that were located between the bearing posts on the bed of the casting were faced off. Next the casting was clamped on the table of the machine in a position at right angles to the one shown and the end of the casting faced off, after which the casting was reversed and the opposite end machined. In this latter position the holes that may be seen through the end of the casting and the bearing posts were bored and counterbored by means of suitable boring-bars. When setting up for boring the holes which were farthest away from the head of the machine, it was found that the overhanging arm was not long enough to support the end of the boring-bar; consequently an improvised bracket was brought into use and clamped to the end of the casting. By means of a bearing hole, which was in line with the holes to be bored in the main casting, the end of the

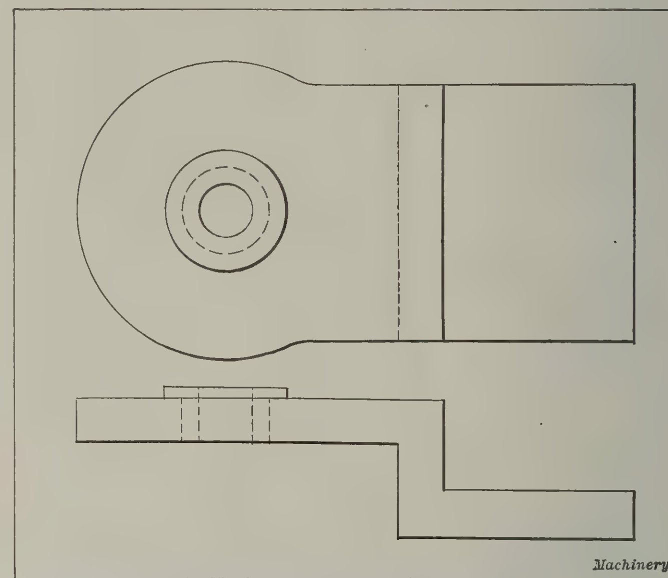

Fig. 2. The Bracket that was used to support the End of the Boring-bar when boring the Holes in the Bearing Posts

boring-bar was adequately supported and the job successfully finished.

The fact that the table of this machine is wider and longer than that of other machines of its type, and that the table travel in both directions is also greater, together with the fact that the machine can be converted into a vertical milling machine in a few seconds, explains how this job was possible on so small a machine.

* Associate Editor of MACHINERY.

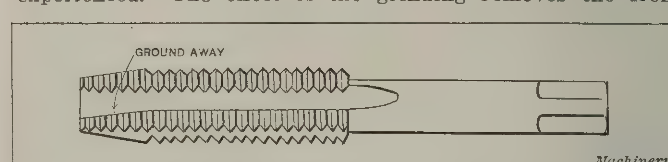
TAPPING HARD METAL

A useful kink for tapping hard metal is given in the *Practical Engineer* (London). When hard metal has to be tapped it is very common that the taps break; if the tap is ground, however, as indicated in the engraving, no difficulty will be experienced. The effect of the grinding removes the front



Method of Grinding End of Flute for Tapping Hard Metal

part of the teeth, so that the cutting edge presented forms a different angle with the thread than on the section not ground away. This method of grinding the tap proved successful in tapping very hard rolled steel plates.

CATERPILLAR ATTRACTION

Mr. Hickman, the self-made man and "super" of the United Street Railways, was enthusiastically explaining the construction and merits of his new journal-box to a friend who had dropped into the super's office:

"But I don't see how the oil gets up to the journal," objected the caller.

"Oh, that's easy; it's done by caterpillar attraction. You see the oil climbs up these wicks just like a lot of caterpillars going up a tree. Simple ain't it?"

* * *

A very disagreeable feature about some foremen is that if a piece of work goes well, it is "I," but if anything goes wrong, it is "You."—*Exchange.*

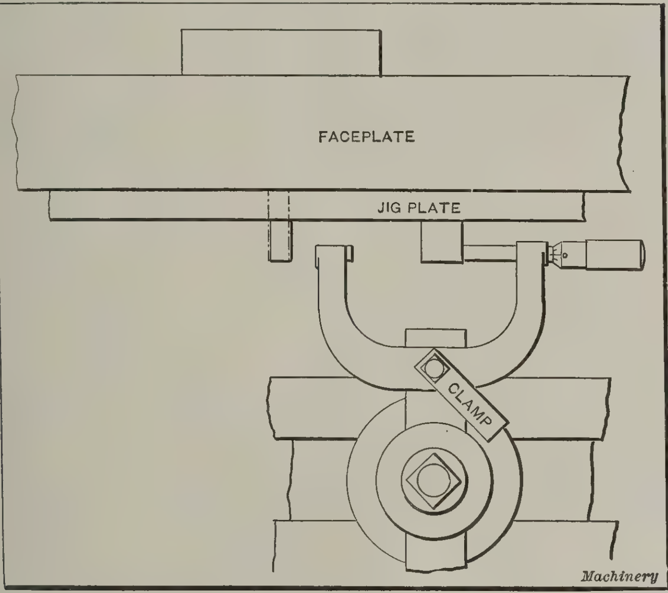
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

LOCATING HOLES TO BE BORED ON THE MILLING MACHINE—A COMMENT

In the April number of MACHINERY an article entitled "A New System for Locating Holes to be Bored on the Milling Machines" is published. The writer wishes to make some comments on the method there explained.

In doing any work, the fewer the liabilities of error the more accurate will be the results. The method referred to does not seem to fully take account of this indisputable axiom. In the layout, one begins with an edge on one side of the plate and then proceeds from a second edge which must be exactly at right-angles to it. If these two edges are at right angles, then the two lines *AA* and *BB* (shown in Fig. 1 in the April number) will be at right angles, but here is a possibility for an error at the very start.



Method of Adjusting Location of Center

The problem presented, as the writer understands it, is to locate with extreme accuracy the two centers *C* and *D* a given distance apart. There are two ways of locating a point; that is, by vision or by feeling, and in the method referred to the latter is adopted. Lines are scratched at right angles to each other; the three feet of the center locating punch are, by the sense of feeling, made to engage with these scratched lines, the center thereby being located at the intersection of the lines. Here, again, are chances for errors. The center plunger may not fit closely, its center may not be ground exactly concentric with the body of the punch, or the feet may not be exactly in their right positions. Furthermore, the punch may not be placed exactly as required. It is admitted, however, that the form of point used for scratching the lines seems to be very good, and the two lines scratched by it would show a very clear point of intersection.

The writer also fails to see the value of the indicator illustrated and questions the advantage of a hole and plug over the visual system. Of course, the taper hole in the milling machine spindle may be perfect, but it is not likely to be, except when the machine is new. In using the indicator, the writer would revolve the milling machine spindle, and not the sector as explained, in order to be more likely to have the center of revolution of the spindle established in so doing.

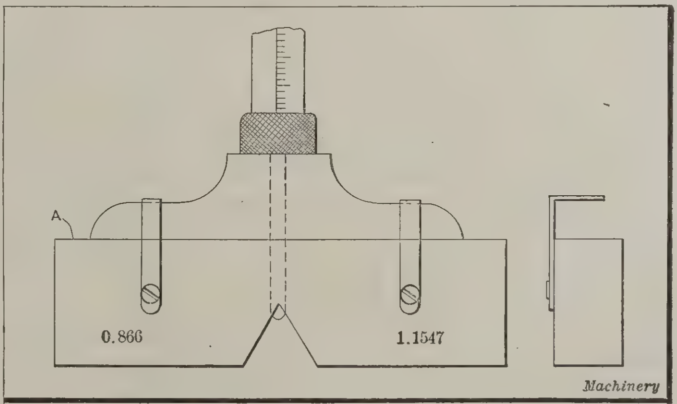
If the piece of work were, say, 10 inches long and square, the writer would locate and bore the hole in the lathe. The faceplate would first be trued off; that should be done at a time when the job could be finished before night, as for very accurate work the escape of oil in the bearings of the lathe over night will affect the accuracy. Should it be required to have the point *D* located a given distance from side *F*, line *AA* could be laid out by means of a try-square, the accuracy of which is easily determined, allowing about 0.005 inch for grinding after the two holes were bored. Line *BB* could be drawn with a height gage.

After locating point *D* by means of a common center indicator, a parallel should be bolted to the faceplate so as to allow the sliding of the plate along it after the first hole is bored. Assume that the two holes are 2 inches apart and each is to be ½ inch in diameter; before boring the first hole set a pair of dividers to 2 inches, and from center *D* scratch a line across *BB*, so as to approximately locate point *C*; then bore the first hole to gage and fit it with a plug, the plug projecting say ½ inch. Now loosen up the holding clamps or bolts and slide the plate along the parallel and with the indicator locate the second hole *C* and bore it to ¼ inch diameter; then fit a plug into this hole and measure with a micrometer the distance over the outside of the two plugs. If the reading should be 2.375 this would indicate that the setting is exact, but this would seldom happen, and the error found may be 0.005 inch over this dimension, which means that center *C* is located 0.005 inch too far away from *D*. The error being known, it can now be corrected without further trial, and to do this the micrometer is clamped to a tool held in the toolpost, as shown in the accompanying illustration. The reading of the micrometer is brought to zero and the point of the micrometer screw is brought into contact with the ½ inch plug. Then loosen up the clamps and feed the plate 0.005 inch by means of the screw, reclamp the plate, and bore the second hole to a ½ inch diameter. The centers now will be located exactly 2 inches apart. If there be any errors they will be found rather in the production of the holes than in the locating of the centers.

It may be merely a personal peculiarity, but the writer always trusts the "feel" of a pair of calipers rather than a stiff gage or a micrometer; but the great advantage of the latter lies in that it tells exactly how great the error is instead of merely denoting that there is an error. NEW LONDON

TOOL FOR MEASURING THE WIDTH OF THE POINT OF U. S. THREAD TOOLS

The accompanying illustration shows a tool for measuring the width of the flat at the point of U. S. thread tools. The device consists of a block of steel, say, 1 inch by ½ inch, with a 60-degree V-groove, and a hole for the rod of a depth gage. There are also two flat springs to hold the depth gage to the block. In making the block, a ¼-inch plug gage is laid



Tool for Measuring the Width of Flat on Thread Tools

in the vee, and the top surface *A* of the block on which the depth gage base rests, is ground until the gage, when in contact with the plug, reads 0.625 inch. To measure the width of the flat of a tool point, set the gage at zero, slip it under the springs, and run the rod out ½ inch. Now insert the tool to be measured in the vee and measure to its point with the depth gage. The amount that the gage reads over ½ inch, multiplied by 1.1547, equals the width of the flat of the thread tool. If it is required to set the tool for any desired width,

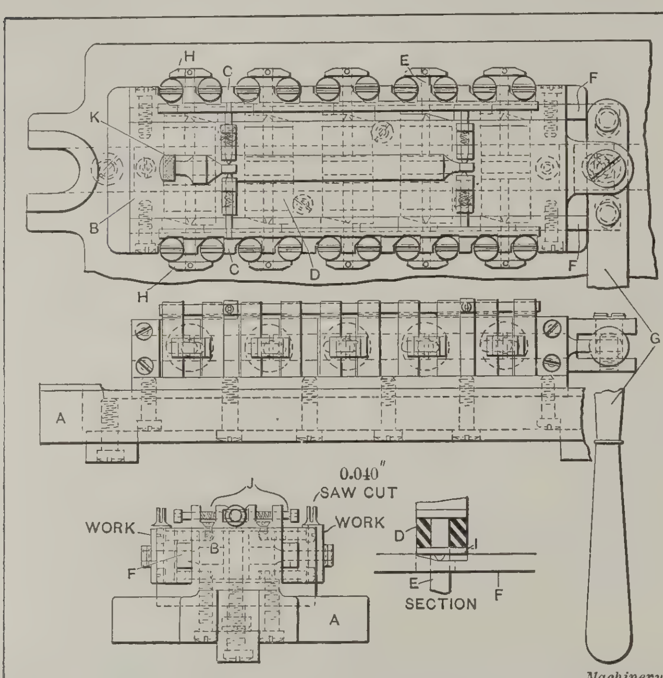
multiply this by 0.866 and set the tool to ½ inch plus this product.

Revere, Mass. GUY H. GARDNER

[The accuracy of the rules given above for setting this tool can easily be ascertained by anyone who knows the first principles of the solution of triangles. A tool similar to the one described, but somewhat more elaborate in its design, and intended exclusively as a thread gage for the width of flat on thread tools, was illustrated and described in MACHINERY, April, 1907.—EDITOR.]

A MULTIPLE MILLING FIXTURE

The milling fixture shown in the accompanying illustration was designed for holding the small pieces illustrated, which were made from a cast composition. As the parts produced were not of exactly the same size, it was necessary to provide some means so that the clamping members would hold all the parts rigidly. We had some rubber in our works which, upon testing, was found to have considerable resiliency; this gave me the idea that we could overcome the difficulties presented in clamping by using rubber collars as an equalizing medium to provide for the variations in the diameters of the work.



A Multiple Milling Fixture for Holding Pieces of Varying Diameters

The fixture shown in the accompanying illustration consists of a base casting *A* to which a central block *B* is held by screws. The two jaw strips *C* which are milled out, as shown, to fit the work are, in turn, fastened to the block *B*. This center block *B* is bored out to receive the rubber collars *D* and draw-in spindles *E*. The two sliding bars *F*, of rectangular section, are milled to fit a slot in the jaws *C*, and are operated by the handle *G*. The clamps *H* are pinned to the draw-in spindles *E* provided with a head against which the rubber collar *D* is compressed by the pressure plates *I*. These pressure plates are provided with projections which operate in the beveled slot in the sliding bars *F*.

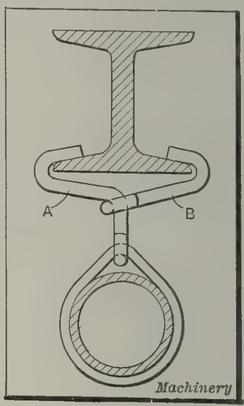
As the handle *G* is fulcrumed in the block *B* and is pivotally connected to the sliding bars *F*, it will be seen that by moving the handle *G* to the right, the sliding bars *F* are moved in opposite directions to each other. The resulting action of the tapered portion of these slides forces in the pressure plates *I*, compressing the rubber collars *D* against the collars on the draw-in spindles, and thus operating the clamps. It is, therefore, evident that by interposing these rubber washers, compensation is made for any variation in the diameters of the work.

The mechanism shown at *J* consists of two strips which extend along the entire length of the jaws, and is used for lining up the pieces parallel to the fixture after they have been placed at random in the jaws. To operate this device, the rod *K* is pushed in which forces the longitudinal strips against the work bringing them all in line, so that they can be clamped, and the cut taken. This fixture makes a very compact device and can be adapted to a large range of small work, which is difficult to hold in an ordinary fixture.

V. W.

SIMPLE PIPE HANGER

About two years ago the writer was requested to design some pipe hangers for a 4-inch steam pipe supported from an I-beam in the factory. The hanger as shown in the accompanying engraving is very simple, as it is made entirely from ⅜-inch iron rod. The clamp grips the beam more strongly, the greater the weight that is applied to the hanger. Being made without bolts, it is simpler to put in place than many of the pipe hangers one sees regularly about the shops, and there are no holes to drill. Part *B* should be made short enough so that it will act as a fulcrum for hook *A*, as otherwise the hooks will not grip the I-beam properly. This is really the most important point to be considered in the making of this simple hanger.

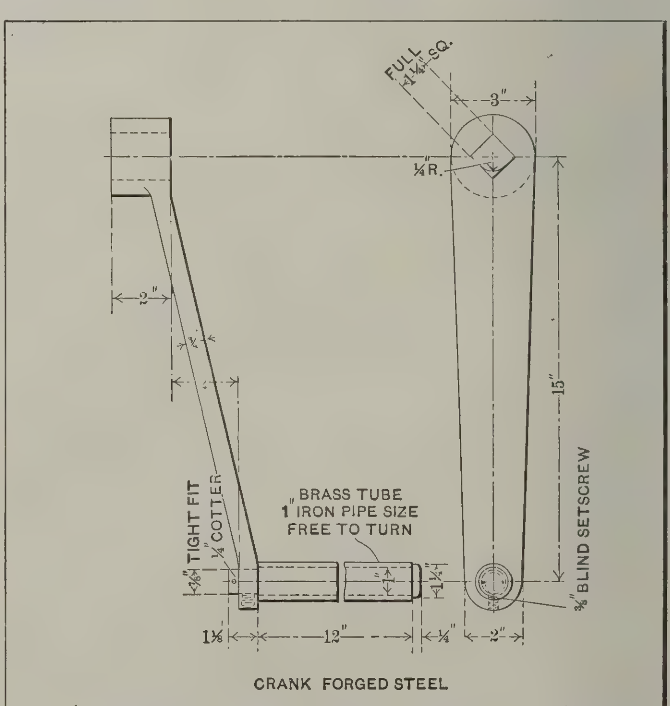


Simple Pipe Hanger

S. Boston, Mass. JOHN WALSH

PROPORTIONS OF HAND-CRANKS

The proportions of hand-cranks given in the December number of MACHINERY, interested me very much. While not attempting to criticize the proportions and design there given, I would like to submit a more suitable crank for out-door work. Hand-cranks are used in all climates and under various conditions, and are subject to much abuse. A handle twelve inches long is about right for a one-man affair, but who can tell whether one or two men will operate the crank? Twenty-five pounds is a good "all day" allowance as a working load



Proportions of Hand-cranks for Out-door Work

for one man, but it is an easy matter for him to exert seventy pounds for a short time.

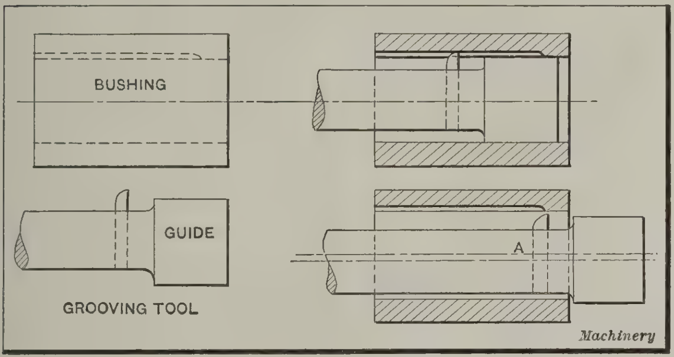
In general, the class of men who use hand-cranks, do not know what good judgment is, and too often use the handles of hand-cranks as seats when tired. To prove the lack of knowledge displayed by men of this class, I will cite an instance that came under my notice. A hand-lever of the walk-around type, with a five-foot lever arm, was used for opening

and closing a valve. One man was all that was needed, but three men were crowded onto the handle to raise the valve. Not knowing that the valve was raised to the full travel, they continued to work until the valve struck a positive stop, and thinking the stop a nuisance, pushed still harder and snapped the chains.

Another good point is to have the handle offset a slight amount; this places the man's body away from the end of the crankshaft, and lessens the liability of jamming it at every turn of the crank. A piece of brass pipe makes a good grip, as exposure to inclement weather will not cause it to split or warp. When it is necessary to use two men on a crank, it is preferable, if possible, to have two cranks placed 180 degrees apart. This gives a much steadier action at the other end than if two men are placed on one crank. C. P. W.

CUTTING OIL-GROOVES IN BUSHINGS

The tool shown in the accompanying engraving is used to cut oil-grooves from one end to within ¼ inch of the opposite end on the inside of the bushings. A good clean job is secured in a very short time. The illustration indicates how the work is accomplished. The tool consists of a piece of machine steel, one end of which is turned to fit the hole in the bushing, this end acting as a guide. The other end



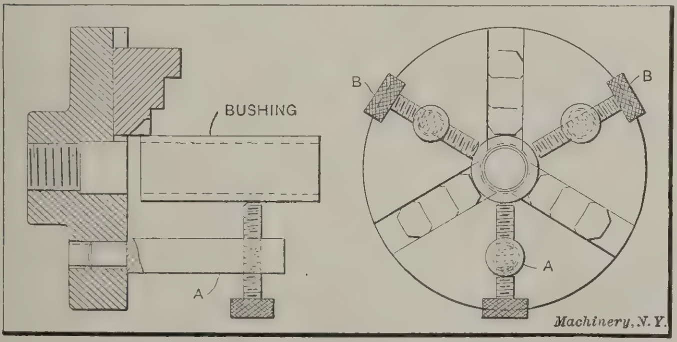
A Convenient Method of Cutting Oil-grooves

is turned smaller in diameter, and in it is inserted the cutter used to cut the groove. Three cuts with three different settings of the cutter were required to complete each bushing. The cutter is made a drive fit in the hole in the arbor. The tool is pushed through all the bushings to be grooved after each setting. The distance from the end of the guide to the cutter determines the distance that the end of the groove will be from the end of the bushing, the illustration showing at *A* how the tool is relieved from the cut before the groove has been cut clear through the bushing. The whole job was done on an arbor press.

Springfield, Ohio. A. J. DeLille

GRINDER CHUCK FOR HOLDING LONG WORK

A chuck which can be used for holding long bushings when grinding them internally is shown in the accompanying illustration. This is an ordinary three-jawed chuck in which



Chuck for Holding Long Bushings when Grinding Internally

three holes are drilled and tapped through the body for holding three studs *A*. Screwed into these studs are three knurled screws *B*, which are used for supporting the work.

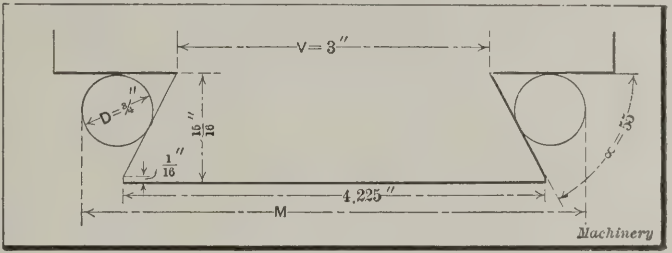
In operation, the bushing to be ground is chucked in the regular way by letting the jaws of the chuck grip ¼ inch from the end, thus leaving sufficient clearance for the wheel to pass through the bushing. The three knurled screws *B* are then brought to bear lightly on the work, so that they will hold the bushing securely without springing it. The outer end of the work can be trued in the chuck by operating these knurled screws. When the studs are not necessary for supporting the work, that is, when the work is not very long, they can easily be removed. William H. Vockell

Cincinnati, Ohio.

FORMULA FOR GAGING DOVETAIL SLIDES

The following rule may be used for finding the dimensions over the wires or plug gages when measuring dovetail slides as indicated in the accompanying illustration:

Add 1 to the cotangent of one-half of the dovetail angle, and multiply by the diameter of the plug gage. Add the



Notation used in Formula for Gaging Dovetail Slides

product obtained to the "vertex" distance of the dovetail. The sum is the required micrometer reading.

Expressed as a formula this rule takes the following form (see illustration for notation):

$$M = (1 + \cot \tfrac{1}{2}a)\, D + V.$$

In the example indicated by the dimensions in the illustration, we find:

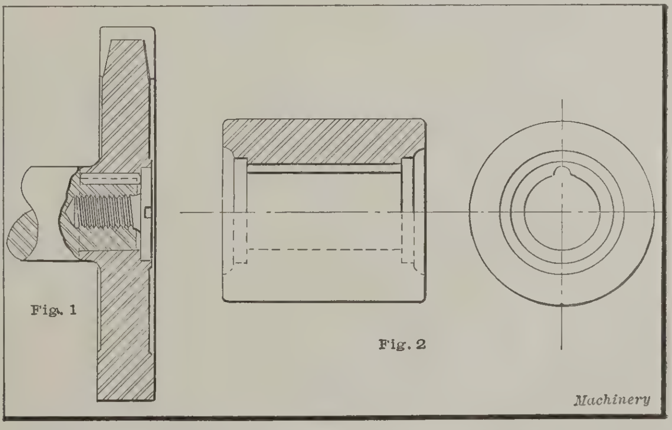
$$M = (1 + \cot 27\tfrac{1}{2}°)\ \tfrac{3}{4} + 3 = 5.191 \text{ inches}$$

The derivation of the formula is based on the first principles of trigonometry, and anyone familiar with this kind of mathematics can easily prove it for himself.

Revere, Mass. Guy H. Gardner

FASTENING SMALL MILLING CUTTERS TO ARBORS

In the article in the February issue, "Device for Fastening Threaded Milling Cutters to Spindle," a very good and satisfactory method is described. In the accompanying engraving is shown a method extensively used in the plant where the writer is employed, for fastening T-mills to arbors, and also



Figs. 1 and 2. Method of Fastening Small Milling Cutters to Arbors

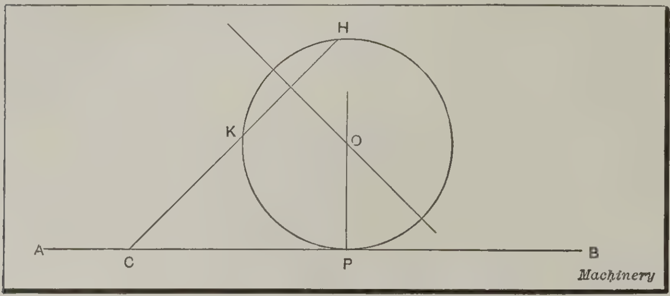
for mounting and using shell mills as end mills. In Fig. 1 a T-mill mounted on the end of an arbor is shown. It is prevented from rotating on the arbor by a round key, and is held in position by the screw in the end of the arbor. This method was adopted after several other methods of constructing T-mills were tried. By making the holes in the cutters of standard size, and using a uniform length of hub, a large range of work can be covered with but few cutters and arbors. For instance,

the same cutters may be used on arbors having No. 9, 10 or 11 shanks; in fact, only a few sets of these arbors are used in the plant which the writer has in mind, while a large variety of mills are used, including regular shell mills, made as shown in Fig. 2. These mills are made alike at each end, thus giving a choice of a right- or left-hand mill. They are easier to grind than an ordinary end mill, and last twice as long, there being two ends to dull before grinding is necessary. Of course the arbors on which these shell mills are used are longer than those used for T-mills. T. COVEY

A GEOMETRICAL PROBLEM

In the March, 1912, number of MACHINERY appeared a brief article by Mr. C. W. Hinman entitled, "A Geometrical Problem." Below is given a solution of this problem which eliminates the construction of a parabola.

As will be remembered, the requirements are to draw a circle that is tangent to line AB and that passes through the points H and K. Draw a straight line through H and K and let C be the point of intersection between this line and the line AB; then the point of tangency P, is found in accordance with the well-known geometrical proposition that



Solution of the Geometrical Problem

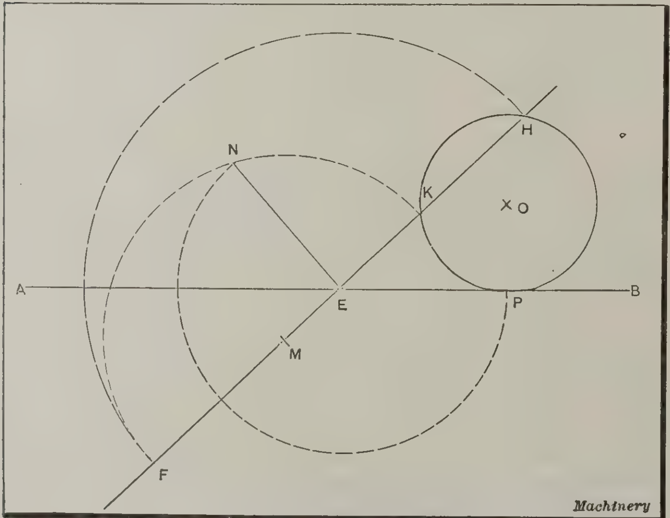
$$CK \times CH = \overline{CP}^2$$

Hence, line CP should simply be made the mean proportional between CH and CK; this determines the point P. The required circle now must pass through the points H and K, and be tangent to AB at P. The center O of the circle is then easily found by means of well-known geometrical methods.

Moscow, Russia. R. POLIAKOFF

ANOTHER COMMENT ON "A GEOMETRICAL PROBLEM"

In the solution of "A Geometrical Problem" proposed by Mr. C. W. Hinman in the March, 1912, number of MACHINERY, the draftsman is confronted with the necessity of constructing a parabola before solving the problem. This makes the solution of little practical value to the ordinary draftsman, although it may be of interest mathematically. A simple and practical solution of the problem is, however, possible.



Complete Construction necessary for Determining the Mean Proportional

In the accompanying engraving let K and H be the two points through which the required circle is to pass, and AB the line to which it must be tangent. Draw a line through H and K and prolong it indefinitely, crossing line AB at E; make EF equal to EH; bisect line KF at M; with M as a center draw a half-circle FNK, and erect a perpendicular EN; then make EP equal to EN. Point P is now the point of tangency, and by any well-known method for describing a circle through the three points, the required circle can now be constructed.

The proof of the accuracy of this method is based on the fact that, according to a well-known geometrical proposition,

$$EK \times EH = \overline{EP}^2$$

If, according to the construction, EP is the mean proportional of EH and EK, this requirement is filled. Now, EN is a mean proportional between EF and EK, or

$$EK \times EF = \overline{EN}^2$$

But EF equals EH, and EN equals EP; hence,

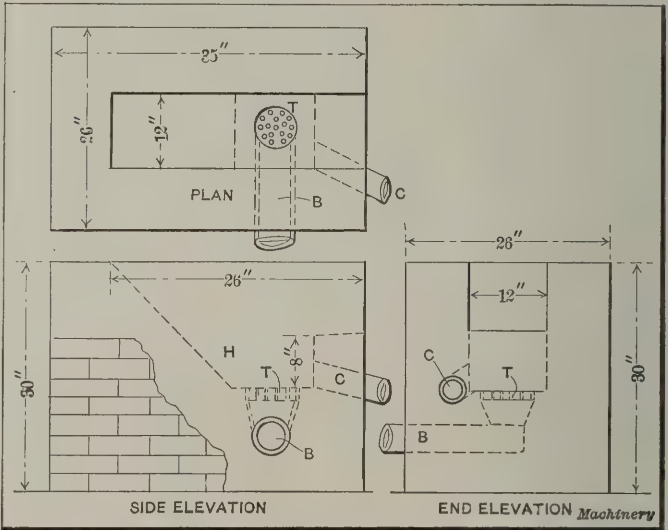
$$EK \times EH = \overline{EP}^2$$

Consequently, P is the point of tangency with the circle passing through H and K, tangent to line AB. A. M. S.

[A solution similar to that just given has also been submitted by Mr. George W. Burley, Sheffield, England; Mr. Samuel McAnally, Stratford, Ontario; and Mr. George W. Hammond, Manchester, England.—EDITOR.]

WELDING NICKEL-CHROME STEEL

The following is offered in reply to C. L. L.'s question in the February number of MACHINERY, relating to the welding of nickel-chrome steel. There are no physical or chemical reasons why nickel-chrome steel should give trouble in welding in an ordinary forge fire. There may be mechanical reasons for having difficulty with these steels, but these are wholly caused, and can be controlled, by the person doing the welding. Broadly speaking, nickel and chromium increase the susceptibility of the steel containing them, to heat treatment, which includes not only hardening and tempering, but forging and welding as well. It seems sufficient to say that these steels weld as readily as any carbon steels of the same "temper."



Blacksmith's Forge, especially Suitable for Heating Steel for Welding

It is generally recognized by all blacksmiths that the lower the carbon contents of steels, the easier they weld. That this is true is readily seen when two pieces of iron, which are free from carbon, are heated to the proper welding temperature and then brought into contact; they instantly weld perfectly. The carbon steels in general use, and with which the average blacksmith is familiar, usually contain about 0.25 per cent carbon. Nickel-chrome steels are made in grades of 0.08 to 0.15 per cent carbon, and 0.16 to 0.25 per cent carbon, and higher. The grades containing the higher percentages are seldom met with by the blacksmith, as these are generally used for structural purposes, though they too can be welded by carefully heating to slightly lower temperatures than used for carbon steels of the same carbon percentages.

With the lower carbon grades of nickel-chrome steels it can be readily seen from the carbon contents that these should weld without the slightest difficulty. In general, these steels should be heated to 2300 or 2400 degrees F., but the heating

should be done slowly, because of the denseness of the grain and to insure an even distribution of the heat throughout the piece. The forge fire should be clean and of ample volume to completely surround the steel to be welded. Use care that a good bed of clean fire is kept between the tuyere and the steel. See that the air blast does not strike the latter directly, while heating, as under these conditions the steel will burn before the proper welding temperature is reached. More trouble is caused in welding with dirty coal fires than from any other reason.

The accompanying illustration shows a modified blacksmith's forge used for heating small pieces for welding; *B* is the blast pipe, *C*, the cleaning flue, and *T*, a small tuyere perforated with a number of one-half inch holes. The hearth *H* is made eight inches deep and the fire is always kept up to the top of this hearth. This insures a good, clean, clear fire at all times, and keeps the steel to be welded far enough away from the blast to prevent burning. Pea-coke is generally used in a forge of this kind. This forge can also be used for heating high-speed steel for hardening with excellent results. If the directions given are followed carefully, there should be no difficulty whatever experienced in welding nickel-chrome steels. E. D. ALLEN

Latrobe, Pa.

VALUE OF DIFFERENTIAL OR PLANETARY GEARING

Properly designed and properly made differential or planetary gears offer an excellent means of reducing the speed of rotating shafts. In the summer and fall of 1905 the writer designed a mechanism in which the main shaft made 120 revolutions per minute and was to drive another shaft at 12 revolutions per minute. To accomplish this, a planetary train of four gears was used, one gear of 48 teeth meshing with one of 20, and one of 44 teeth meshing with another gear of 20 teeth. These gears have been in almost constant use for the past six years, and the 20-tooth gears have in that time made over 230,000,000 revolutions. The most remarkable fact about this train is that it has run these six years as quietly as if it were a worm-gear arrangement, and has never given any trouble except once, through an accident, when a loose piece of metal fell into one of the larger gears breaking some teeth.

The gears with 44 and 48 teeth were of cast iron, while the 20-tooth gears were made of machine steel, but not hardened. The satisfaction derived from this drive speaks in favor of the use, in the proper place, of properly constructed planetary gears, as a simple speed reducing mechanism. To give such satisfaction, however, the gears must be properly cut so that they will run smoothly together, and retain the same distance between the centers. The diameters of the gears must be correct to within 0.0005 inch. One particular feature of this job was that the writer cut all of the gears with one gear cutter, cutting all the teeth to exactly the same depth. They were cut with a special cutter. The writer is of the opinion that if the gears had been cut with ordinary involute teeth, they would not have given the same satisfaction.

An improper method of making a planetary gear speed reducing device is to place the larger gears side by side and then make the driving pinion in one piece, so as to mesh with both, its length being equal to the total width of the two gears. This is a poor method even if the two large gears vary only one tooth, because the pinion will not be in proper mesh with both of the gears, and the drive is apt to be noisy.

Springfield, Mass. FRANCIS W. CLOUGH

"PATENTED" ON MACHINES

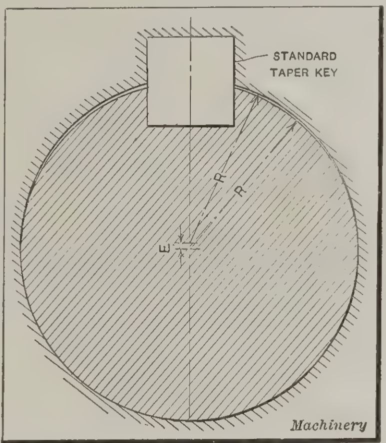
I am interested in your remarks on "Status of Patented on Machines" in the April number. A friend of mine in Wisconsin some years ago began to make slot machines such as were popular for some time for gambling purposes. The machines were going like "hot cakes," and he wanted to prevent anyone from imitating his machines, which were not patented and on which he did not expect to secure a patent. He used a Yale lock to fasten the door through which the owner of the machine was to secure access to the inside of the machine to remove coins, etc. Yale locks are patented. The locks were countersunk in the frames of the slot machines, only the key-holes showing. There was no chance to show the patent notice of the Yale locks, so the following was placed on the machines; "The locking devices on this machine are patented under Nos. ———."

This statement conveyed the impression that the slot machines were patented and avoided any interpretation of the patent law which would apply in marking as patented an article not patented. The impression lasted long enough for the manufacturer of the machine to prevent competition until such a time as the machines were adjudged gambling devices by the police and then destroyed. After that his competitors did not want to make the machines anyway.

Norwood, Ohio. ALBERT STRITMATTER

METHOD OF BORING HOLES IN KEYED PULLEYS

When large pulleys or gears are fitted to shafts in any other way than by a press or shrinkage fit, there must necessarily be some difference in diameter between the bore and the shaft. If a taper key is used, the shaft is always forced to one side of the bore, and the pulley or gear becomes eccentric. In many cases this may not do any harm, but it certainly is of no advantage; and unless the play between the bore and the shaft is small, it is likely to cause trouble. Furthermore, if there is too slight a difference between the bore and the shaft, the wheel will frequently stick, especially if it is to be pulled over a considerable length of the shaft. This condition is especially exasperating when making emergency repairs.



Fit between Shaft and Bore when Method outined is followed

The accompanying illustration shows a simple way of avoiding both difficulties. The idea is not new, but has been used by two or three companies to the writer's knowledge for more than ten years. Nevertheless, the method is one which is not generally known. After the pulley is bored, it is shifted in the chuck or on the faceplate, an amount as represented by *E* in the illustration; then, without changing the setting of the tool, the hole is rebored. The first hole should be exactly equal to the shaft diameter. Then, after the taper key is driven home there will be an exact fit on the lower half of the shaft, instead of a fit theoretically along one line only, which would be the case if the bore were circular, and larger in diameter than the shaft. The main reason for this method of boring the pulley is, however, the ease with which even a big heavy wheel can be put on or taken off.

The exact dimension *E* cannot be given, because it would vary considerably in different shops. It depends on the size of the shaft and the grade of the work. However, the writer would say that on heavy gears, pulleys, etc., 1/32 inch is not too much. There will be an open space between the shaft and the bore on the keyseat side anyway, and it is difficult to see why a 1/32 inch space at the top would be any more objectionable than a 1/64-inch space. The extra cost of this method of boring is small in comparison with the advantages obtained. Next to a press fit this method provides theoretically and practically the most satisfactory means for fitting a shaft to its bore. F. D. BUFFUM

Ellsworth, Pa.

ROLLING BLUEPRINTS

Trivial as it may seem considerable energy is lost by mechanics, engineers, architects, and others on account of the fact that blueprints are almost invariably rolled with the face

in. A moment's consideration of the subject will convince the least observing of men that such is the case, but why it is so done is unanswerable except that it seems to be intuitive, just the same as putting money inside of a pocket-book instead of outside of it. The reason for putting money in a pocket-book is obvious, but protection in the case of blueprints is fallacious as the back of the paper is as necessary as the face.

The objection to rolling a print with the face in is that it is a very difficult matter to make it lie open properly when unrolled for reference. Weights or thumb-tacks, or four hands are then in demand, when if the print has been rolled face out it may be unrolled and placed on a board or held in two hands without trouble. Try rolling a blueprint both ways and be convinced. You will not be likely again to roll a blueprint face in. C. H. Casebolt

St. Louis, Mo.

[The same reason for rolling blueprints face out applies to the rolling of magazines for mailing. If rolled with the title page out when mailed, the unrolled copy will soon settle down and lie flat on a table with the title page up. Machinery has been mailed for the past few months with the title page rolled out.—Editor.]

DRAWING AN ODD-SHAPED CUP

In answer to the question on drawing an odd-shaped cup in the "How and Why" columns of the March issue of Machinery, the following solution is offered. By this method four operations would be required to complete the drawing of the cup and Fig. 1 illustrates the successive drawing operations. The first operation consists in drawing from the center of the blank a cup-shaped depression 5/8 inch diameter and 1/4 inch

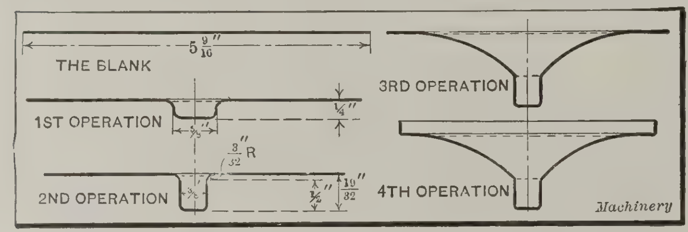


Fig. 1. Results of the Four Drawing Operations

deep, as shown. The die for accomplishing this part of the work is shown in Fig. 3. This die is an ordinary drawing die with a spring blank-holder and needs no further explanation. The second operation consists in drawing the cup-shaped depression to the depth of 1/2 inch, and at the same time reducing

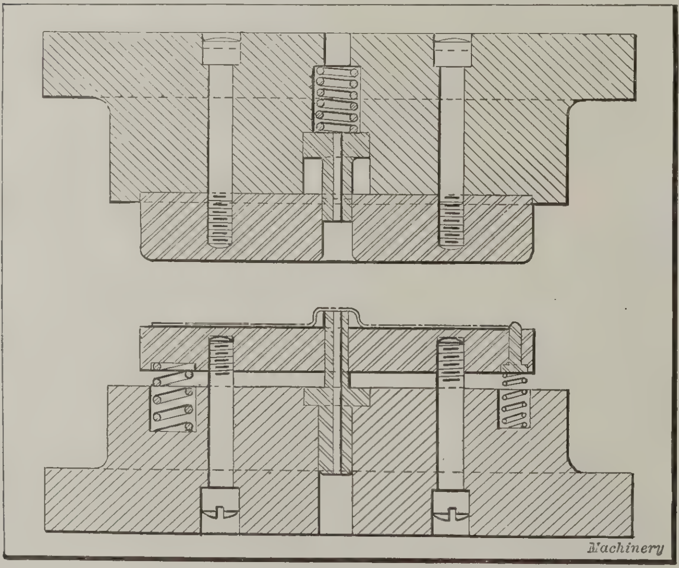

Fig. 2. The Second Operation Die

the diameter to 3/8 inch. The tools for this work are shown in Fig. 2. While this is a somewhat unusual type of die, it has worked out very successfully on similar work. The spring blank-holder should be supported by very weak springs. The third operation consists in forming the central part of the shell by means of the dies shown in Fig. 4, and the same dies are used for the fourth operation of turning up the flange at the outside edge by simply adding the ring shown in Fig. 5.

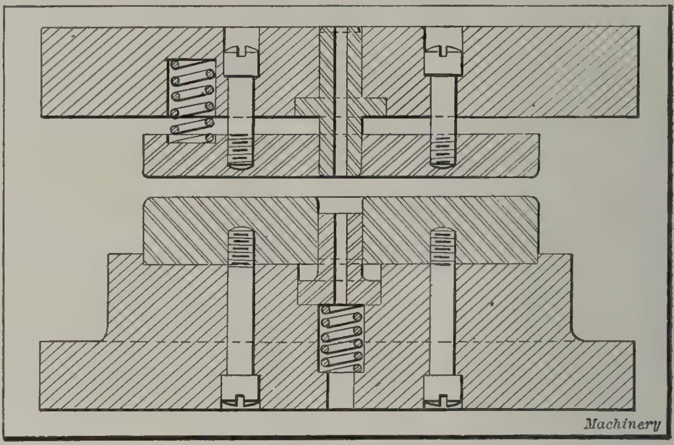

Fig. 3. The First Operation Die

This ring slips on over the lower half of the third operation die, and for this reason it is essential that the outside of this

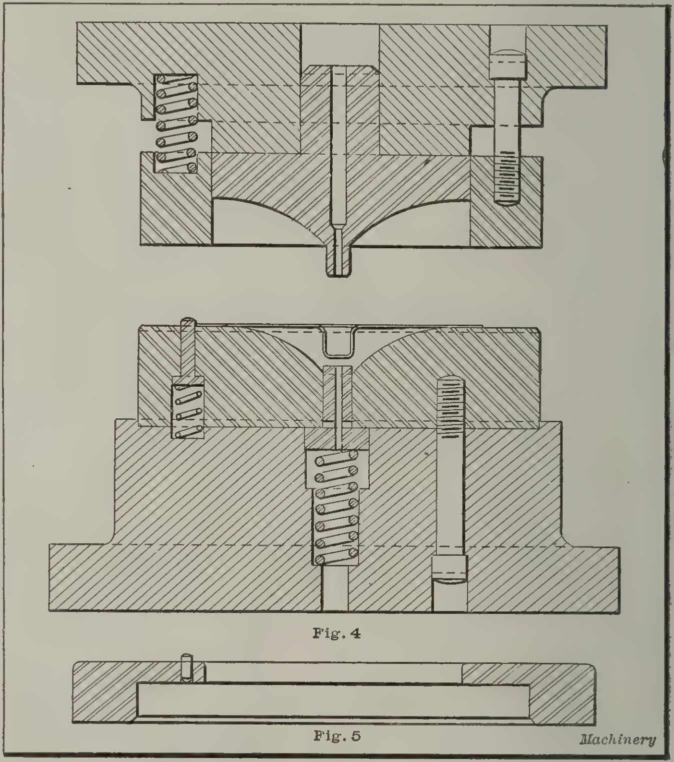

Fig. 4. The Third Operation Die. Fig. 5. The Ring used on the Third Operation Die to perform the Fourth Operation

part of the die be absolutely concentric with the depression in this die.

Thomas Alma

REMOVING BURRS FROM METAL PRODUCTS—REJECTED WORK

Referring to the inquiry of D. A. H. in the February number regarding economical methods of removing burrs from metal products, we break up discarded emery wheels and put them into a revolving iron cylinder having internal projections. We put in about an equal amount of sawdust with the broken emery pieces and then the parts from which burrs are to be removed. The tumbling of the parts with the sawdust and emery quickly removes all the burrs that should be allowed on any punched work.

On parts for electrical apparatus that are rejected by inspectors it is our practice to treat them individually so as to bring them up to the standard where it is possible. In a great many cases the stock is of so much more importance than the labor that we find it pays to treat the parts individually.

West Lynn, Mass. Thomas A. Wry

A REVOLVING-HANDLE SCREW DRIVER

The accompanying illustration shows a sectional view of a revolving-handle screw-driver which is found useful for assembling work. It consists of a crank shaped shank *A* made from drill rod, a brass sleeve *B*, a steel thrust button *C*, and a hard wood handle *D*. To assemble these parts the brass bushing *B* is slipped over the shank *A*, after it has been

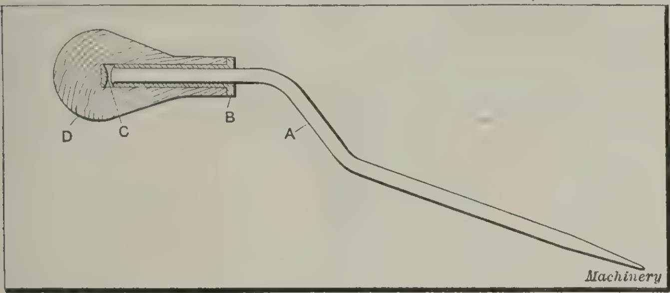

Fig. 1. A Revolving-handle Screw Driver for Rapid Assembling of Work

bent to the required shape; then the shank is upset on the end. Thrust button *C* is now slipped in place on the handle and the brass bushing with the shank in it is forced in. The hole in the handle should be deep enough to leave about 1-64 inch play between the end of the shank and the thrust button.

The screw-driver is operated by simply holding the knob

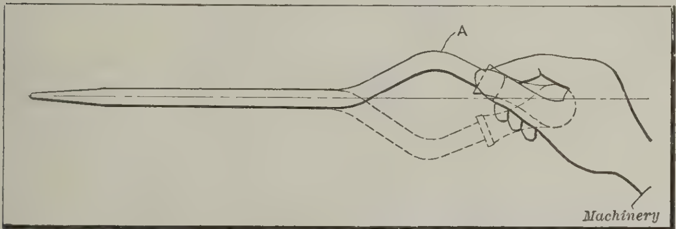

Fig. 2. Illustration showing the Method of Operating the Screw Driver

of the handle against the palm of the hand and gripping the small portion of the shank with the fingers of the same hand and twisting it around without moving the wrist. After a few minutes' practice this screw-driver can be worked with great speed in both directions. J. E. U.

BALL AND ROLLER BEARINGS IN MACHINE TOOLS

In reply to your criticism in the February number of Mr. Henry Hess's remarks on the application of ball bearings to the main spindle of machine tools, it might be interesting to cite the fact that several eminent tool builders in England have already, with apparent success, put them to this use. Messrs. Kendal & Gent, of Manchester, are producing a hexagon turret lathe which takes bars up to 3 inches, the headstock of which is fitted throughout with ball bearings. They claim to have reduced the power consumption per unit of metal removed about 50 per cent. Messrs. Parkinson & Sons, of Shipley, are fitting ball bearings to milling machine spindles. Messrs. Alfred Herbert, of Coventry, are using them on the spindles of automatic chucking machines and turret lathes. This firm, before finally adopting ball bearings for the spindles, gave them a test extending over several years on some of the shop machines. The machines worked satisfactorily under heavy forming cuts.

The type of bearing used in every case is that known as "single track journal," which has, of course, no provision for adjustment. In the writer's personal experience, he has found that if a ball bearing is fitted, no adjustment is needed for the simple reason that a bearing of ample proportion practically does not wear, and ball-bearing makers are now turning out so perfect a product that the clearance between the parts of a journal bearing is only just sufficient to insure free running —not exceeding, at any rate, that of a well scraped bush bearing.

In the case of thrust bearings of the ball type, where thrust is taken by the balls in both directions, it is absolutely unnecessary to provide adjustment. If adjustment is found to be needed, this is only a proof that the proportions have been undercalculated, and the remedy, therefore, is obvious. The initial adjustment should be made in construction by the makers and in such a way that it cannot, by any means, be tampered with by the user.

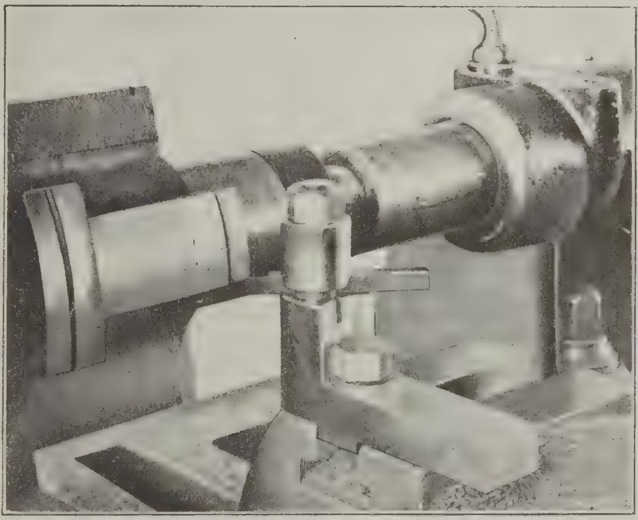
Some months ago the writer designed a lathe headstock of the all-geared type, in which the journal pressures were entirely taken care of by the ball journal bearings, and the end thrusts, by double ball thrust bearings. The body of the headstock formed an oil bath, which was necessary to lubricate the gears. At the same time, the spray from the oil was sufficient to keep the ball bearings in good condition, rendering quite unnecessary the provision of other means for lubrication; in fact, the headstock was entirely without lubricators. In this particular case, the diameter of the spindle would have been excessive for the load and speed, and ball bearings gave a means of getting over a very troublesome proposition.

The writer has a very strong conviction that in ten years, so far as machine tools are concerned, practically every bearing of importance will be a ball bearing. The days of bronze and babbitt are numbered. A fifty per cent reduction of the power bill is not to be lightly considered, particularly in these days of coal strikes.

A method successfully applied in a grinder head was the fitting of a long bush behind the ball bearing, this bush having a little more clearance than the balls in the ball bearing. The idea was that the solid lubricant with which the shaft in the bush was oiled would act as a deterrent against vibration, for before vibration could take place, the grease would of necessity have to be squeezed out. A SUPPORTER OF HENRY HESS

A TOOL-HOLDER FOR THE LATHE

The accompanying illustration shows a tool-holder which holds square turning tools or cutting-off blades made from high-speed steel. The holder consists of a stud held in the L-block which is fastened to the cross-slide, as shown. The cutting tool is retained by a collar, which, in turn, is acted upon by



A Lathe Tool-holder of Rigid Construction

a nut. As can be seen, this holder is provided with a slot in which cutting-off blades can be rigidly held. Another good feature about this holder is that there is practically no overhang at all, thus enabling heavy cuts to be taken without chattering. CHARLES K. TRIPP

West Lynn, Mass.

PACKING BOX NAILS

I have just seen what seems to be an improvement in the use of packing-box nails—*viz.*, the employment of paper disks about ¼ inch thick under their heads. These disks or washers are used in order to lessen the jar on the contents of the box, and to prevent damage to the box itself during transit. When opening, the ordinary pliers or the special nail-pulling devices draw the nails without mauling the box cover. The disks are furnished perforated ready for use.

Dresden Germany ROBERT GRIMSHAW

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

ORIGIN OF COTTER-PINS

A. C. C.—I am desirous of securing information in regard to the origin of the use of cotter-pins as well as the derivation of the word itself. How far back does the use of cotter-pins date? In what country did they originate, and wherein lies the significance of the word cotter-pin?

This question is submitted to the readers.

DIAMETER OF STEEL BALL

A. J. C.—Please give a formula for solving this problem: If a steel ball 0.718 inch diameter weighs 380 grains, what must the diameter of a ball be to weigh 383 grains?

A.—The cubic contents of spheres are to one another as the cubes of their diameters. Therefore, the relation between two balls is expressed by the proportion $x^3 : y^3 = a : b$, in which x and y represent the diameters of the balls and a and b the given weights. From this we obtain the expression $x^3 : 0.718^3 = 383 : 380$; clearing for x yields

$$x = \sqrt[3]{\frac{0.718^3 \times 383}{380}} = 0.720 \text{ inch},$$

the required diameter.

PORTABLE BORING BAR

J. H.—I am foreman of the machine shop of a large factory manufacturing tinware and sheet metal goods, and have a number of stamping presses to keep in repair. I have now the job of repairing a broken crankshaft. The bearings for the shaft are badly worn and need reboring. I wish to rig up a boring bar and bore out just enough to true up the bearings, which are about 3 inches diameter and 18 inches apart. Can you refer me to the design of a simple boring bar that can be rigged up for the purpose of boring out the holes in the press frame while in position?

A.—The situation described is typical of many repair jobs requiring the reboring of two or more holes dead in line. The regular portable boring bars designed for reboring engine cylinders are generally too heavy and cumbersome for machinery repair work, and even if a given situation is such that an an engine boring bar could be used, the cost and time required to obtain one are generally prohibitive for emergency repair work. Suggestions are invited describing simple portable means which can be provided by almost any machine shop for efficiently boring holes from 2½ inches diameter up, and employing a traversing bar or traversing tool head.

DESIGN OF DROP-FORGING DIE

A. C. F.—I desire to make drop-forging dies for the piece shown in Fig. 1. This piece is to be a steel forging, and the

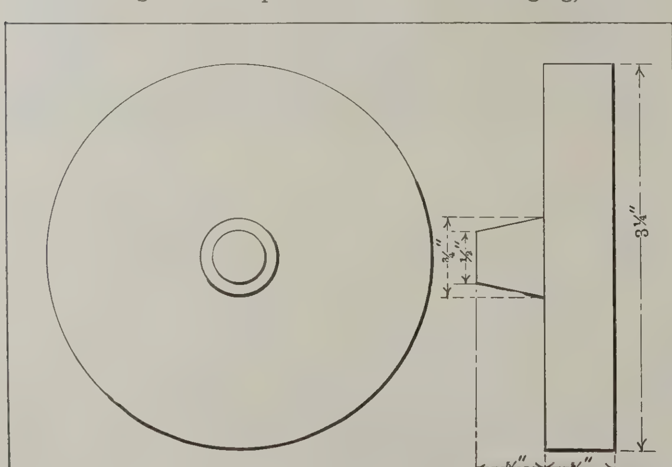


Fig. 1. The Forging to be made

principal point on which I require information is the proper shaping of the breakdown in order to distribute the stock so that the raised projection at the center may be brought up easily; also advise me what size bar steel to use and to what lengths the bars should be cut for forging.

Answered by J. W. Johnson, Revere, Mass.

A.—The drop-forging of the piece shown can be easily accomplished by making the breakdown in the manner shown in Fig. 2. The outline of the breakdown should be laid out about ⅛ inch smaller than the finished forging is to be, and the corner should be well rounded at the parting line. The face of the breakdown should be wider than it is ordinarily made, in this instance being two inches wide in order to

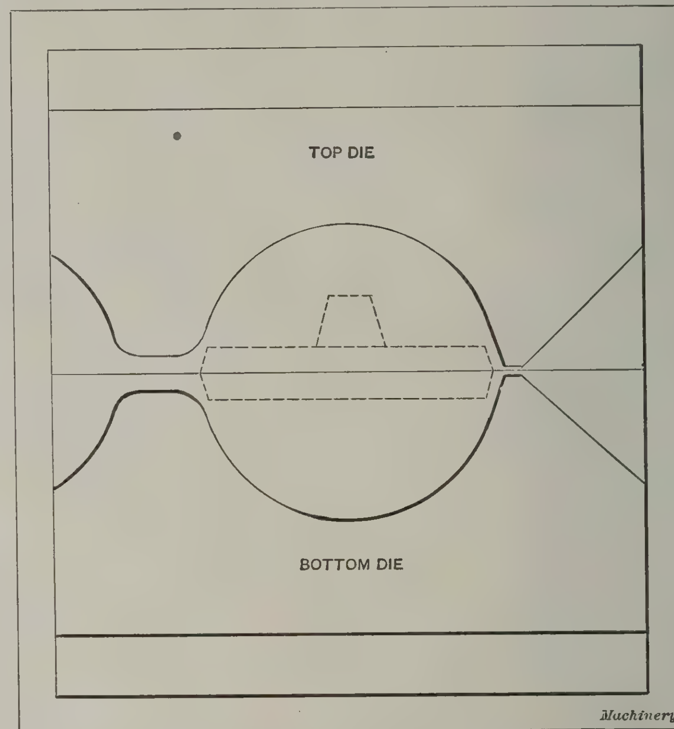

Fig. 2. Showing the Outline of the Breakdown

facilitate the rapid breaking down of the stock. In cutting the face impression in the die it should be remembered that the impression that is to form the projection on one of the faces of this piece should be cut in the upper die on account of the fact that the metal is more easily forced up than down into a depression.

The dimensions of the stock should be very close to 3 inches by 1 inch, and in cutting the bars for forging, the lengths should be just long enough to make four pieces. The first piece forged will leave the bar in the condition shown in the upper view in Fig. 3. It will be noticed that the gate to the breakdown is cut away so that one-half of the outline of the

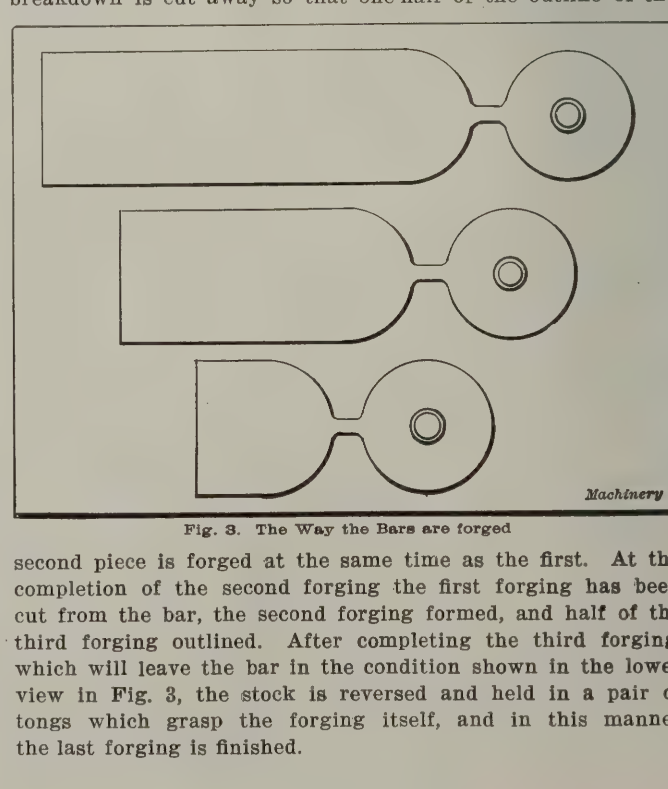

Fig. 3. The Way the Bars are forged

second piece is forged at the same time as the first. At the completion of the second forging the first forging has been cut from the bar, the second forging formed, and half of the third forging outlined. After completing the third forging, which will leave the bar in the condition shown in the lower view in Fig. 3, the stock is reversed and held in a pair of tongs which grasp the forging itself, and in this manner the last forging is finished.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

THE FELLOWS HELICAL GEAR SHAPER

Spur gears with helical teeth have long been used in Europe in place of ordinary straight-tooth spur gearing. They are also coming largely into use in this country, particularly for automobile engine gears. The advantage claimed for them is that they run more quietly than old-fashioned spur gears. The difference in the action of the two forms is this: With the spur gear the tooth makes contact with its mate instantaneously along the full width of the face. With helical-tooth gears, on the other hand, the teeth do not come into engagement with each other for the full length at once. Contact is made at one end of a pair of teeth first, then a little further in from the end, then a little further still, and so on to the other end of the tooth; and by this time the next pair should be making contact at the front end. Thus it comes about that the teeth are making contact all the time and are going out of contact all the time, the engagement being continuous instead of intermittent. This tends to make the action smooth and regular.

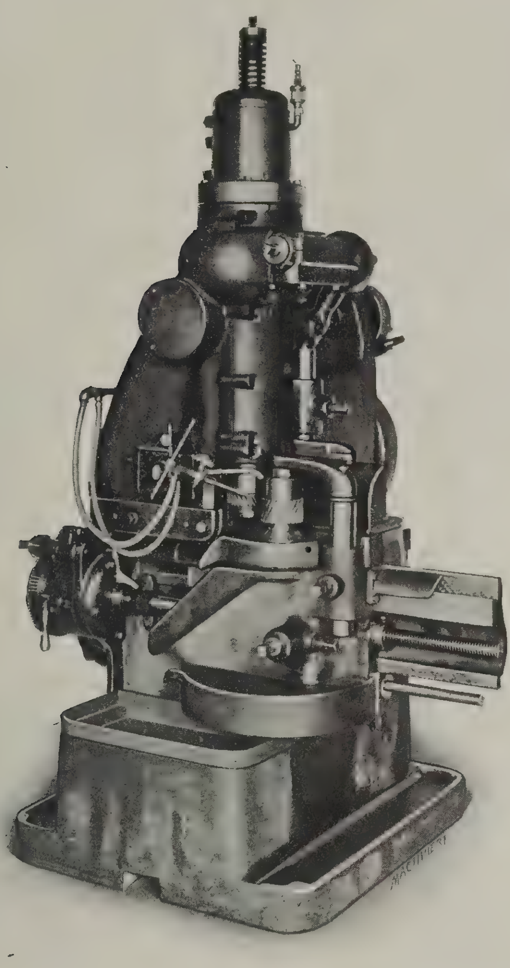

Fig. 1. Helical Gear Shaper built by the Fellows Gear Shaper Co.

The Fellows Gear Shaper Co., 25 Pearl St., Springfield, Vt., some time ago began a series of experiments and investigations on the problem of a simple and accurate process for cutting these helical gears. As the result, a helical gear shaper and a hardened and ground helical gear shaper cutter, have been produced, which extend the accuracy and output of the gear shaper process, to the cutting of helical gears.

Principle of the Helical Gear Shaper

The principle of the shaper's operation is identical with that of the regular gear shaper for spur gearing. Fig. 3 shows a helical gear of steel or other metal rotating in engagement with a blank made of putty, wax or some other plastic substance. It is evident that the teeth of the generating gear will mold, in the plastic blank, teeth of the proper shape to engage with it or with any other gear of the same pitch and helix angle. If the plastic blank could then be hardened, it would be a serviceable gear for use in an actual machine. The practical problem, of course, is to adapt this molding process to the cutting of hard metal gears. This may be done as shown in Fig. 4 where the generating gear is of high speed steel with the tooth outlines sharpened to a cutting edge. This gear, or gear-like cutter, is rotated with the metal blank as if they were in mesh with each other the same as in Fig. 3. In addition, the cutter is given a cutting stroke with a helical motion, which sweeps its cutting edge through the exact space occupied by the tooth surfaces of the generating gear in Fig. 3, and the cutter generates helical teeth in a metal blank, in exactly the same way that the gear molded teeth in the plastic blank; any gear so generated and having twelve teeth or more, will mesh with any other gear of twelve teeth or more, cut by the same cutter.

Special Features of the Machine

Two views of this new helical gear shaper, are shown in Figs. 1 and 2. The only change in the design, as compared with the gear shaper previously built by this company, is the provision of a helical guide for giving the twisting motion to the cutter spindle as it is reciprocated up and down for the cutting and return strokes. Fig. 5 shows the cutter spindle, guide and cutter removed from the machine. The guide, as may be seen, is a solid block of cast iron, which is planed by special machinery to a helix of the proper lead. The mating guide (see Fig. 6) is seated in an enlarged hub bolted to the face of the index wheel. It is of large dimensions and has planed and scraped helical surfaces. It is split in the middle

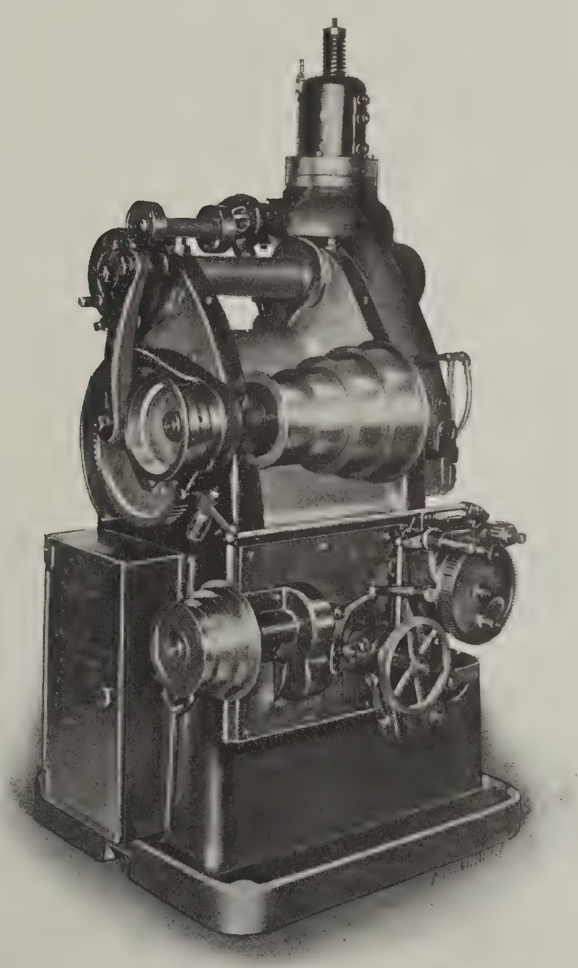

Fig. 2. Rear View of Helical Gear Shaper

and is provided with an endwise adjustment for taking up the wear. The bearing surfaces are so generous, however, that the wear is negligible. The location of the helical guides in the machine is plainly shown in Fig. 8, where the internal member is seen projecting beyond the hub in the upper index wheel.

This guide mechanism is worthy of particular study. Change gears have been invariably employed for obtaining the desired helix angle in previous designs of commercial helical gear-cutting machines. This is convenient where constant changes

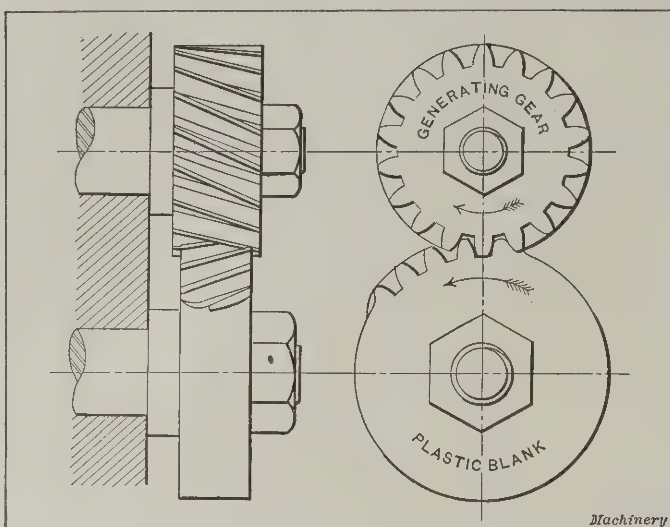

Fig. 3. Diagram illustrating Molding-generating Principle

in helix angle are to be made, but it is a disadvantage as a manufacturing proposition. The control of the motion is elastic and complicated. Furthermore, the change gears usually have to be reset for each new number of teeth cut, even though there may be no change in the helix angle, and often the machine is so designed that a change of feed cannot be made without a re-calculation of the helix change gears. The result is that it may be impossible to do more than approximate the desired helix angle, so that two gears of different numbers of teeth will be found to have slightly different helix angles when the attempt is made to run them together, this being due to approximations in the gearing for the two cases that were different in amount or direction.

With the helical guide mechanism of the helical gear shaper, the cutter is directly connected through the spindle to the

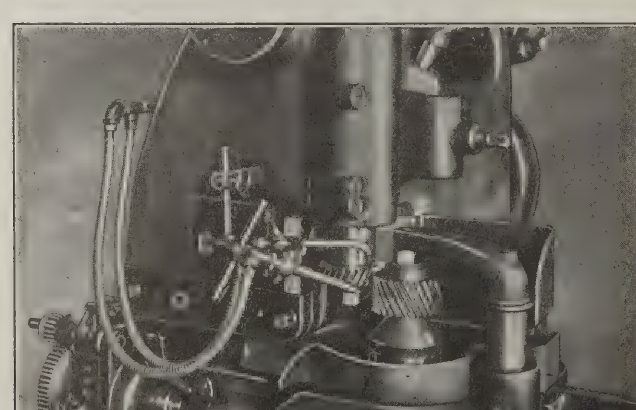

Fig. 4. Detail View of Helical Gear Shaper

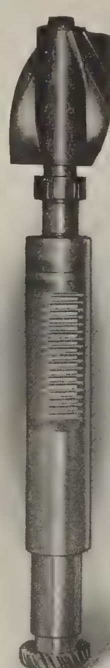
guide which determines the lead of the helix. The control of the motion is direct, rigid and positive. The mechanism is independent of the feed, cutting stroke, indexing or any other function of the machine. It is made of the exact helix desired in the first place and never changes. By means of special machinery, any number of guides of any angle can be made, all exact duplicates of each other. The helix angle of the gears likewise never changes, so that this source of error is removed. Only ten or fifteen minutes is required to change cutters or guides when changing from one helix to another or from a right-hand to a left-hand gear.

A pair of helical cutters used on this machine, is shown in Fig. 7. Like the straight, spur-gear shaper cutter, the helical cutter is hardened before finishing the tooth outline, so that all error from change of shape in the fire is avoided; and it is ground to shape by a generating process after hardening. Every curve on these cutters is a generated curve that is not copied in any way and is formed without the use of templets or master tools. With original curves generated in place on the cutter after hardening, great accuracy is secured.

General Description of the Machine

Aside from the special features previously referred to, the machine is practically a No. 3 Fellows gear shaper of the well-known design. The machine is naturally divided into the following parts: The cutter drive; helical guides; relieving mechanism; index and feed mechanisms. The separate sections will be described briefly.

The cutter drive is operated from the four-step cone pulley seen in Fig. 2. A pinion at the rear end of the cone pulley shaft meshes with a large gear shown at *A* in Fig. 9, which is provided with a graduated crank slot for crankpin *B* operating connecting-rod *C*. The upper end of *C* is pivoted to a wrist-pin



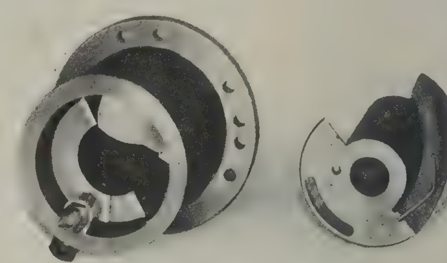


Fig. 6. Mating Helical Guides for Cutter spindle

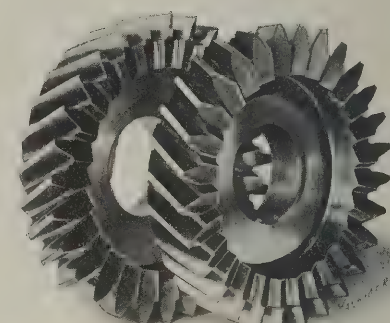

Fig. 5. Cutter-spindle and Helical Guide

Fig. 7. Helical Gear Cutters

in casing *D* which has bearings for worm *E*. This worm engages worm-segment *F* keyed to rock-shaft *G*. The rock-shaft at its other end carries spur gear segment *H* meshing with rack teeth cut in spindle sleeve *J*, Fig. 11. By means of these connections the cutter spindle *K* and cutter *L* are reciprocated. Adjustment of crankpin *B* in the graduated slot, adjusts the length of the stroke to agree with the graduations. The turning of worm *E* adjusts the position of the stroke to agree with the location of the face of the gear being cut, and screw *Y* clamps this adjustment.

The helical guides, illustrated separately in Figs. 5, 6 and 8, are shown in place in Fig. 11. The fixed guide *M* is seated in the extended hub *N* of the upper index wheel *O*. The movable guide *P* is keyed to cutter spindle *K*. Guide *M* is split into longitudinal sections adjustable on each other by means of screw *Q*. This allows the adjustment to give the proper closeness of fit.

The relieving mechanism operates as follows: Crank gear *A* is keyed to shaft *R* which extends through to the front of the machine where it carries a double-throw cam *S*. Cutter spindle *K* and all the attached mechanism is mounted in the head casting *T* which, as shown most plainly in Fig. 9, is free to swivel through a short arc about the axis of shaft *G*. At the beginning of the cutting stroke, cam *S*, bearing on roll *W*

(see Fig. 11), throws this cutter head forward into the position shown for cutting. On the return stroke, the cam bears against spring support roll *V* on the left, swinging head *T* free and relieving the cutter from the work. On the cutting stroke, the head is swung against positive stop *W* which brings it always to the same position.

As explained in connection with Figs. 3 and 4, the cutter

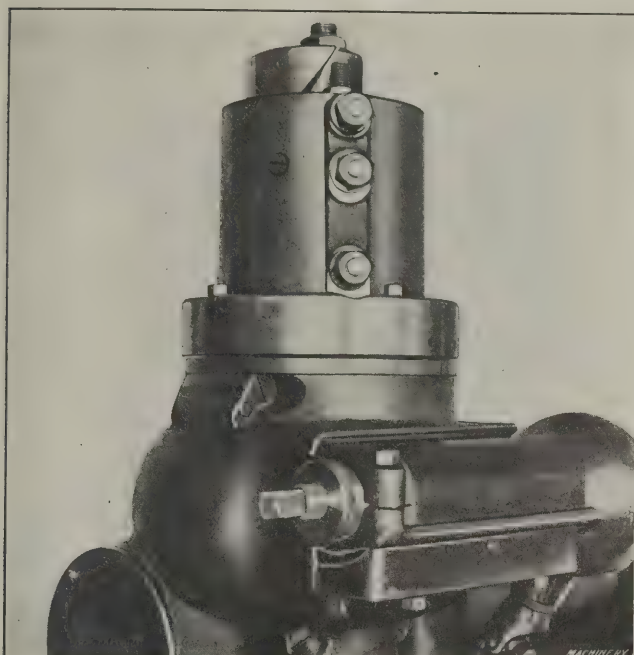

Fig. 8. Detail View of Hub containing Helical Guides

and work are revolved in mesh with each other as if they were a pair of gears. Index wheel *O* for the cutter, and the work index wheel, revolve continuously during the cut, a single revolution of the latter sufficing to complete the work in ordinary cases. They are connected by change gears set for the desired number of teeth.

Four points should be noticed with reference to this index motion: First, it is continuous, steady and slow in movement; second, there is but one revolution per cut, which greatly increases the life of the index mechanism; third, the index

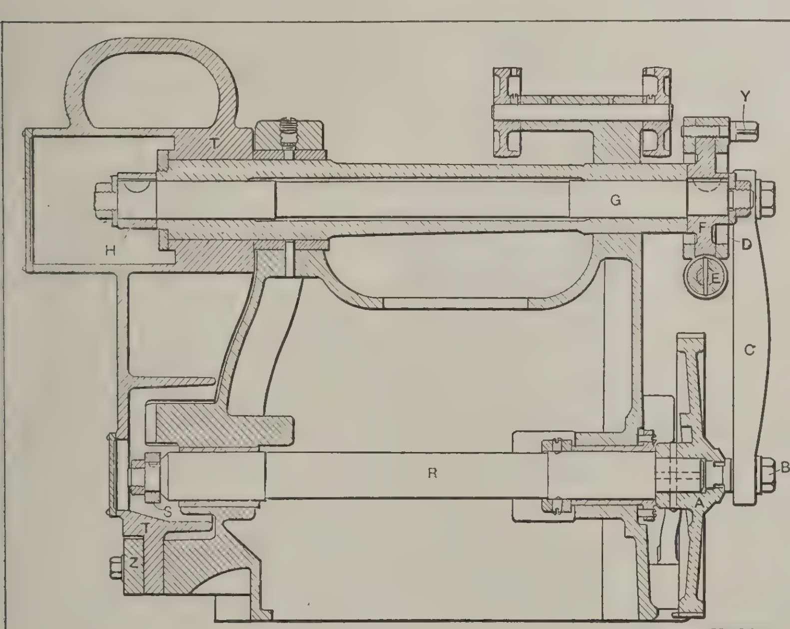

Fig. 9. Vertical Section, showing Drive for Cutter-spindle and Relieving Mechanism

worms revolve so slowly that it is possible to make them self-locking so that the helical thrust of the cutter does not disturb their connection; and fourth, the index mechanism is independent of either the cutter drive or helix mechanism, and is thus free from the irregular action of the former or the complication inherent in the usual design of the latter.

The standard reverse taper work arbor of the gear shaper is retained, thus tying the work, arbor and spindle into a solid whole and giving the entire structure great rigidity. As shown also in Figs. 1 and 4, an outboard support is provided for the work arbor as well as a work support clamped directly to the main frame of the machine. These provisions hold all work firmly, support it against the thrust of the cutter, and permit the machine to "get out" of the cutter all there is in it. Two heavy streams of oil are directed on the cutting edge, cooling the tool and giving a fine, smooth finish on steel work.

The feed mechanism is identical with that of the regular gear shaper. It comprises the rotary motion for the index mechanism, together with means for feeding the cutter in to depth at the beginning of the cut and stopping the feed when the cut is finished. It is entirely automatic in its action.

The double-cut mechanism furnished with every machine, is invaluable when the coarseness of the pitch or the hardness of the material makes it necessary to take a roughing and a finishing cut. The adjustment of a clamp-screw in a graduated slot, determines the amount of stock left for finish.

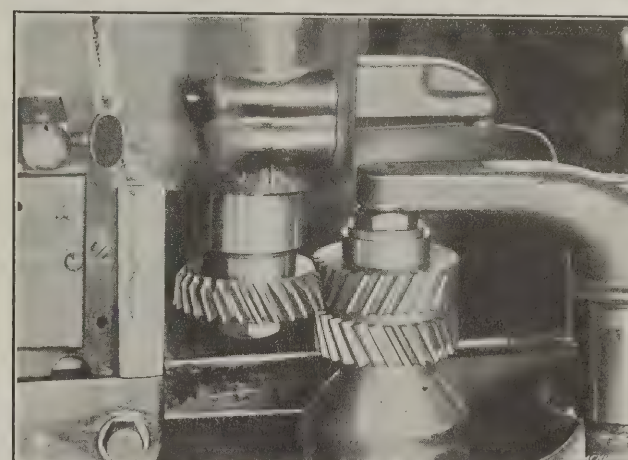

Fig. 10. Cutting a Herringbone Gear

When set for the double cut, with the feed thrown into operation, the following sequence takes place automatically: First, the cutter is fed in to roughing depth. The work then makes one full revolution with the cutter at roughing depth. The cutter next feeds in to finishing depth, and the work makes one full revolution at this depth. Finally, the feed is stopped and a bell rings to call the operator.

Cutting Special Forms of Helical Gearing

The helical gear shaper, like the spur gear shaper, will cut teeth in to a narrow recess. It is therefore easy to cut teeth to a shoulder or to cut cluster-gears with two or more diameters on the same piece. This same feature makes it possible to cut solid, double helical or herringbone gears. With this design of gearing, it has been necessary hitherto to leave a wide space between the two sections for the cutter to run out into, or else the gear has been made in two pieces which are cut separately and fitted and fastened together afterwards. One of these expediencies wastes space, the other time. With the helical gear shaper, a herringbone gear can be made in one solid piece with a narrow groove between the two sections. One-quarter or five-sixteenths inch will do, depending on the pitch or helix angle. The teeth are cut in to this narrow recess from either side. Fig. 10 shows such a gear with the right-hand teeth already formed, and the cutter at work on the left-hand teeth. Where the mating gear is to be cut in the same way, a simple locating fixture brings the teeth on each side of both gears, into position so that a full bearing is obtained on each side of the recess.

Specifications of No. 30 Helical Gear Shaper

The maximum capacity of this machine for cutting helical gears is as follows: Outside diameter, 18 inches; face width, 4 inches; diametral pitch in cast iron, 6; diametral pitch in

steel, 8. It can also be arranged for cutting regular external spur gears, having a maximum outside diameter of 24 inches; face width, 4 inches; diametral pitch in cast iron, 6; diametral pitch in steel, 7. The strokes per minute are 45, 64, 100 and 140. The strokes per inch of pitch diameter of the gear blank are 216, 286, and 418.

In the construction of the machine, particular attention is paid to such vital parts as the index wheels and worms, guides, cutter ram, work spindle, bearings, etc. The materials used are carefully selected for the service required of them. The

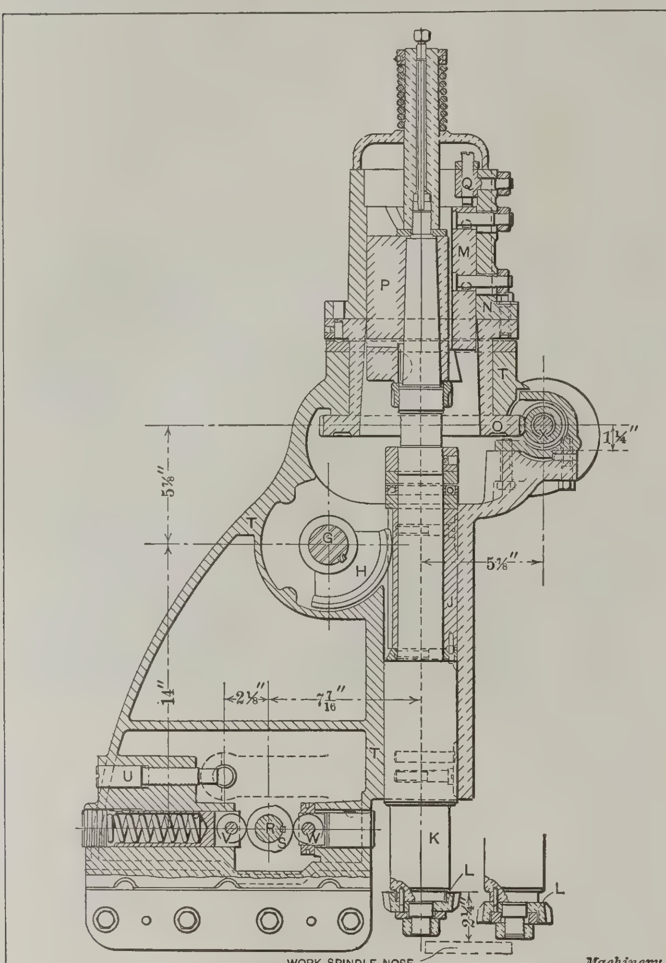

Fig. 11. Section through Cutter-spindle

cutter spindle is hardened and ground. The fast running bearings are lined with phosphor-bronze.

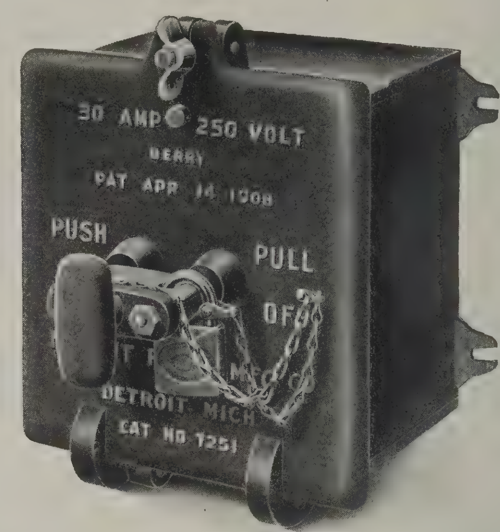
In addition to the machine, the following equipment is furnished: Oil pump and all connections; flexible tubing; two oil nozzles; countershaft complete with tight and loose pulleys; change gears for spacing all numbers of teeth from 12 to 50, and from 50 to 450, excepting the prime numbers and their multiples; one pair of right- and left-hand helical guides of any helix angle specified, up to 30 degrees; all necessary wrenches, etc.

DETROIT SWITCH WITH SAFETY LOCK

Those who read Professor Hutton's article in the April number on the "Prevention of Industrial Accidents," will recall the reference to a safety lock for electric switches, to prevent the unauthorized closing of a switch when repairs are being made along some part of the circuit. The Detroit Fuse & Mfg. Co., 1400 Rivard St., Detroit, Mich., has just brought out an "ironclad" fused switch which is equipped with a padlock for locking the switch in the "off" position, to prevent a circuit from being closed at the wrong time.

The switch is operated by means of a plunger-actuated mechanism with rods projecting through the cover of the box. This mechanism is controlled by a handle on the outside of the switch, and it carries the fuses. The mechanism is attached to the inside of a rubber-gasketed hinged door, and the fuses may be replaced by opening this door. All current-carrying parts are "dead" when the door is open, and the "live" connections are all at the bottom of the switch box, so that it is impossible to make accidental contact with them.

The cover of the switch can be clamped shut by an eye-bolt and wing-nut which engages lugs as shown. A drilled rivet is fastened to the cover, and by running a car seal through this rivet and a hole in the wing-nut, the switch can be sealed to prevent tampering with the fuses. By means of the padlock and clamp shown, the box can also be locked in the "off" position. This feature makes the switch ideal for the control of



Switch with Padlock for Locking it in the "Off" Position

elevators, special machinery or any electrical service where it is desirable at times, to prevent an unauthorized person from closing a circuit. When repairs are being made to a motor, power circuit or lighting circuit, the one making them can lock the switch in the "off" position and secure absolute protection. The padlock and clamp are attached to the switch cover by short brass chains.

POWERFUL HYDRAULIC JACK

The United States government has recently purchased from the Duff Mfg. Co., of Pittsburg, Pa., a hydraulic jack capable of lifting a load of 500 tons. This jack is to be used in the Washington Navy Yard. It is of the independent pump type

Duff-Bethlehem 500-ton Hydraulic Jack

and is composed of two separate parts, one of which contains the water reservoir with its pump chambers, and the other the ram or lifting mechanism.

Flexible copper tubing capable of withstanding a pressure of 10,000 pounds per square inch, connects the two members as the illustration shows. With this arrangement, the ram can be placed in any position where there is room enough for it, while the pumping mechanism can be located at a sufficient distance to allow the operator plenty of working room.

The pump is an improved duplex type, providing an accumulative stroke on the upward motion of the pump piston, and

a working stroke on the downward movement. The pump is so arranged that a light load can be lifted five times as fast as a heavy load. This differential speed is automatically spring controlled, and requires no regulation of valves by the operator. The high speed is used for loads up to 35 per cent of the jack's capacity. In lifting loads greater than 35 per cent of the total capacity, the spring controlled valve automatically opens at the predetermined pressure per square inch, and the pump becomes single acting, working on the down stroke only.

Another feature of this jack is the gage, which shows the exact lifting pressure that is being applied. This gage acts as a scale and registers in tons the weight that is being lifted. The jack is simple in construction and has no parts to get out of order.

CLAMPS FOR MACHINE TOOLS

The clamping of castings or forgings to the table of a planer, milling machine or other tools, frequently requires more time than the actual operation of machining the work. Furthermore, a great deal of unnecessary time is often consumed

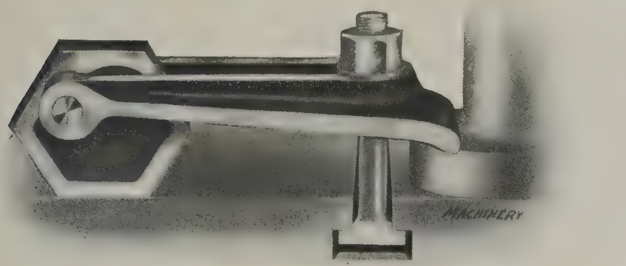


Fig. 1. Clamp Eccentrically Pivoted to Hexagonal Block

because of the lack of proper clamping facilities, as every machinist knows. Schuchardt & Schütte, Cedar and West Sts., New York, have placed on the market the different styles of clamps shown in Figs. 1, 2 and 3, which are designed to reduce the time required for setting up work.

The construction and application of these clamps is so clearly

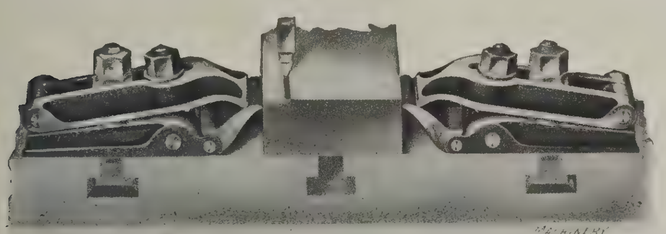

Fig. 2. Type used for Side Clamping

shown by the illustrations that a description is scarcely necessary. The type illustrated in Fig. 1, has a clamp or claw which is pivoted eccentrically to a hexagon block, with the advantage that six different heights may be obtained by simply rotating this block. The design illustrated in Fig. 2 is intended especially for side clamping, whenever the nature of

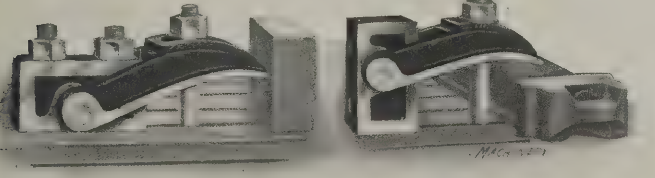

Fig. 3. Combination Clamp for Side and Top Clamping

the work is such that clamps on top would interfere with the movement of the tool. This clamp has two bolts, one of which holds the base while the other tightens a hinged upper member which wedges a hinged claw at the end against the side of the part to be machined. The clamp illustrated in Fig. 3 may be used for side clamping, as indicated to the left, or for top clamping as shown in the right-hand view. This clamp is, in some respects, a combination of the two types previously referred to. The outer end of the clamp is pivoted to a rectangular packing block, in such a way that four different heights are available. These clamps are made in a number of different sizes.

MAGNALAMP FOR MACHINE TOOLS

Operators of machine tools frequently have trouble in adjusting an electric lamp so that the light falls on the right spot. The device illustrated in Fig. 1 is designed to overcome this difficulty, as it can be attached to the machine (as shown in Fig. 2) or work by means of an electro-magnet which con-

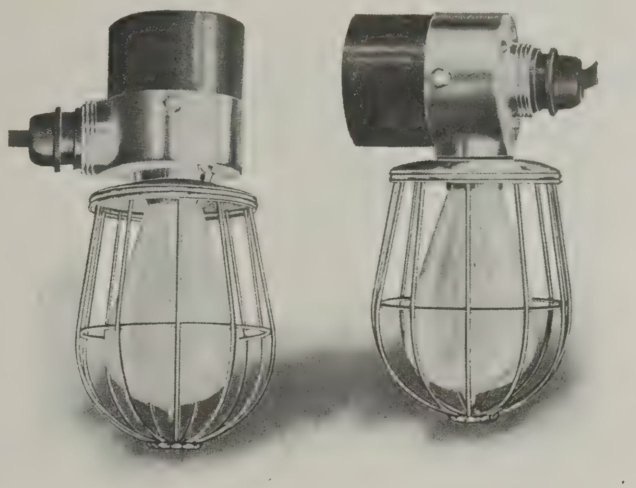

Fig. 1. Electric Light with Magnet for Attaching it to Machine or Work

tains an ordinary incandescent light bulb. It can be applied to iron, steel or any structure that is entirely or partly composed of iron and steel, and the magnetism causes it to stick tight enough to withstand considerable pull. The light bulb extends either from the end of the cylindrical magnet, as shown in the view to the left, or radially from the side, as indicated in the right-hand view, and its position can easily be changed. The same current supplies the lamp and magnet, although the latter consumes a very small amount of energy. The current is controlled by a quick-acting switch operated by a knurled disk which forms the central pole-piece of the magnet. When this knurled pole-piece is turned in a clockwise direction, the switch is opened or closed with each snap. This switch cannot be operated when the magnet is in use. After the current has been turned on and the lamp is lighted, the magnet can be de-energized (so that the lamp may be placed or removed) by pressing the little push button seen extending from the side of the casing above the magnet. By releasing this button, the magnet is instantly brought into service again. After the lamp has once been lighted, it remains lighted, irrespective of whether the magnet is energized or not; consequently, it is never necessary to be without light.

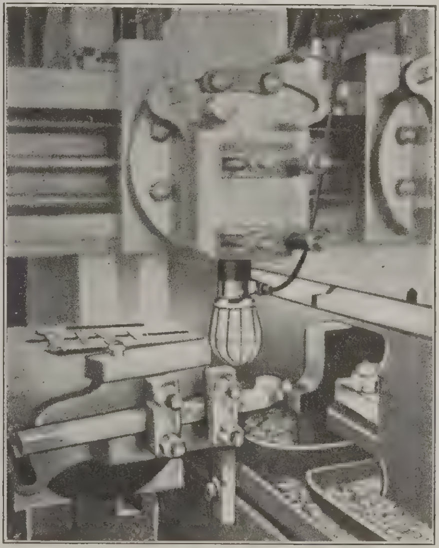

Fig. 2. Magnalamp attached to Planer

This lamp should be supplied with direct current, and it is furnished for the two standard voltages of 110 and 220 volts. This lamp is also supplied with a counterbalance device when it is to be used as a permanent lighting fixture. With this equipment, it serves as an ordinary drop-light when not at-

tached magnetically, and it can be quickly adjusted to the required height. The magnalamp is made by the Sachs Laboratories, Inc., 103 Allyn St., Hartford, Conn.

LODGE & SHIPLEY HEAVY FORGE LATHE

The Lodge & Shipley Machine Tool Co., Cincinnati, O., has recently designed a lathe for taking very "heavy" cuts in connection with the rough turning of shafting and forgings. The power and cutting capacity of this machine is shown by a recent performance, which is said to be safely within the capacity of the lathe for continuous service. A 0.45 carbon steel axle was reduced 1½ inch in diameter by a single cut, with a 9/64-inch feed per revolution, and a surface speed of 63 feet per minute. The lathe is unusually massive, as the accompanying illustrations show, so that it will withstand continued service of the most severe nature.

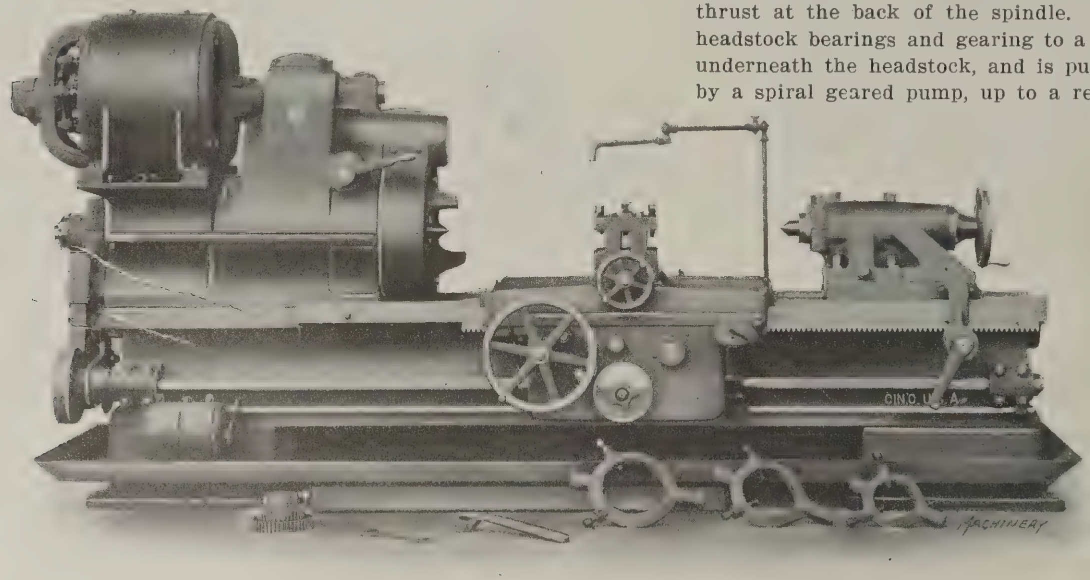

Fig. 1. Powerful Motor driven Lathe built by Lodge & Shipley

The actual swing over the carriage is 15 inches, and the swing over the bed 30½ inches. The arrangement of spindle speeds is such that the lathe is adapted only for turning work between centers; that is, the speed range suits only diameters which will swing over the carriage. The spindle speeds provide for turning at a rate not to exceed 140 feet per minute on 3-inch diameters, and not less than 61 feet per minute on 15-inch diameters.

The headstock is designed to receive a 30-horsepower direct-current, variable-speed motor, having a speed range of from 400 to 1200, but any type of motor can be applied and of any horsepower up to 40. There are two gear ratios, which, with the motor range of 3 to 1, give spindle speeds varying from 15.6 to 173 revolutions per minute. Any ratio of gearing may be provided to accommodate motors of higher speeds or to give the driving spindle any desired slower speed. The reducing of the spindle speed will, of course, increase the gear ratio. The driving gears within the headstock are of steel, and are hardened and heat treated. The lightest driving gear is 4 diametral pitch. The front spindle bearing is of large diameter and gives a projected area of 60 square inches.

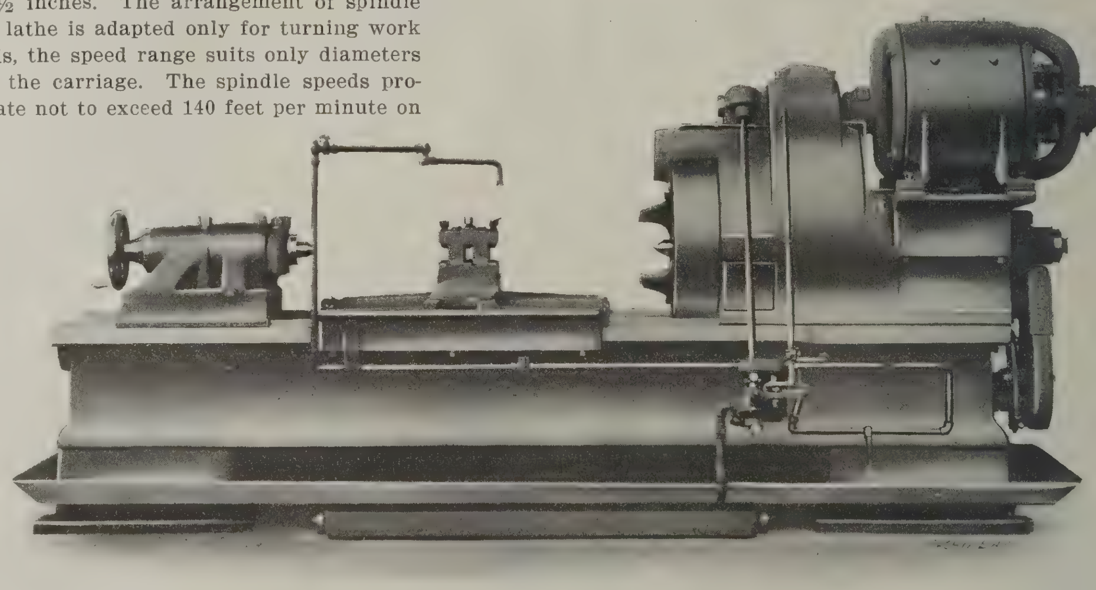

Fig. 2. Rear View of Forge Lathe showing Separate Pumps for Oiling Headstock and Supplying Lubricant to Cutting Tool

The spindle bearings are of standard composition metal. All other headstock journals are bronze bushed. The back spindle bearing is also of large diameter and gives a projected area of 47 square inches. The machine is provided with a compensating faceplate drive. The faceplate is 22 inches in diameter and is made of steel, as are the dogs which act as drivers. These drivers can be adjusted radially on the faceplate to accommodate driving dogs of various capacities and lengths. The driving shafts within the headstock are supported on both sides of the gears, thus eliminating all overhang.

Forced lubrication is provided for all of the driving gears and journals, including the main spindle bearing and the thrust at the back of the spindle. The oil drains from the headstock bearings and gearing to a reservoir cast in the bed underneath the headstock, and is pumped from this reservoir by a spiral geared pump, up to a reservoir at the top of the head, from which it is piped to the various bearings and gears. The spindle is solid, and runs against a solid, hardened steel plug at its back end, to oppose the tremendous thrust.

The centers are No. 6 Morse taper, and the one in the headstock is fitted into a hardened steel bushing forced into the spindle. The headstock is 48 inches long overall, and has covers which entirely enclose all the driving gears. The machine will deliver, with a 30 horsepower motor, about 19,500 pounds pull on an 8-inch shaft, and with a 30 per cent overload of motor, about 25,000 pounds. This would ordinarily create a pressure of 400 pounds per square inch on the spindle bearing, but the driving pinion is so placed that the pressure of the cut is opposed by the driving pinion itself; consequently this amount of pressure per square inch is greatly reduced.

The tailstock arbor is of large diameter and length, and is reamed for No. 6 Morse taper. It is made of tool steel. The tailstock has a long bearing on the bed, and a locking pawl engages a rack cast inside the bed.

The smallest gear in the apron is 3½ inches in diameter, and the finest pitch used, 5 diametral pitch. The smallest face of any gear in the apron is 1½ inch wide. All apron gears are of steel, and all bearings are bronze bushed. The friction

for locking the feed is placed on the outside of the apron to insure close inspection of friction faces at all times. The apron is double webbed, giving support at both ends of all studs. A rear view of the apron is shown in Fig. 3. The handwheel is 18 inches in diameter, and is geared so that one turn moves the carriage about ⅞ inch.

The carriage is very long, and the entire length bears on the bed. The total area of bearing surfaces on the bed is 245 square inches. It is gibbed both front and rear, and also under the inside V's. The bridge is extremely wide and strong, the tool-block is steel, and rests on a cast-iron cross-slide. It has one center slot to accommodate tools 1¼ inch by 2½ inches, and two open sides for tools of the same dimensions. Serrated and hardened tool-steel plates are secured to the tool-block to give the tool a long bearing. The cross-slide is very long, and has 168 square inches of bearing surface on the top of the carriage. The cross-feed screw is of large diameter, and is placed as high as possible to resist the action of the cut. There is an oil trough cast entirely around the carriage, and this trough is placed below the inverted dovetail so that the lubricant from the cutting tool will not flood around the sliding surfaces. The carriage drains at the four low corners, back into the drip pan under the bed.

A separate and very substantial pump is provided for the cutting compound, which is geared positively from the headstock, and this pump will deliver a ¾-inch stream of lubricant to the cutting tool at the rate of 16 gallons per minute. Instead of the usual flexible tubing there is telescopic tubing, (see Fig. 2) with proper stuffing boxes to take care of the longitudinal traverse of the carriage.

The bed is very wide at the top and unusually deep. It is mounted on cabinet legs, and has a heavy steel oil pan the entire length. This oil pan does not rest upon the floor, but is high enough to permit a cast-iron drip pan, mounted upon rollers, to be run under it. The lubricant from the chip pan is drained directly into the cast-iron pan and is pumped from this again to the cutting tool. This method separates the chips from the lubricant, and the chip pan itself is always comparatively dry.

The feed rod is of large diameter, and has two keyseats diametrically opposite for driving a steel bevel gear in the apron. The rod is driven by plain change gears, and four changes of feed are provided as follows: 1/16, 3/32, 9/64 and

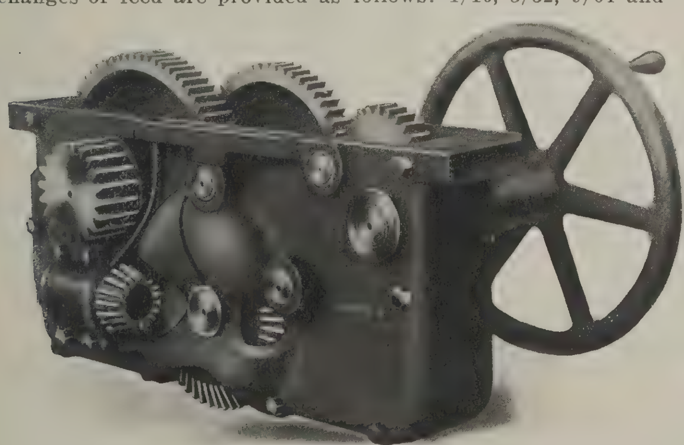

Fig. 3. Rear View of Forge Lathe Apron

3/16 inch per revolution. The feed gears are steel, of wide face, and coarse pitch. The motor controller rod extends along the front of the bed, and is operated by a handle near the top of the carriage.

BICKNELL-THOMAS CLUTCH

The Bicknell-Thomas Co., of Greenfield, Mass., is now manufacturing a roller grip clutch which contains few parts and is self-adjusting for wear and varying load conditions. It requires a small amount of space and is easily engaged. The construction of the clutch is shown in Figs. 1 and 2. Inside of the body *A*, which is free to rotate upon the shaft, there is a hardened steel bushing *B*, which is keyed to the shaft. A hardened steel cam-ring, which may be seen to the right in Fig. 1, is loosely mounted on the end of the clutch body. Fitting into slots in the body *A* and interposed between the cam-ring and bushing *B*, are three hardened steel rolls *D*. One end of a flat coil spring *E* is attached to body *A* and the other end

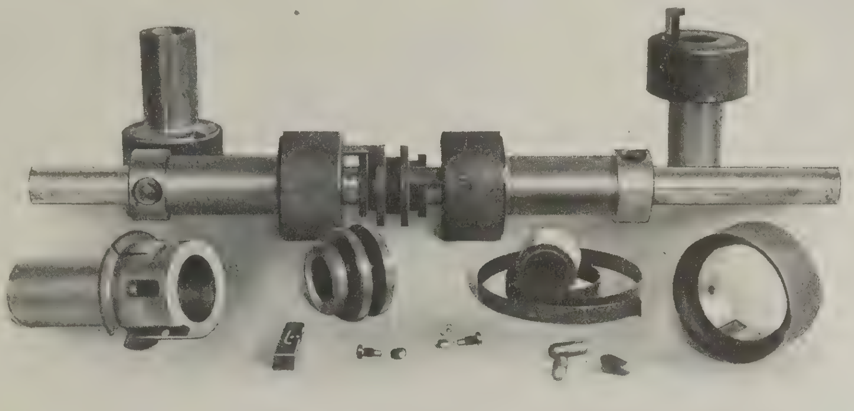

Fig. 1. View showing Single and Double Bicknell-Thomas Clutch and Component Parts

to the cam-ring, which is held onto the body by a screw and roll *F*. On the inside of the cam ring and directly over the rolls, there are cam surfaces. The clutch is operated by shifting slide *G* which causes the coil spring *E* to slightly rotate the cam-ring upon the clutch body. As the result of this rotary movement, rolls *D* become wedged between the fixed

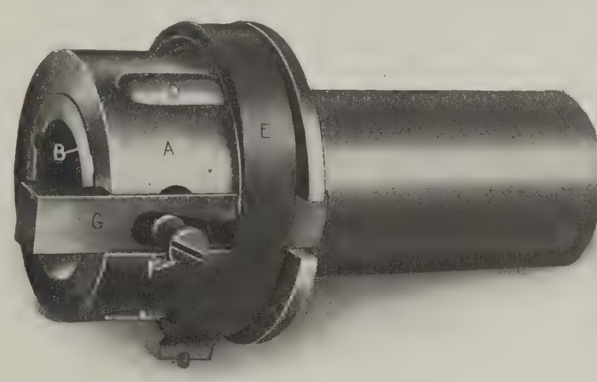

Fig. 2. Single Clutch with Cam-ring Removed

bushing *B* and the cam-ring, thus causing the clutch and shaft to rotate as a single unit. A single clutch is composed of only sixteen parts, including the oil cup, shifter, thimble and collar, and all parts are interchangeable.

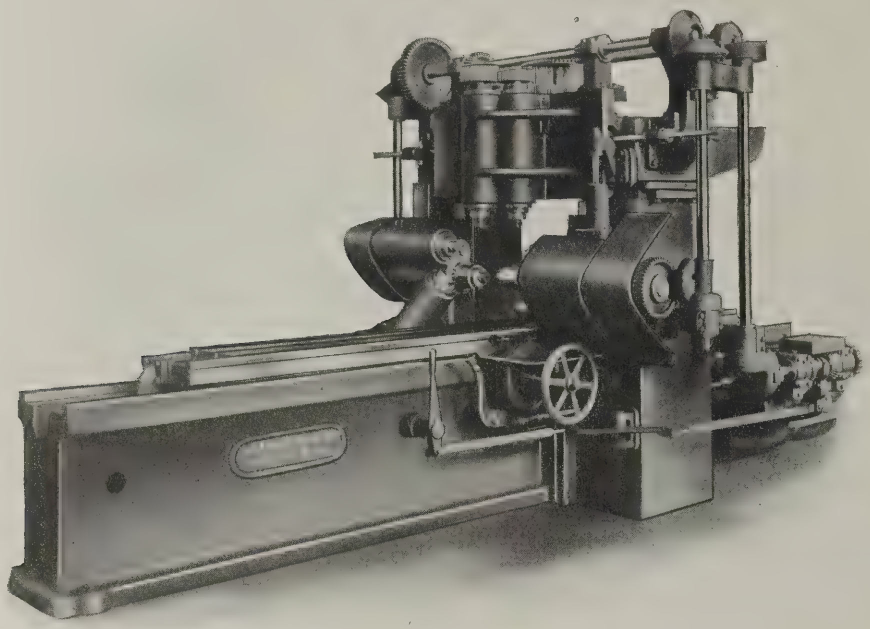
BEAMAN & SMITH NINE-SPINDLE MILLING MACHINE

The nine-spindle milling machine illustrated herewith is a special design recently built by the Beaman & Smith Co., Providence, R. I., for automobile manufacturers. This machine finishes, in one operation, three sides of as many "T-head" cylinder castings as the table will accommodate, thus greatly increasing the rate of production and giving a uniformity to the work that is impossible when each casting is machined separately.

The construction of the machine is similar, in many respects, to the regular planer or horizontal type, except for the arrangement and number of cutter spindles and the necessary changes in the driving mechanism. A saddle on each upright carries three spindles, five of which are in a horizontal position parallel with the platen, whereas one is at an angle of 45 degrees with the platen, as the illustration shows. In addition, three vertical spindles are carried by the saddle on the cross-rail. The saddles on the uprights have vertical movements and the one on the cross-rail, a horizontal movement.

The work-table has a maximum traverse of 10 feet, 10

inches on the bed, and it is 17 inches wide and 10 feet long. It has quick power movements in either direction, varying from 3½ to 14½ feet per minute. The table is operated by a screw which engages a revolving bronze nut, and the thrust is taken by ball bearings. An automatic stop is provided, and the feeds are so arranged that the desired rate can be secured for any spindle speed. The feed movements are positive in either direction, being transmitted through gearing contained in a conveniently located feed box. Nine changes are available, varying from 1 to 6 inches. The spindles are of crucible steel and run in hard bronze boxes. The 45-degree spindle has a 2-inch endwise adjustment and the others have a 1½-inch adjustment. The ends of the spindles are made to fit cutters according to specifications. The spindles all operate in unison and the speeds vary from 17 to 69 R.P.M. The front bearings are 3 inches in diameter, 4 inches long, and means are provided to compensate for wear. The rear bearings are 2½ inches in diameter and 4½ inches long.

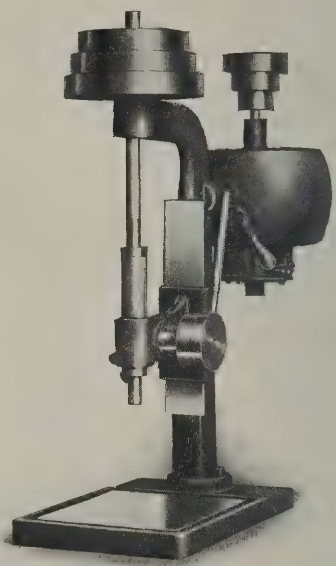


Special Beaman & Smith Nine-spindle Milling Machine

This machine is driven by a 7½-horsepower motor through gearing having a ratio of 23 to 1. The distance between the uprights is 31 inches and the maximum and minimum distances between the ends of the horizontal spindles are 15 3/8 inches and 5 7/16 inches, respectively. The minimum distance from the top of the table to the ends of the vertical spindles is 18 1/16 inches and the maximum, 19 9/16 inches. The distances between the centers of the spindles in each saddle are fixed, the positions of the spindles being governed to suit requirements. The weight of the entire machine is approximately 20,000 pounds. All fast-running shafts have bronze-lined boxes; the bearings are finished by grinding; the sliding surfaces are scraped, and all the gears, many of which are of steel, are cut from the solid.

WILLEY 12-INCH SENSITIVE DRILL

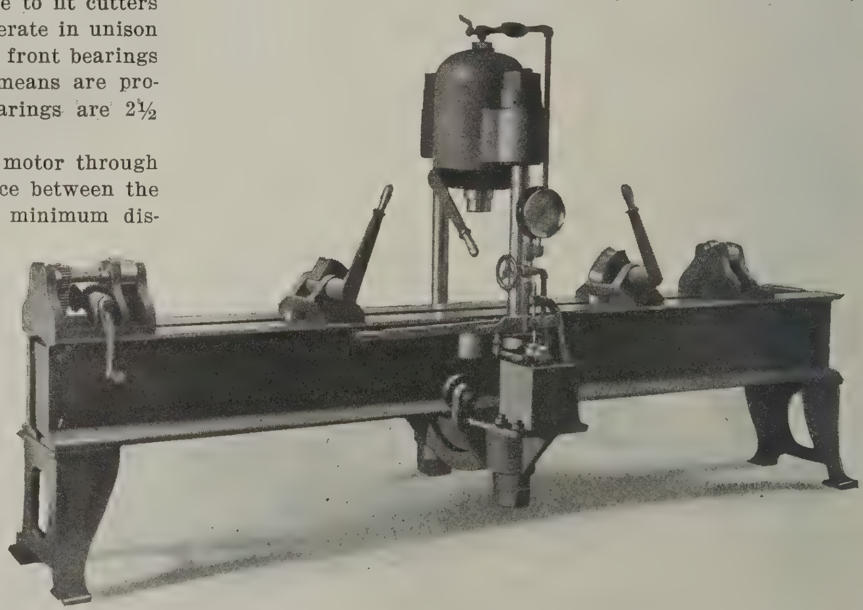
The Willey Machine Co., Jeffersonville, Ind., has brought out a new design of 12-inch sensitive drill. This machine is of the bench type and is driven by a motor which connects with the spindle by a belt operating on the three-step cone pulleys shown. Three changes of speed are available. The motor is adjustably mounted for varying the belt tension. The starting switch is within the motor frame. The motor can easily be detached and exchanged for another, in case it is necessary to use a different voltage or an alternating current. The motor is mounted high enough on the column to be out of the way of dirt and chips. The sliding head has a movement of 8 inches on the column, and the machine drills to the center of a 12-inch circle. The greatest distance from the spindle to the table is 11 inches, and the traverse of the spindle is 3 inches. The total height of the machine is 26 inches, and its weight, 90 pounds. The maximum power of the motor is ¼ horsepower.



Twelve-inch Motor-driven Bench Drill

HYDRAULIC BAR STRAIGHTENER

An improved hydraulic bar straightener has been designed by the Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mount Gilead, Ohio, for use in machine shops, automobile factories, garages, etc. This machine will quickly bend or straighten bars, shafts or axles and it is adapted to various sizes of stock. The construction is simple and a powerful pressure can easily be exerted on a bar or axle.



Hydraulic Bar-straightener built by the Hydraulic Press Mfg. Co.

The press frame is formed of two steel I-beams having rigid stands at the ends, and the press itself is mounted on a carriage which rolls along the lower, outer flanges of the I-beams. A bracket on the carriage supports the pump and water-box, as the illustration shows. The cylinder strain rods are extra strong and have a large factor of safety. A pressure gage and safety valve are provided to eliminate all danger from overstrain. The upper surface of the I-beams is machined, thus

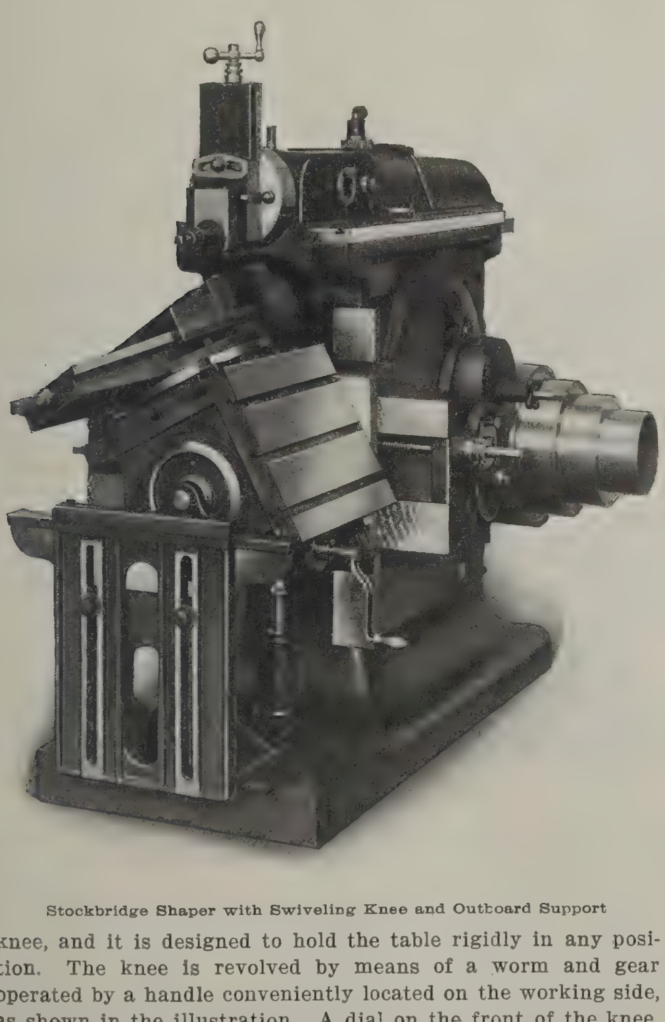
providing a true surface upon which the bending blocks and the tail roller center can slide. By means of the roller centers, axles or shafts can easily be turned to the required position by the hand crank shown. The press can be rolled to either end of the frame with one hand, thus permitting the work to be placed in position without pushing it in endwise.

When the press is in use, the axle or shaft to be bent is placed on the roller centers and turned to the required position. The levers of the bending blocks are then thrown back, thus lifting the axle from the roller centers. The ram is next lowered to the proper position by a hand-lever attached to it, which operates through a rack-and-pinion movement. Everything is now ready for applying the pressure. The pump is operated by hand, and as it is provided with a 30-inch extension handle, pressures up to 125 tons are easily obtained. A pressure of 75 tons is sufficient to bend a solid iron bar 4½ inches in diameter, with the supports 30 inches apart, whereas a pressure of 125 tons will bend a bar 6 inches in diameter with the supports 36 inches apart. It is evident, of course, that larger bars can be bent by increasing the distance between the supports. The ram has a movement of 4 inches, but by using extension blocks which can be attached to it by a set-screw, the advantage of a longer travel can be secured. This makes it possible to straighten large or small bars.

This type of straightener is made in various sizes, having a beam length of from 9 to 25 feet, and with pressure capacities varying from 75 to 125 tons. In addition to the roller centers, the machine may also be equipped with spring centers, both forms being interchangeable.

STOCKBRIDGE SHAPER WITH SUPPORT FOR SWIVELING KNEE

The Stockbridge Machine Co., Worcester, Mass., is now equipping shapers of the swiveling knee type with an outboard support. This support is similar to the type used previously on the shapers built by this company having a standard stationary



Stockbridge Shaper with Swiveling Knee and Outboard Support

knee, and it is designed to hold the table rigidly in any position. The knee is revolved by means of a worm and gear operated by a handle conveniently located on the working side, as shown in the illustration. A dial on the front of the knee, which is graduated in degrees, permits setting the table to any angle when planing bevels. One side of the knee can also be equipped with a tilting top, thus making it possible to plane compound angles.

This swiveling knee support is now applied to the 16-, 20- and 24-inch back-geared shapers, and the 18-inch all-geared type. The machine illustrated is a 24-inch size. The necessity for supporting a knee of the swiveling type is just as great as, if not greater than, for a stationary knee, as shapers having the former design are frequently used for planing parts requiring considerable accuracy.

HAYES CIRCULAR FILE

The circular file shown herewith is intended for filing aluminum, solder, babbitt, and other soft metals. The particular file illustrated is 14 inches in diameter and 1 inch thick. There are teeth on both sides of the file and these are cut by hand. When the file is in use, it is mounted on a stand like an emery-wheel and is rotated at a speed of 200 revolutions per minute.

Circular or Rotary File for Filing Soft Materials

The Ford Motor Car Co. uses a file of this type for filing connecting-rod caps, the babbitt on these caps being "surfaced" by simply holding them against the side of the revolving file. This file is manufactured by the Hayes File Co., Detroit, Mich. It can be obtained in any diameter desired, and either the thickness or grade of cut is varied to meet individual requirements. The file does not clog, and it is especially valuable for finishing soft metals such as those mentioned.

BLISS DOUBLE-DRAW PRESSES

Double-draw presses are the latest development for producing cupped articles or shells by the drawing process. They differ mechanically from the ordinary double-action press in having three, instead of two moving slides, and, therefore, might appropriately be called triple-action presses. The primary object sought in the double-draw press, is to save time and increase production by making two drawing operations on a single article with one stroke of the press, or to draw and re-draw, or re-draw twice in a single operation. It will be seen that this type is, therefore, particularly adapted for articles that require more than one drawing operation to bring them to required dimensions.

The economies effected by this method of drawing, are not due to the simplicity and rapidity of mechanical production alone, but also to reduced handling of shells and the smaller space occupied by the machinery and partially finished product. In addition, the annealing of shells between operations is unnecessary. With the double-draw press, annealing is avoided, as one drawing operation immediately succeeds another, and the heat generated in the first drawing remains in the shell. As annealing involves much expense in the maintenance of furnaces, handling and cleaning annealed shells, etc., the economy, in this respect, is important.

The double-draw presses illustrated herewith are two of a line of six sizes built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. The performance of these machines is said to be very satisfactory. The presses range in drawing capacity

for blanks up to 25 inches in diameter, and the material varies from 1X tin to steel 1/16 inch thick. Shells have been produced having depths up to 10 inches. The smaller sizes are of a somewhat different construction than the larger, being arranged for dies with cutting edges, in order to cut blanks, draw and re-draw in one stroke. The larger sizes (beyond a 12-inch diameter blank capacity) are not adapted for the use of dies with cutting edges.

The slide movements in these presses operate the dies as follows: A double die with the blank on its top, is brought in contact with a blankholder. A tubular punch then descends into the top section of the die, making the first draw. The tubular punch then stops and dwells, thus acting as a blankholder during the second draw. The second draw is performed by a punch that descends through the tubular punch into the lower section of the die, the second draw beginning immediately after the first is completed.

Fig. 1 shows a machine used for cutting blanks up to 12 inches in diameter, from brass sheets or strips up to No. 22

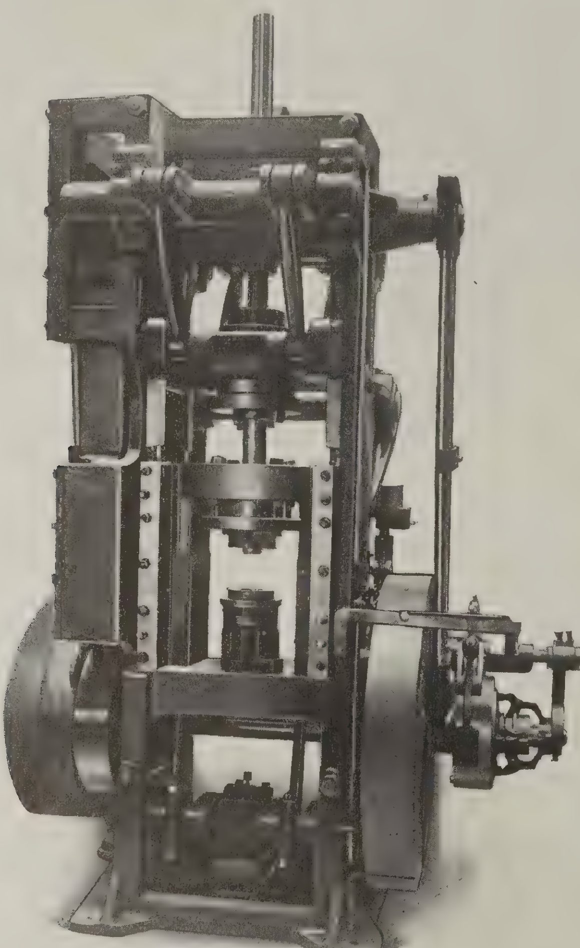


Fig. 1. Double-action Press arranged for Cutting and Drawing

gage thickness, and performing two drawing operations on them. In this machine, the die bed is fixed and rigid and the blankholder carrying the top cutting edges, moves in long adjustable guides. The moving parts are mechanically balanced, as far as possible, and are started and stopped by means of a combined, toggle friction-clutch and brake, either automatically or by hand. The blankholder is actuated by toggles that receive their motion from a cam. These toggles produce a perfect blankholder dwell during the drawing period and receive the blankholder pressure, thus relieving the cam of pressure during that time. The first draw punch slide is actuated by a crank and toggle motion, and the second draw punch by a simple crank motion.

Fig. 2 shows a machine that takes blanks up to 21 inches in diameter and of steel to No. 20 gage thickness. It will receive first draw punches up to 14 inches in diameter and produce shells up to 8 inches final depth. In this machine, the lower dies are fastened to a table that has motion and are brought up against a stationary adjustable blankholder. The table is moved up and down by toggles actuated by a large cam groove in the main gear. The toggles take all the pressure due to the blankholder and the descent of the punches, so that the cam only moves the table up and down. As the table is counterbalanced, its work is very light, which eliminates wear.

The first draw punch slide receives its motion through tog-

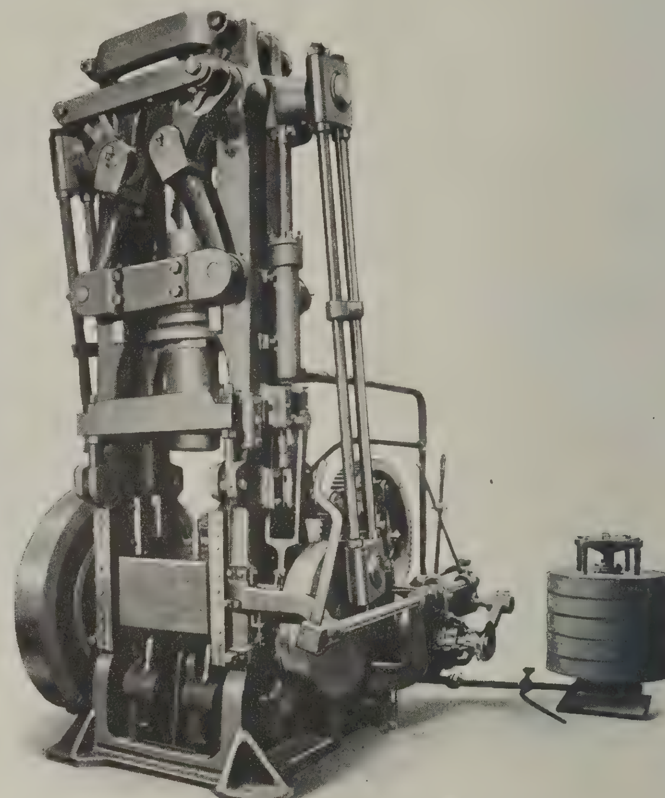

Fig. 2. Double-action Press for Blanks up to 21 Inches in Diameter

gles from the second draw punch slide. These toggles provide a fine dwell for the first draw punch, during the drawing period of the second punch. All the moving parts mentioned, are counterbalanced during their up and down movements by a hydraulic plunger and accumulator system, which makes the starting of the press easy, certain and safe. The hydraulic

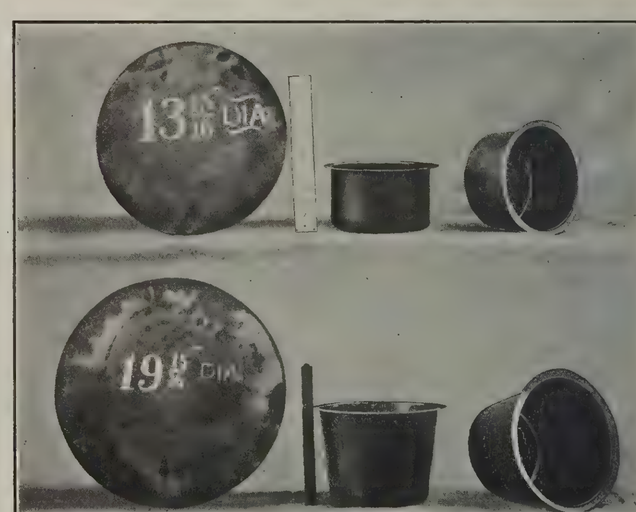

Fig. 3. Blanks and Shells produced from Flat Blank in one Operation on Bliss Double-draw Press

accumulator can be placed in the most convenient position, either below or above the floor line. The machine is driven and controlled by means of a powerful combined, friction clutch and brake fitted with both hand and automatic control. Larger machines have hand control only. Convenient adjustments are provided for the first and second draw punches and stationary blankholder.

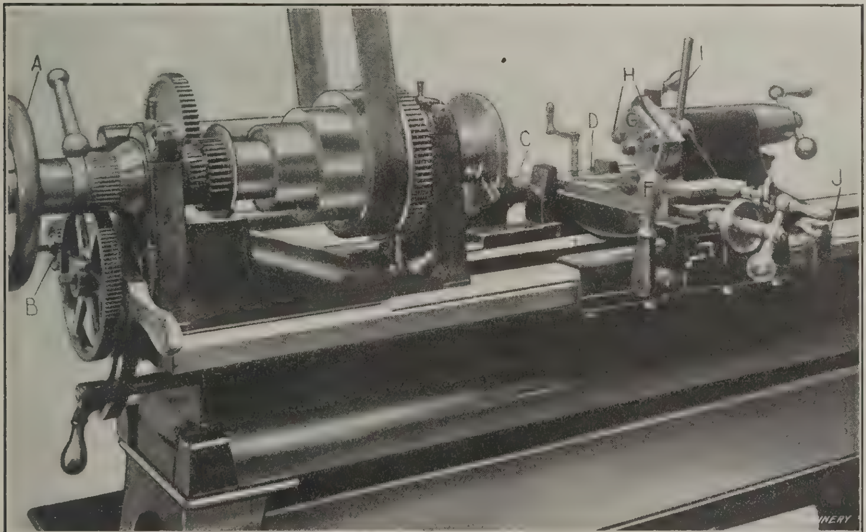
These machines embody many improvements in detail, resulting from a long experience with drawing presses of this type.

BICKFORD SPECIAL THREADING LATHE

The Bickford Machine Co., Greenfield, Mass., is now building a threading lathe designed with special reference to the needs of tap makers. The general construction of this lathe is similar to an ordinary engine lathe, there being a regular back-geared headstock and a divided tailstock having a lateral adjustment for taper work. The bed has short legs and is mounted in an oil tank base. The spindle is hollow and is provided with a draw-in collet attachment operated by hand-wheel *A*. The capacity of the largest collet is 1 inch. The lathe swings 13 inches over the ways, 4 inches over the compound carriage, and takes 28 inches between the centers. This lathe is so designed that threads can be cut in a comparatively short time.

The lead-screw *C* is mounted in a bracket at the rear of the bed and it can be adjusted to any position. Motion is transmitted to this lead-screw through change gears and a telescoping shaft, and it is driven at the ratio of 1 to 1; 1 to 2; 1 to 3 or 1 to 4. With these ratios, a 4-pitch lead-screw can be used to cut a 4, 8, 12 or 16 pitch thread. The change gear on the lead-screw is shown at *B*. The carriage is so divided that the upper part slides across the lathe and carries a half-nut *D* which can be meshed with the lead-screw. This part of the carriage is operated by raising lever *F*, which not only engages the nut with the lead-screw, but is used as a handle for returning the carriage to the starting point. This lever moves to a "dead center" position, so that the cutting tool does not tend to crowd away from the work. The lead-screw thread is of the buttress form, and there is a simple clutch dog at one end, so that the screw can easily be replaced with another of different pitch. The half-nut is also easily detached.

The roughing and finishing thread chasers *H* are of the Landis or milled type. These are held by holder *G* which, in turn, is supported on a compound slide. The chasers are fed in nearly to the required depth by this slide so that the benefit of an angular shear cut is obtained. The chasers are clamped to the holder by lever *I*. The maximum length of thread that can be cut at one setting is 10 inches, but the convenient adjustment afforded by the compound rest for aligning the chasers, makes it feasible to cut a length of 10 inches and then slide the lead-screw along for threading another section. A positive stop *J* is provided for the carriage.

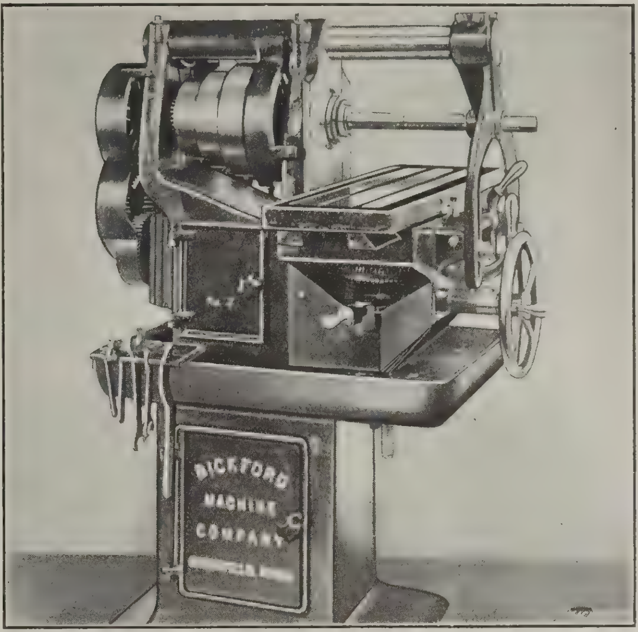


Bickford Threading Lathe of Special Design

BICKFORD PLAIN MILLING MACHINE

The milling machine shown in the accompanying view is built for plain manufacturing operations, in connection with which a rigid design is more desirable than one possessing a wide range. The knee and saddle are formed of one solid casting, which gives the table a rigid support. The table has a bearing 24 inches long and 8 inches wide. The feed is of a rack-and-pinion type. By means of a special clutch and gear device inside the knee, a handwheel at the side of the machine can be connected to operate the knee up or down, or the table in either direction. This change is made by simply moving a lever at the front of the table, to the right or left.

The spindle is of crucible steel and runs in phosphor-bronze bearings. The front bearing has a taper hole in which the spindle is held from end motion by a special clamp collar. This bearing may be adjusted a distance of ¾ inch through the main housing to which it is splined and held by a nut at each end. The front end also has a graduated collar provided with a clamp screw for setting it back to zero from any position. The cone pulley runs free on the spindle and has a small gear which drives the back-shaft, and the latter drives the main gear on the spindle. The ratio of this gearing is 6 to 1. The pulley is held in position by a spring collar located between one end and the main driving gear which travels longitudinally with the spindle.



Bickford Plain Milling Machine

The feed motion is transmitted through a coarse pitch worm in mesh with a large gear on the pinion shaft. The end pressure of this worm is taken by a ball thrust bearing. The feed shaft is all gear driven. The feed changes are effected by opening the door in front of the machine and shifting a lever. The gear box gives ten feed changes for each of the three spindle speeds or a total of thirty changes in all.

The overhanging arm is of steel and 3¼ inches in diameter. The drop arm and braces are cast integral. The levers operating the power feed and stop are conveniently placed. The table has a deep oil channel extending around the platen and loose "splashes" (not shown) are provided for carrying the overflow of oil to a tank in the base. The lubricant is forced to the tool by a gear pump at the rear of the machine. The working surface of the table measures 7¼ by 29½ inches. The weight of the machine is 1750 pounds, and this same type is built in larger or smaller sizes. It is built by the Bickford Machine Co., Greenfield, Mass.

CHAMBERSBURG STEAM-HYDRAULIC PRESSES

The Chambersburg Engineering Co., Chambersburg, Pa., has developed a line of steam-hydraulic forging presses which are built in both the single-frame and four-column types. The single-frame presses range in size up to and including 400 tons pressure, and the four-column types up to and including 5000 tons capacity. These presses have a double-lever control, and multiple tonnages for the larger sizes. With the double-lever control, the entire operation of the press is governed by

the two hand levers seen in Fig. 1 of the accompanying illustrations. As these levers perform the same functions as the two levers on a steam hammer, the operation of the press

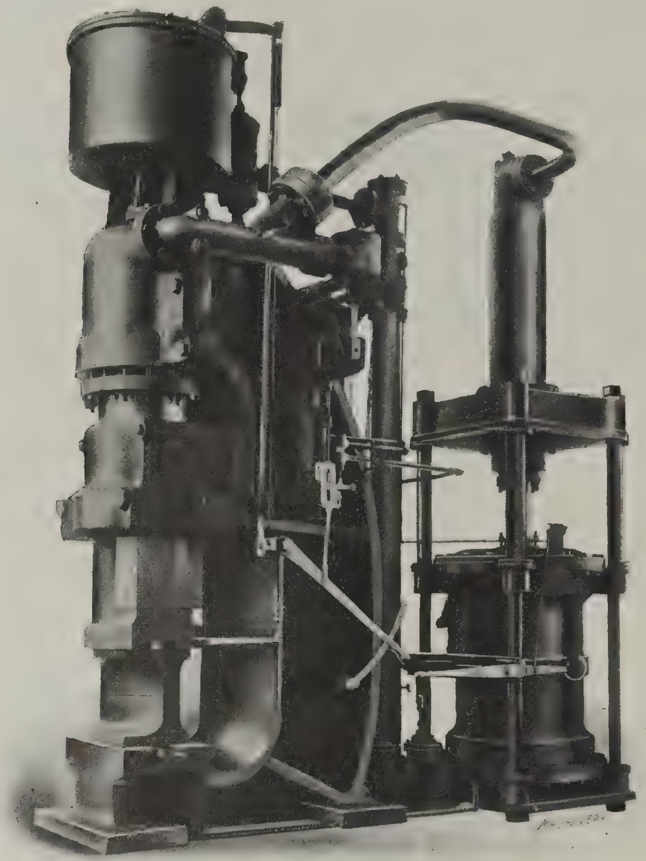


Fig. 1. Chambersburg Steam-hydraulic Press with Triple Intensifier

comes naturally to the workman. With one lever, the position of ram is adjusted for the length of stroke, and with the throttle lever, the power of the stroke is varied. In both cases the ram follows the direction in which the lever is moved.

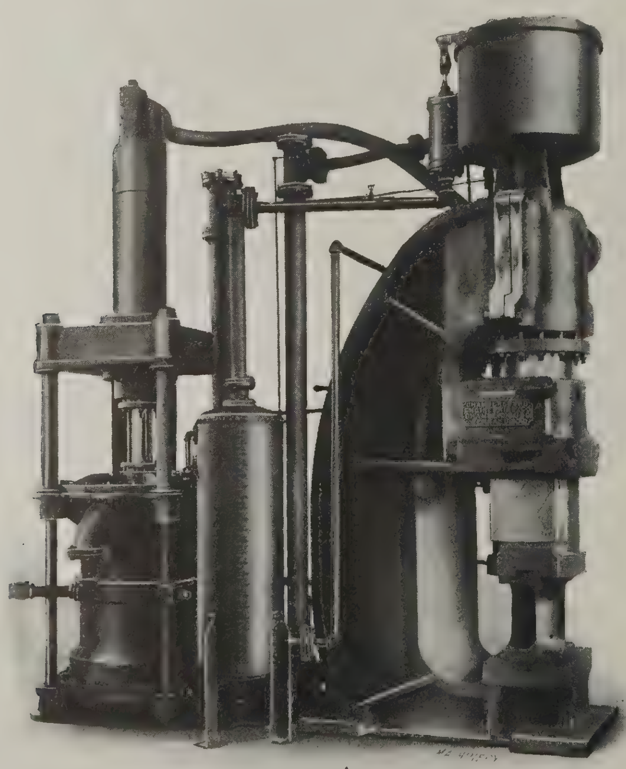

Fig. 2. Opposite Side of Steam-hydraulic Forging Press

For the larger size presses, great economy in steam consumption is said to be effected by means of a triple intensifier which enables the operator to use selective pressures in proportion to the varying necessities of the work; in other words, the amount of steam used is regulated in accordance with the requirements of the work being forged. The usual practice has been to use a single-cylinder intensifier which consumes a constant volume of steam, whether the press is exerting a 500-ton pressure, or 2000 tons in a press having a maximum capacity of 2000 tons. In the Chambersburg design, a press having a maximum capacity of 2000 tons is arranged for three multiple pressures of 600 tons, 1200 tons or 2000 tons, with the steam consumption proportional to the tonnage being used.

The main frame of the 400-ton single-column press illustrated, is an open-hearth steel casting of I-beam section, the web being stiffened by heavy ribs. Projecting flanges at the base form a support for the press. The frame has heavy guides for the ram, fitted with a cap which is held rigidly by bolts to take care of strains in any direction when forging beveled work. The dies are skewed so that the work will clear the frame when either drawing or finishing, and the notches in the ram and die seat can be planed to suit any existing dies.

NIAGARA DOUBLE-ACTION CAM PRESS

The Niagara Machine & Tool Works, Buffalo, N. Y., has added to its line of presses the double-action cam press, shown herewith. This machine is intended for cutting and drawing shells, and possesses several new and interesting features.

Instead of making the adjustment on the blankholder slide (to accommodate dies of various heights) by means of screws

Niagara No. 85 Cam Press

connected to the cam roller yokes, a threaded sleeve is used on the lower end of the blankholder slide, which enables the adjustment to be readily and accurately made. This arrangement also makes it possible to locate the guides for the blankholder slide, directly in line with the center of the crankshaft. Adjustable gibs are provided, not only for the blankholder slide, but also for the inner slide, which is a decided advantage when using combination cutting and drawing dies.

The design of the press, in other respects, conforms with the most improved practice on machines of this type. The outer slide or blankholder is positive in its motion and it is raised and lowered by two cams keyed to the main shaft on each side of the crank. The cam roller yokes are rigidly connected with the blankholder, and provision is made for taking up wear. The lower cam rollers are set in oil boxes to insure good lubrication for both rollers and cams. The inner slide

receives its motion from the crankshaft by means of a pitman, which has vertical adjustment. The press illustrated is equipped with a single roll feed attachment. Presses of this design are made in several sizes.

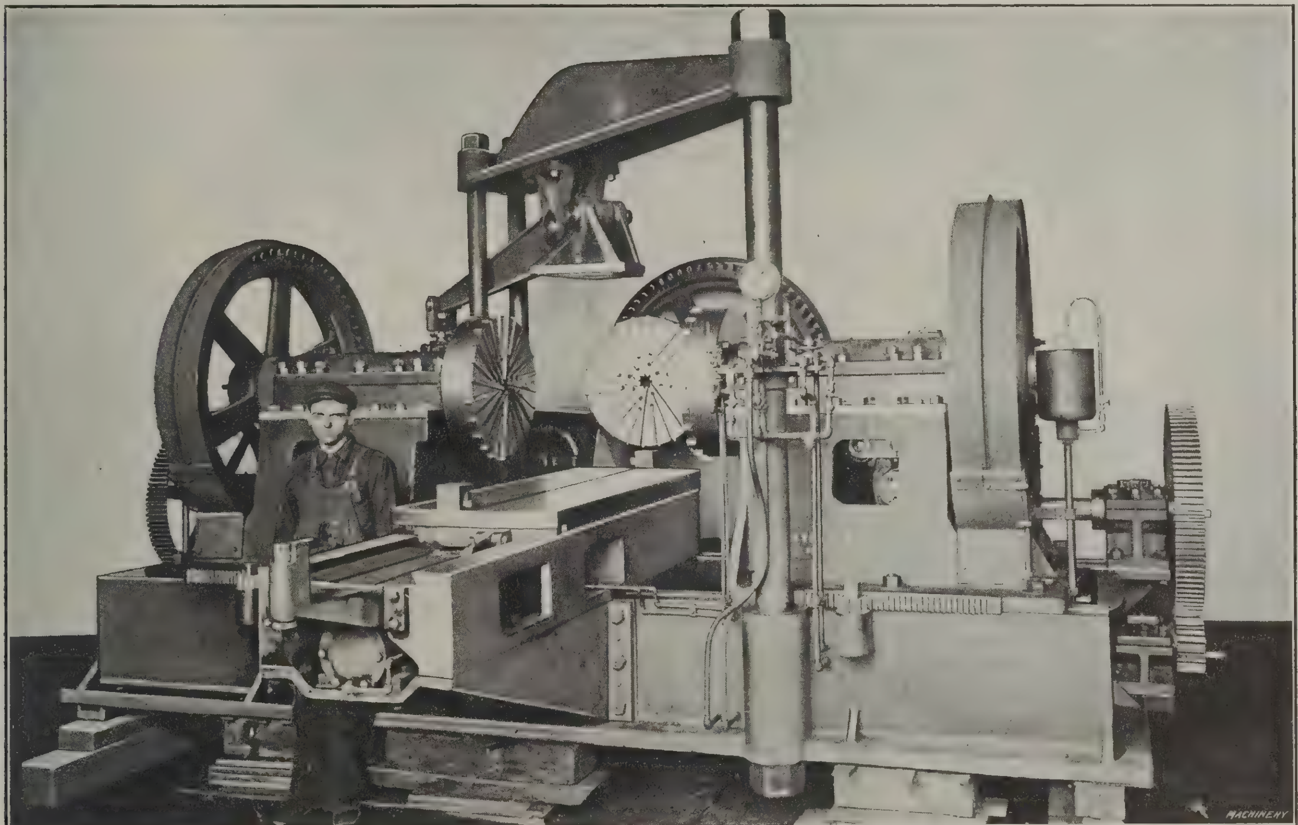
LARGE THREE-WAY FLANGE FACING MACHINE

The Pottstown Machine Co., Pottstown, Pa., has designed a very interesting machine for facing the flanges of large pipe fittings, valve bodies, and similar work. This machine is equipped with three 25-inch facing heads which operate simultaneously. The arrangement of the heads and method of driving them will be seen by referring to the accompanying illustration. The power is derived from a 35 horsepower motor at the rear, which drives through gearing having a ratio of 256 to 1. The spindles are carried by slides which are mounted in heads resting on the main bed. The spindles have a longitudinal movement of 1½ inch, which is sufficient to clear a rough casting and face the flanges to the finished dimensions. Each spindle is fed into the work by an air cylinder, and the feed is controlled by an oil cylinder. These cylinders are located inside the bed and connection is made with the spindle slides by levers which give a powerful feeding movement. The heads carrying the spindles can be adjusted along the bed to accommodate work of different widths. This adjustment is effected by racks and pinions located at the base, as shown in the illustration. Each head is rigidly secured to the bed by six 1½ inch bolts, and the back thrust is further provided for by jack-screws which rest against the ends of the bed and give a positive support.

The work is held in position by a massive steel yoke located above the machine and equipped with a lever and pneumatic cylinder, which is capable of exerting a pressure of fifty tons on the fitting. The movements of the work table, pneumatic clamp, and the facing heads, are controlled by three air valves, which are conveniently located on the yoke column at the right side of the table. An air gage is provided to show what pressure is being applied to the fitting, in order to prevent feeding the cutters against a casting before it is firmly clamped. The work table is long enough to permit using a double set of fitting holders or fixtures, so that the workman can load one fixture while the casting on the other end of the table is being faced.

The method of operating this machine is as follows: The fitting is placed in the fixture and the table is moved in by air to the working position. The three heads are then fed in to the required depth, and while this is taking place, the operator places another casting in the fixture attached to the outer end of the bed. When the inner casting is faced, the cutters are withdrawn and the table is moved outward to clear the heads, after which it is turned halfway around, thus bringing the rough casting in to the facing position. As all of these movements are pneumatically controlled, they are effected quickly by simply working the small air-valves shown. It should be mentioned that the distance which each head feeds inward is predetermined by a stop that arrests the movement of the feed lever and prevents further cutting.

Each facing head has twenty-two high-speed steel cutters which are mounted radially and operate across the entire surface of the flange. The cutter-head spindles are 8 inches in diameter, and the driving gears have a diameter of 51 inches and a face width of 7½ inches. The maximum distance between the front cutter-heads is 45 inches, or 22½ inches from the center of a fitting. The two front heads will face to a minimum width of 9½ inches. The height from the top of the table to the center of the spindle is 16½ inches. The total floor space required by the machine is 17 feet, 4 inches, by 16 feet, 5 inches. The over-all height is 8 feet from the floor line, which is about 8 inches below the top of the main bed. The weight of this machine is 60,000 pounds.



Special Flange Facing Machine built by the Pottstown Machine Co.

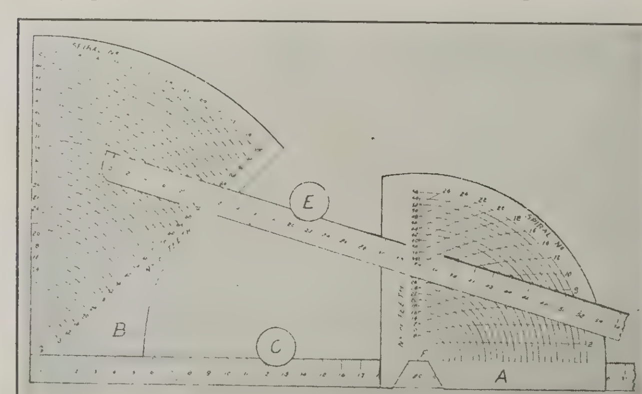
LINEOMETER FOR DETERMINING CHAIN LENGTHS

The Diamond Chain & Mfg. Co., 240 W. Georgia St., Indianapolis, Ind., has developed an instrument by means of which the length of a sprocket or driving chain can be quickly determined without making a calculation. This instrument is known as a chain lineometer, and it enables the length to be ascertained by making three simple adjustments. The instrument in its simplest and cheapest form is made of paper (as shown in the accompanying illustration), and there is also a high-grade steel instrument, which operates on the same principle.

Referring to the illustration, there is a fixed scale *C* laid off in half-inch divisions, each representing a distance equal to the pitch of the chain. On the movable scale *E* each half-inch

division represents a distance equal to two pitches—one for the upper half of the chain and one for the lower half. The circles on the sectors *A* and *B* are the pitch circles or 1-inch pitch sprockets, drawn half size. These circles are crossed by spirals having numbers which represent the number of chain links from the point where each spiral crosses a given circle to the corresponding point on the lower half of the circle.

As an example for illustrating the use of this instrument, suppose it is desired to find the chain length for sprockets having 72 and 36 teeth, respectively, a center-to-center distance of 15 inches and a pitch of ¾ inch. If the center distance is divided by the pitch, the result is 20, which is the center distance *in terms of the pitch*, and the sector *A* is set at this figure on scale *C*. The straightedge *E* is next set approximately tangent to the two pitch circles at *A* and *B*, corresponding to 36 and 72 teeth, respectively. The point where the spirals cross these pitch circles is then noted and the straightedge is shifted so that it covers all but one of these points. The zero point on the scale is set to coincide with the point not covered on the left-hand dial, and the point not covered on the right-hand dial should just touch the straightedge. In other words, place the straightedge in the position that the center line of the chain would occupy in passing from one sprocket to the other. The straightedge reading at the intersection of the spiral and pitch circle lines on the right-hand sector, equals twice the number of links in the span of "free"



Instrument made by Diamond Chain & Mfg. Co. for Determining Chain Lengths

chain. For example under consideration, this is 38, and the number marked on the spiral passing through the zero point is 44, whereas, the number of the spiral passing through the thirty-eighth division is 14. The sum of these three numbers (96) is the chain length *in terms of the pitch* and 96 × ¾ inch = 72 inches, which is the length in inches.

As the length of a roller chain must, in general, be a multiple of twice the pitch, the reading on straightedge *E* must be an even number. If the spiral does not pass exactly through one of the even-numbered scale divisions, the next higher even number is used. If an offset connecting link is employed, this number must be odd, and if the chain is of the "block" type, the reading may be either even or odd, since the chain length can be any multiple of the pitch. With the steel instrument previously referred to, the adjustments are greatly facilitated. The right-hand sector is quickly clamped into position by a thumb-screw, and the zero point of the straightedge is brought to the proper pitch circle by a slide which is graduated on the left for roller chains and on the right for block and twin-roller chains. There is also a linked connection which allows the straightedge to swing about its zero point.

If it is desired to determine a center distance which will eliminate slack in the chain, shift the right-hand sector until one of the regular divisions of the straightedge is on a spiral; then take the center distance reading and multiply by the pitch. To find the length of a belt, a special set of sectors must be used.

CINCINNATI EIGHT-INCH PRECISION BENCH LATHE

The Cincinnati Precision Lathe Co., Cincinnati, Ohio, has brought out a new precision bench lathe which is a decided departure from conventional designs. This lathe is a friction-driven type and has a single constant-speed belt pulley. This arrangement does away with a cone pulley on the spindle, thereby permitting the use of exceptionally long bearings; in fact, the spindle has a bearing that is practically continuous (as will be seen by referring to Fig. 1) which gives a very rigid support and obviates chattering.

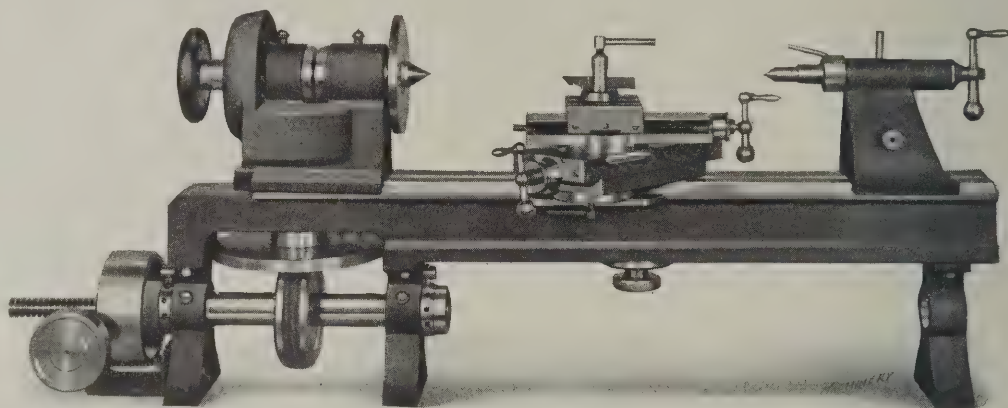


Fig. 1. Precision Bench Lathe built by the Cincinnati Precision Lathe Co.

The method of transmitting power from the main belt pulley to the spindle is shown more clearly in Figs. 2 and 3. The main driving pulley is keyed to a hollow, slotted driving shaft which contains a rack shaft, by means of which the position of the driving friction disk is varied, as will be explained later. A key passes through both of these shafts and engages the driving friction disk which transmits the movement to the horizontal driven disk above it. The latter is keyed to a vertical spindle which drives the lathe spindle through a pair of accurately cut miter gears, as shown in Fig. 2. There is a ball thrust collar bearing between the horizontal friction disk and the lathe bed, and the miter gears run in oil.

The mechanism for varying the speed adjustment is shown in the sectional view, Fig. 3. The rack shaft, previously referred to, meshes with a pinion attached to a handwheel on the outer edge of which is a speed indicator. By means of this handwheel, the friction driving wheel is shifted on the driven disk for obtaining any desired speed in either a forward or reverse direction. When the position of the disk is changed, the driving key slides in a slot cut in the hollow shaft. There is a depression in the center of the driven disk, so that the machine can be stopped independently of the

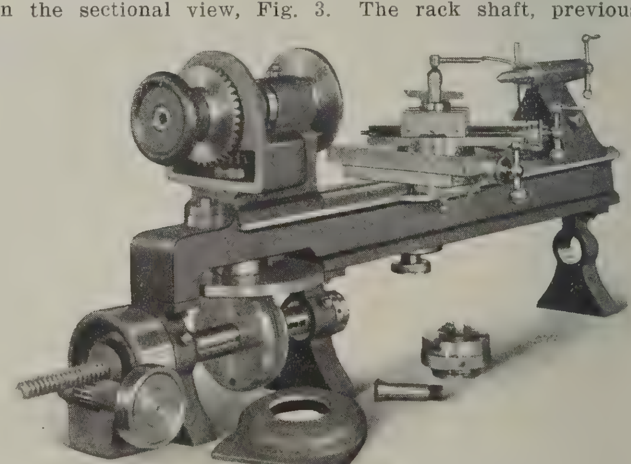

Fig. 2. Another View of the Precision Lathe—Spindle Gear Guard removed

driving belt. If desired, the friction disk can be chamfered at the outer edge to permit stopping the machine by placing the driver either at the central or outer positions. This friction transmission is said to give a strong drive, thus making it possible to take heavy cuts as well as light delicate cuts. The face or periphery of the driving friction disk contains layers of specially treated oak-tanned leather, subjected to a high pressure in order to increase its durability.

Any wear which may occur between the friction disks, can be taken up by means of eccentric bushings so arranged that the friction driving shaft may be raised or lowered parallel to the face of the driven disk. The power required for the heaviest cuts taken on a precision lathe, is so small in proportion to the efficiency of the drive that the friction mechanism cannot be overloaded.

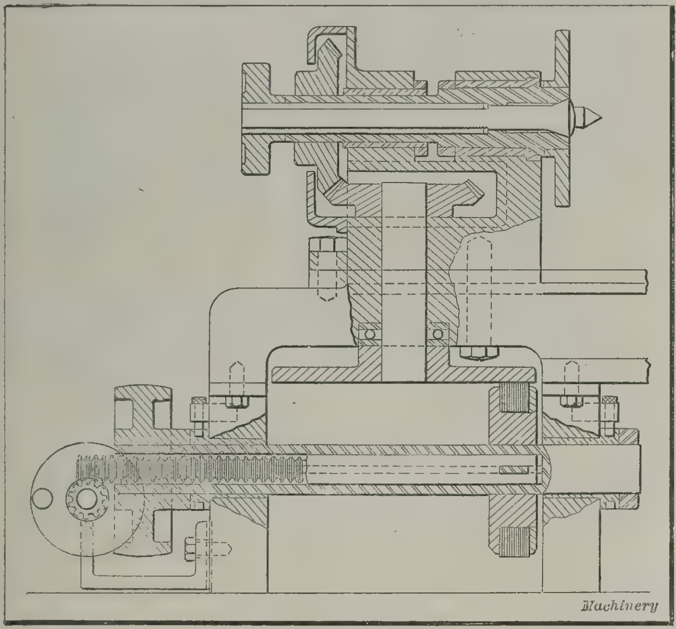

Fig. 3. Sectional View showing Arrangement of Driving and Speed Adjusting Mechanism

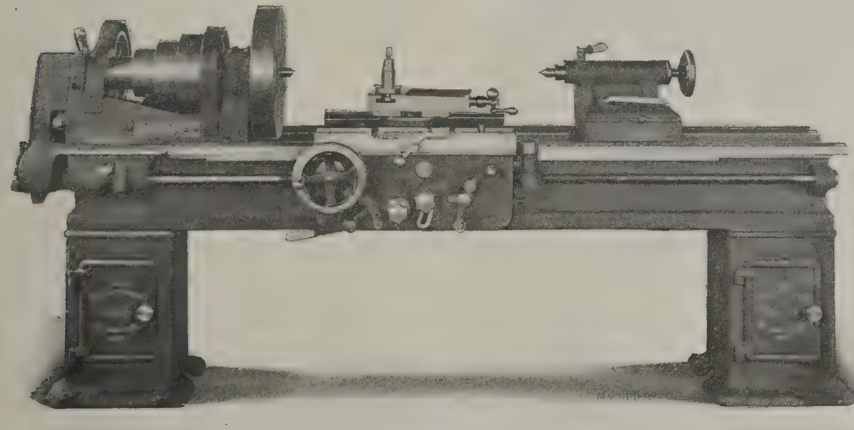
The location of the belt pulley eliminates overhead countershafts and permits driving from beneath the bench if desired. When the power is applied from beneath the bench, clutch friction pulleys are used, thus doing away with the tight and loose pulleys. This machine is constructed throughout of high-grade materials. The castings are of "close" iron and they are properly seasoned after being roughed out, before finishing. The spindle is hardened, ground and lapped and its bearings are of high-grade phosphor-bronze. The swivel slide rest is designed along modern lines and is built to withstand heavy service, if necessary. This lathe was designed by Mr. J. M. Tatman of Cincinnati.

ADVANCE NO. 2 ENGINE LATHE

The Advance Machine Tool Co., 591 Twenty-second St., Milwaukee, Wis., has brought out a heavy-duty engine lathe which embodies a number of improvements. The feed mechanism is located in the apron (see accompanying illustration), where it is always within convenient reach of the operator, regardless of the position of the carriage along the bed. This mechanism gives four feed changes varying from 0.015 inch to 0.060 inch. A wide range of feeds can also be obtained through change gears operated by a lever at the headstock end of the lathe.



Lathe built by Advance Machine Tool Co.

This machine has a swing over the V's of 18½ inches, and a swing over the carriage of 12 inches. The tailstock is of the offset type, thus permitting the compound rest to be set parallel to the centers when close to the tailstock. The headstock is extra heavy and has large bearings for the spindle. The spindle is made of chrome-nickel steel and has a 1 9/16-inch hole extending through it. The apron is the double-plate pattern and has no loose brackets of any kind. There is only one friction clutch for both the lateral and cross feeds, thus making it impossible to engage more than one feed at the same time. The lead-screw nut is provided with a stop so that the feeds cannot be operated while chasing threads, and *vice versa*. This lathe is of the heavy pattern, and is tested for alignment within a limit of from 0.001 to 0.0015 inch.

AMES UPRIGHT DIAL GAGE

The upright gage illustrated herewith is an addition to the line of dial gages manufactured by B. C. Ames Co., Waltham, Mass. It is of a low, compact design which is not easily upset and can be placed in the most convenient position for the operator. This gage is desirable for measuring paper, flexible cardboards, fabrics, and rubber, as well as metals of all kinds which have flat surfaces. It can be arranged with a small surface in place of the platen, for measuring sheet metals or any other material which does not have a flat even surface. The spindle of the gage has a travel of 3/10 inch, the same as the regular upright gage made by this company.

Dial Gage made by B. C. Ames Co.

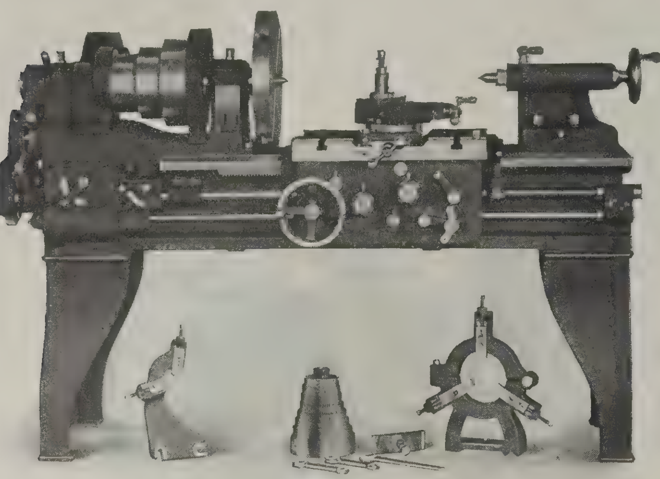
ROCKFORD 16-INCH LATHE

The lathe illustrated herewith is a 16-inch double back-geared design built by the Rockford Lathe & Drill Co., Rockford, Ill. This machine is constructed throughout to meet the conditions of modern shop practice. The bed is of deep section and has wide cross braces. The headstock is massive and is equipped with large bearings lined with the best quality of babbitt metal. The spindle is of high-carbon steel and is accurately ground. It has a 1½-inch hole extending the full length, and draw-in collets up to ⅞ inch capacity may be used. The tailstock is of the offset type and has double clamping bolts to hold it securely to the bed. The carriage has a wide bridge and a bearing of 26¼ inches on the ways, with self-oiling felt wipers.

The thread cutting indicator is so arranged that it can be disengaged when not in use. The apron has a double bearing for all shafts. The gears are of wide face and coarse pitch and are cut from steel. The feeding movements are reversed

in the apron, and an interlocking arrangement makes it impossible to engage the feeds and lead-screw simultaneously. The gear box gives three quick changes of feed for each change of gearing, by means of sliding steel gears and hardened steel clutches. The gear box simplifies the thread cutting and the compounding of gears is avoided.

The regular equipment includes the follow- and steady-rests, large and small faceplates, a full set of change gears, double-friction countershaft and wrenches. Extra attachments are also provided, including a draw-in attachment and collets, taper attachment, turret for the carriage, and a turret on the shears, with or without power feed. The lathe swings over the ways 18½ inches, and over the carriage, 11¾ inches. The maximum distance between the centers (with a 6-foot bed) is



Rockford 16-inch Double Back-geared Lathe

28 inches. The ratios of the back gears are, respectively, 3.5 to 1 and 11.13 to 1. The thread cutting capacity varies from 2 to 96 threads per inch. The net weight of the lathe with a 6-foot bed, is approximately 2150 pounds.

JONES & LAMSON DOUBLE-SPINDLE FLAT TURRET LATHE

The Jones & Lamson Machine Co., Springfield, Vt., is now building a flat turret lathe equipped with two spindles. This double-spindle machine is not intended to displace the well-known single-spindle type built by this company, but it has been developed for producing large quantities of duplicate parts. It is designed primarily for chuck work and can be

Fig. 1. Jones & Lamson Double-spindle Flat Turret Lathe

used as a single-spindle machine if desirable. When two spindles are employed for machining two duplicate parts simultaneously, considerably more time is required for setting up the machine than is necessary for the regular single-spindle type, but the increased rate of production obtained with the two-spindle design, more than offsets this initial handicap. The single-spindle machine is considered the best type for ordinary machine building operations, regardless of whether the work is turned from the bar or is of the chucking variety. On the other hand, the double-spindle type is preferable when work is to be produced in such quantities that the time for setting up the machine becomes a secondary consideration.

When the double-spindle machine is used as a single-spindle type, a chuck 17 inches in diameter is used, and when both

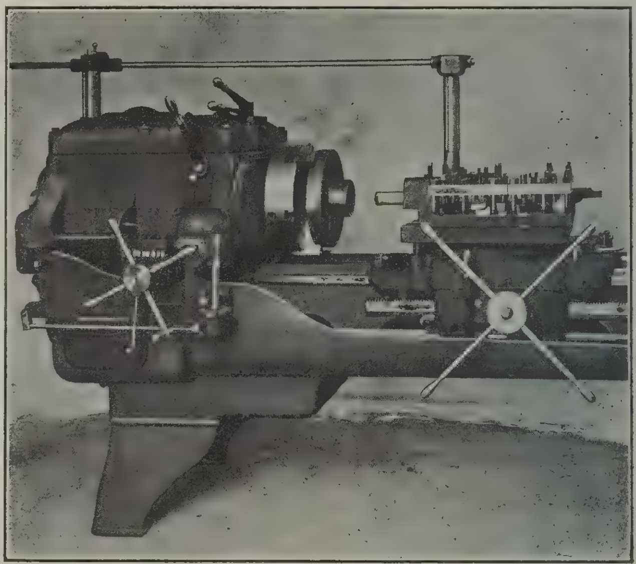


Fig. 2. Double-spindle Machine equipped with 17-inch Chuck for Single-spindle Operation

spindles are in operation, two 9-inch chucks are employed. Fig. 1, of the accompanying illustrations, shows a general view of the machine arranged for using both spindles, whereas, Fig. 2 shows it equipped with the 17-inch chuck for single-spindle operation. Fig. 3 shows the head and a section of the turret at close range. The general construction of the head is illustrated in the line engraving Fig. 4 which indicates the method of adjusting the main spindle for wear and the means provided for receiving the end thrust.

It will be noted that the head is supported by means of rolls *A* bearing upon the hardened steel rail *B*. To provide for vertical "take-up" upon this rail, there are eccentric rolls *C* which bear against the under side, as shown. The cross travel of the head is controlled by rolls *D* which bear against one side of rail *B*, while on the opposite side of the rail, eccentric rolls are similarly placed to provide a means of adjustment.

The two work spindles of the machine have bearings equipped with a form of bushing which enables play to be easily taken up. This arrangement consists of a taper sleeve *F* which bears against the bronze bushing *G*, and when it is necessary to take up wear, the taper sleeve is adjusted by means of the small pinion *H*. Both work spindles are operated by pinion *I* which meshes with the geared faces of the work spindles *J*. Upon this main spindle which supports pinion *I*, a small oil pump provides spray lubrication for the various parts.

The chucks are not attached to the main spindles by hubs of small diameter, in the usual manner, but in a more rigid way as illustrated in Fig. 5. The spindles of the machines, which, by the way, are steel forgings, are provided with heads of the same external diameter as the chucks. The outer end of the spindle *A* is threaded with a right-hand thread, and the inner end of the chuck or faceplace *B* (as the case may be), is threaded with a coarse left-hand thread of the same pitch. After inserting the driving pin *C* in sockets in the spindle and chuck or faceplate, respectively, a right- and left-hand threaded sleeve *D* is screwed on, thus bringing the outer face of the spindle and the inner face of the chuck or faceplate firmly together. To insure the chuck or faceplate being in

the proper position, a seat is bored in the spindle which receives a projection on the inner side of the chuck or faceplate. This construction insures an accurate mounting, and prevents the chuck or faceplate from getting out of alignment.

When the machine is to be used as a single-spindle type, thereby employing a 17-inch chuck and permitting large work to be done, the head of the front spindle is covered with a shield as shown in Fig. 2. In this manner, large chucking work may be easily and efficiently machined. The method of supporting this large chuck on the spindle is exactly the same as has been previously described, although the chuck, of course, extends out beyond the means of support.

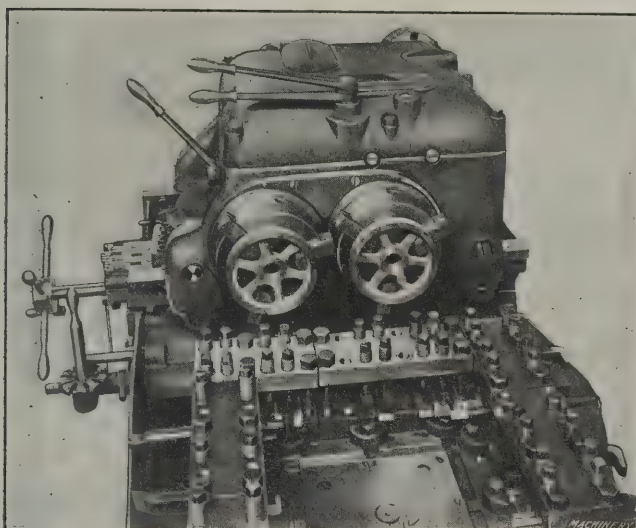

Fig. 3. Turret and Head of Double-spindle Turret Lathe

Fig. 6 shows the construction of the turret and tool-blocks. The general outline of the turret is square, and the tools are rigidly held, with a minimum amount of overhang, by means of the tool blocks and binding screws connected with the clamping plates. All of these parts are plainly shown in this illustration. Two duplicate sets of tools are clamped to each

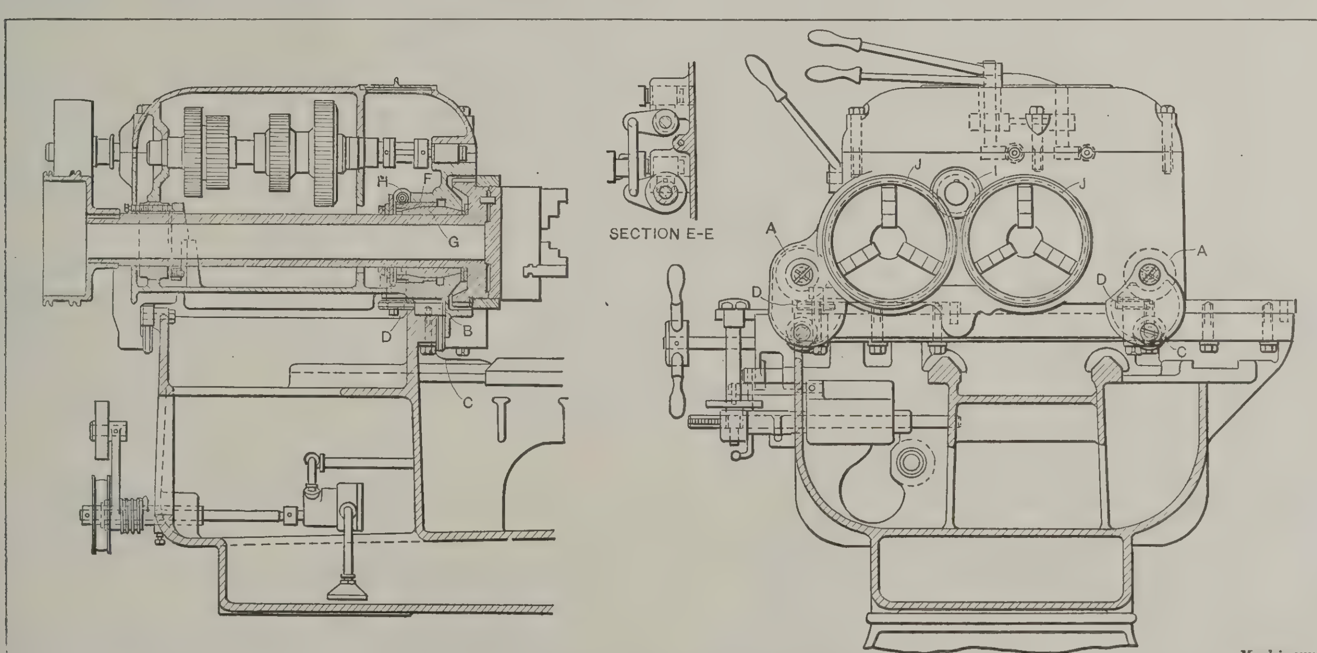

Fig. 4. Views showing the General Construction of the Headstock

side of the turret, and these operate simultaneously on the two pieces held in the chucks or on the faceplates. Primarily the turret is used in but four positions, but when a 17-inch chuck or faceplate is employed, corner blocks may be held by the clamping plates in which tools are supported, giving, if necessary, four additional operations by indexing the turret to eight positions. Provision is made for holding dies at one side of the turret, and each of the corner tool-holding fixtures may be moved to or from its companion tool-holder a slight amount, by means of elongated slots in which the binding screws are placed. As a matter of convenience, the clamping plates are held down by ¾-inch cap-screws, while the set-screws which hold the tools are ⅞ inch diameter. Thus it is possible to clamp through the set-screw holes if this should be necessary on account of a difficult "set-up." Hardened steel supports are provided to support the two inner ends of the turret while in operation. These supports obviate a great

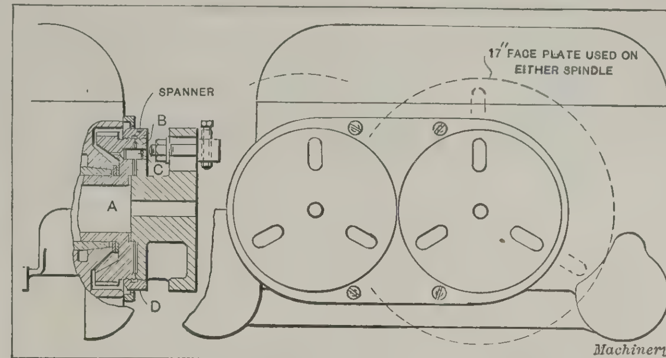

Fig. 5. Method of Supporting Chucks on Double-spindle Machine

deal of chatter and permit the tools to work more satisfactorily. On the under side of the turret, hardened seats are secured which rest upon the carriage supports.

A typical job to demonstrate the application of the double-spindle flat turret lathe is illustrated in Fig. 7. As may be seen, the work consists of sprocket wheels which are held in the two 9-inch chucks. At the first position of the turret, which is the one illustrated, the inside is rough-bored by tools *A*. At the second position of the turret, tools *B* rough-face the inner side of the flange; tools *C* face the outer side of the flange, while tools *D* turn the face of the flange. At the third position of the turret, tools *E* finish-turn the inside of the flange, tools *F* finish-turn the outside of the flange, while tools *G* finish the face of this flange. At the fourth position of the turret, tools *H* finish-bore the work; tools *I* complete the turning on the outside of the flange, while tools *J* accurately size the interior of the flange. It will readily be appreciated that the work done at the first position of the turret, can be accomplished in a much shorter space of time than that done at any of the other three positions.

With the double-spindle flat turret lathe, each operation is a double operation, and, moreover, it is not performed at the same speed; thus, if at one position of the turret, the tools are required to rough out the work, this may be done rapidly, for it has no bearing on the other operations that are subsequently performed. Furthermore, if the following operation has to be performed with great care, this may be done without reducing the speed of the less exacting operations.

A further demonstration of the advantages of a machine of this type involves the time factor. On some machines, of the automatic type, the time for producing any given piece is conceded to be the time of the longest operation performed; thus, if on a four-spindle automatic, the first operation requires 30 seconds, the second operation 30 seconds, the third operation 8 minutes, and the fourth operation 30 seconds, the

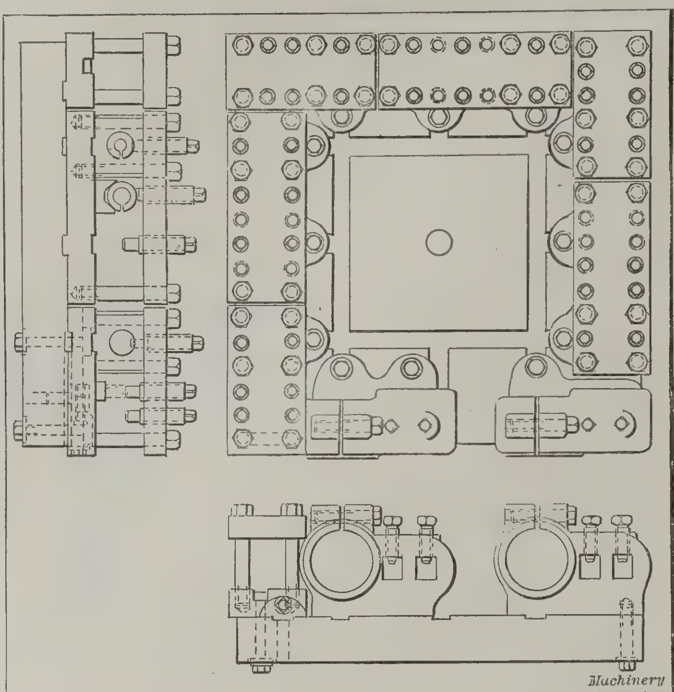

Fig. 6. Elevations and Plan View of Turret and Tool Blocks

time required to produce each piece with this machine will be 8 minutes. With the double-spindle turret lathe on similar work, the time required is the sum of the time of all of the operations divided by two. In this instance, therefore, the time for each piece would be 4¾ minutes, as contrasted with 8 minutes when performed on the multiple-spindle automatic.

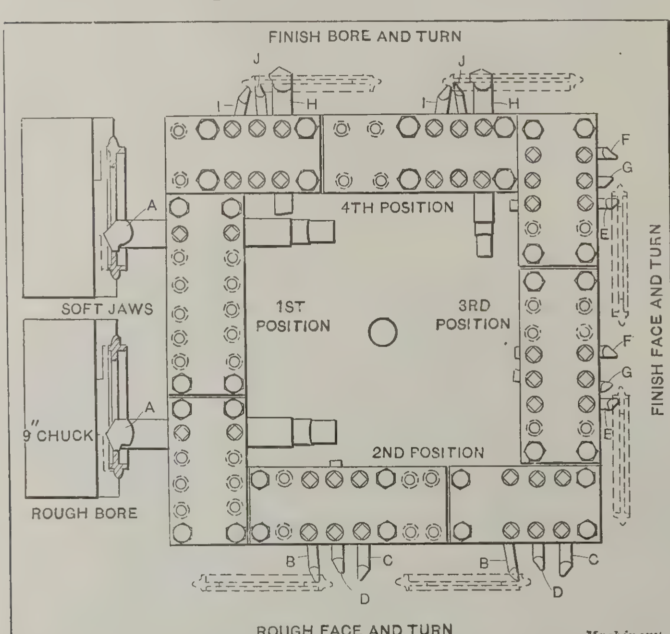

Fig. 7. Diagram showing Tool Equipment and Successive Steps in Machining Sprocket Blanks on Double-spindle Flat Turret Lathe

The double-spindle machine can be used advantageously in connection with the single-spindle flat turret lathe, the single-spindle machine being employed for general work, and the double-spindle machine for the manufacture of duplicate parts in quantity.

* * *

When a boss is made for bolt head or nut, it should be made at least one-quarter inch larger than the largest diameter of the bolt head or nut, so that the head or nut will have a full bearing, even if the hole be cored or drilled out of center.

NEW MACHINERY AND TOOLS NOTES

Filing Machine: Robinson Tool Works, Hartford, Conn. Bench filing machine having a square table which is adjustable for angular work. The stroke of the file may be varied from 0 to 2 inches. All the working parts are protected by a suitable cover.

Turret Head: Milliken Machine Works, West Newton, Mass. Ball turret head for converting ordinary lathe into a turret type, when machining work requiring a number of tools. The turret is held in the tailstock by means of a taper shank, and it is actuated by hand.

Tool Grinder: W. W. Blakely, 100 Leicester Court, Detroit, Mich. Attachment for grinding lathe tools, which is clamped to the ways of the bed and is driven by friction from the cone pulley. This grinder is intended to be used for sharpening tools while cuts are being taken, so that no time will be wasted.

Grinder Countershaft: Rivett Lathe & Mfg. Co., Brighton, Mass. Countershaft built for the grinders manufactured by this company. It is a complete unit and is made to fasten to the wall. The necessary speed changes are obtained by cone-pulleys, and the work-spindle driving-drum is controlled by a clutch so that the work may be stopped independently.

Bolt Cutter: H. B. Brown Co., East Hampton, Conn. Motor-driven bolt cutter built in two sizes, which have maximum capacities for diameters of ¾ inch and 1½ inch, respectively. The small machine is driven direct, and the larger size is equipped with gearing having a ratio of 5 to 1. These machines can be used for nut tapping as well as threading.

Coupling: Valley Iron Works, Williamsport, Pa. Interlocking jaw coupling having compressible sleeves and so designed that the power is transmitted by the jaws and not by the bolts which hold the two parts together. The principal features claimed for this coupling are: greatly increased strength, compensation for any inequalities in the shafts, proper alignment and the elimination of strain on the bolts.

Valve Grinder: McConnell-Browning Engineering Co., Richmond, Va. Hand-operated valve grinder for the grinding of gas or gasoline engine valves. The required reversing motion is obtained by a worm and sleeve, the latter being given a reciprocating movement by turning a crank. Means are provided for shifting the position of the valve on its seat while grinding, without removing the tool from contact.

Gear Hobber: Adams Co., 877 Market St., Dubuque, Iowa. No. 1 gear hobber capable of cutting spur gears, worm-wheels and spiral gears. This machine, in its regular form, will cut spirals of 8 degrees and under, and it can be modified to cut any angle desired, but cannot be adjusted to cut angles differing more than 8 degrees. This is claimed to be a very rigid and efficient machine and comparatively low in price.

Drill Socket: Scully-Jones & Co., 316 Railway Exchange Bldg., Chicago, Ill. Drill socket having a key on the inside and a keyway on the outside, extending almost the entire length of the socket. This gives a positive drive and eliminates the twisting of tangs either on the drill or the socket itself. A reinforcement at the base furnishes means for separating the sockets with a drift, and this type can be "nested" with any other make.

Bench Drill: Monarch Machinery Co., 249 N. 3d St., Philadelphia, Pa. Sensitive bench drilling machine with chuck having capacity for drills up to ¼ inch. The table is 8 inches in diameter and is mounted on a swinging arm. The table has a vertical movement of 7 inches, and the spindle a feeding movement of 4 inches. A two-step cone pulley provides two speeds, and an adjustable idler is used to vary the belt tension. The machine will drill to the center of a 10½-inch circle.

* * *

A WONDERFUL MACHINE

It is possible by the use of a few technical terms to make the description of a simple mechanism rather complicated. The following description of a new machine was supplied by a machinist in order to show how "big" words may complicate matters:

"Well," said James, "I went over and saw that new machine to-day, and it is astonishing the fine work it does. By means of a pedal attachment, a fulcrumed lever converts a vertical reciprocating motion into a circular movement. The principal part of the machine is a huge disk which revolves in a vertical plane. Power is applied through the axis of the disk, and while the speed of the driving arbor is moderate, the periphery of the apparatus is traveling at high velocity. Work is done on this periphery. Pieces of the hardest steel are by mere impact reduced to any shape the skillful operator desires."

"What in thunder is that machine, anyway?" demanded Tom Briggs.

"Oh, it's a new grindstone," replied James, and a silence fell upon the group.

LETTERING TITLES

By E. J. G. PHILLIPS*

To produce a well executed title for tracings, having letters sufficiently large and bold to quickly attract attention, requires considerable time if done in the ordinary way. The method described in the following offers a way of producing very satisfactory titles in a relatively short time. The accompanying illustration is about a half-size representation of a master card, which if carefully prepared will serve as a convenient guide for laying out letters of various sizes, without the use of preliminary construction lines. It may be considered a tedious job to lay out this master card, but as this one layout will last for years, the time required is well spent. If the original is made on tracing cloth, a permanent vandyke negative may be made from it, and then black on white vandyke prints may be produced and mounted on cardboard in sufficient numbers to supply the entire drafting force.

Master Card for Laying out and Lettering Titles on Drawings

The upper half of the card is used for several styles of letters and figures from ⅛ to ½ inch in height; complete alphabets of two styles are shown, the first having vertical and the second slant letters. While the styles shown are very plain, more elaborate ones may be made from the same master card. For these letters the guide lines are laid out in the following proportions: the horizontal spaces are made equal to or one-third of the height and all letters are made two spaces wide, except M which requires three spaces, W, four spaces and I, one space. These proportions may not be exactly correct, but the writer believes that the alphabets given at the top of the illustration show reasonably good proportion.

The lower half of the card is used for block letters and figures from 3/16 to 1/2 inch high, as indicated at the left of each line. The usual proportions are used, *viz.* five spaces high and four spaces wide except M which requires five spaces, W, six spaces and I, one space. These guides may also be used for the Gothic letters as described in the March, 1910, number of MACHINERY. Every fifth vertical graduation is extended above the top line and every tenth graduation is numbered, convenient for locating a title in a certain space.

When the tracing is ready for the title, the master card is placed beneath the cloth, bringing the guides for the desired size of letters in their proper location, and then they are inked in. When slant letters are to be used, the triangle should be set so that when it matches one of the graduations in the top line, it will coincide with the next graduation to the left, in the bottom line.

When it is desired to locate a title in the center of a given space, the spaces required should be counted making the allowances previously given for each letter, and leaving one space between letters and four spaces between words. In this way the number of spaces required for the title can be quickly found, and by referring to the figures above each set of guide lines, the lettering can be begun at the proper place. On the other hand, if the space for the title is limited and it is desired to use the largest letters possible, first determine the number of spaces required; then by referring to the figures and measuring the length of the required number of spaces, the proper size of letters may be found.

* Address: 233 Park Ave., Aurora, Ill.

THAT RED-HAIRED BOY

By A. P. PRESS

We needed another boy in the office, and the boss put it up to me one day. "Say, Jim," said he, "get me a good boy—one that is *good* for something. Get a red-headed boy if necessary—only get him!"

I transmitted the request to the office, just as he told me: "Wanted—One good office boy. *Must be red-headed.*"

The hiring clerk called me up and tried to call me down for it, but I told him that if he didn't like it, he could have it out with the boss, for it was none of my funeral anyhow. I waited a week, but the boy did not show up. I knew I had to get him somewhere, so I commenced watching the trolley cars as I came down mornings; and one day, clinging to the rear end of the running board, I saw what I thought we wanted. So I dropped off the car at the same time he did.

"Where are you working, son?"

"Down at the shear shop, sir."

"What do you make a week?"

"Four fifty, sir."

"Would you like a job at six dollars if you could get it?"

"I certainly would, sir." (Always with the "sir.")

"Well, go down to the hiring office and ask the boss there if he wants a boy. If he says 'No,' take your hat off and say, 'Kindly look at my head, sir,' and he will will hire you."

The kid went, and from what the hiring clerk told me afterwards, I think he did just as he was told. He came to work and made good with the "old man" right off, and stayed with us nearly a year. Every noon after lunch he used to slide off into the die-sinking department and work away on the end of a piece of steel—die-sinking. One day I asked him what he was doing. He answered, "I am going to be a die-sinker bye and bye, and I am working it up now."

A few weeks after that (this I learned long afterwards) he wrote a letter to a silver shop, asking them if they wanted a boy to learn die-sinking, and if so, he would like to hear from them. The boy waited a couple of weeks, then went down to the shop and asked if the boss die-sinker was there. When the boss came out, the boy asked:

"Is there any chance for an apprentice, sir?"

"Not a bit," said the foreman, as he turned to go back.

"But look, sir," he persisted. "I have done a little in that line," and he pulled a piece of aluminum about four inches long from his pocket. It was all covered over with impressions from the lines and stamps he had cut. Now, I never saw a die-sinker who would not leave a funeral procession to look at a scrap of metal. This one was no exception to the rest of them, so back he came, looked over the sample, and it ended with his promising the boy a job later on.

The next night the boy gave notice, having landed the job. It is not difficult to look a little way into the future and see where that boy will be five or ten years from now. Following the mark he has set for himself, he is going to get there—and he will not always be sinking dies either.

MACHINING A FAN MOTOR CASE IN A BARDONS & OLIVER TURRET LATHE

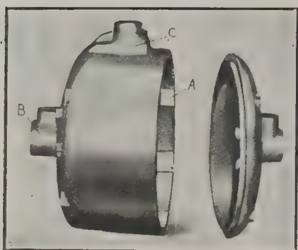

Fig. 1. Fan Motor Case to be machined

An excellent example of accurate turret lathe work is represented in Fig. 2, which shows the set-up used in machining the fan motor case shown in Fig. 1. This motor case is made from an iron casting with eight ribs cast on the inside circumference of the large hole, the remaining portions of the shell between the ribs not being more than ⅛ inch thick. The ribs *A* are to be machined, and a hole is to be drilled, bored and reamed in the shank *B*, which must be concentric with the large hole in the case to within a limit of 0.002 inch. When the shape and character of this casting are considered, 0.002 inch is a very close limit to attain, and can only be accomplished with a first-class tool equipment and considerable ingenuity on the part of the designer.

When being machined, the casting is gripped by the shank *B* in a spring collet, and is additionally driven by boss *C*, which fits in a slot in hood *A*, Fig. 2. Screwed into hood *A* are sixteen knurled thumb-screws *B* and *C*. These are used to support the casting during the roughing operations. The screws *B* in the circumference of the hood are opposite the projections or ribs on the casting, which are to be machined. The screws *C* in the rear of the cap are binder or tension screws for shank *B*, Fig. 1. The order in which the machining operations are carried on is very interesting, and it is due to this layout that such accuracy can be obtained.

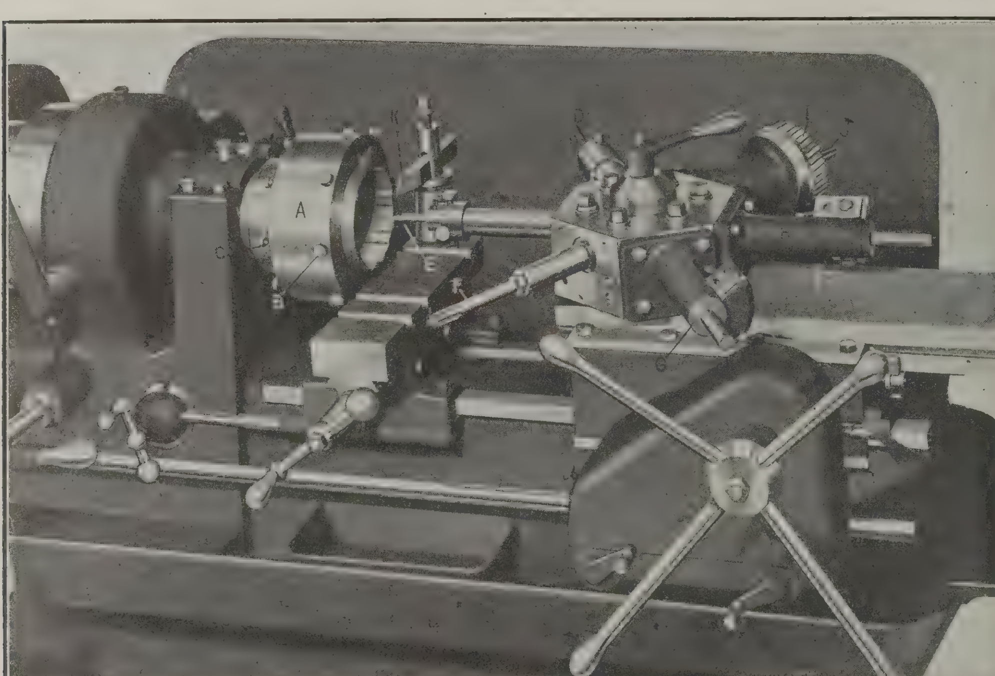

Fig. 2. "Set-up" of Tools for Machining a Fan Motor Case in a Turret Lathe built by Bardons & Oliver, Cleveland

After the casting is placed in the chuck, the knurled screws *B* are tightened, centering the casting so that it will run practically true, and also holding it rigidly in the hood. The order of operations after the casting is placed in the chuck and the screws are tightened, is as follows. (Refer now to Fig. 2).

1. Drill small hole in shank *B*, Fig. 1, with drill held in holder *D* at a speed of 192 R. P. M. (open belt) and a feed of 0.0135 inch per revolution.
2. Bore small hole with boring tool *E* at a speed of 192 R. P. M. (open belt), feed 0.0135 inch per revolution.
3. Ream small hole with reamer *F* held in floating holder; speed 44 R. P. M. (with back-gears thrown in), feed by hand.
4. Rough-bore large hole with boring-tool *G* provided with two cutting tools; speed 44 R. P. M. (with back-gears thrown in), feed 0.020 inch per revolution.
5. Adjust knurled thumb-screws *B*, partly releasing their pressure on the casting.
6. Finish-bore large hole with boring-tool *H* provided with two cutting edges; speed 44 R. P. M. (with back-gears thrown in), feed by hand.
7. Again adjust knurled screws, leaving casting practically loose, and relieving all strains set up by the cutting tools.
8. Finish-ream large and small holes with reamers *I* and *J* (reamer *J* floating); speed 24 R. P. M. (with back-gears thrown in), feed by hand.

It is due largely to the manner in which this last operation is handled that the required accuracy is obtained. Here, it can be seen by referring to the order of operations, that the casting practically floats on the large reamer *I*, the small reamer *J* being guided by the hole which has been previously reamed and not removing any material, but simply acting as a "steady pin" for the large reamer. The cutting tools in the boring-tool holders *G* and *H* are spaced the same distance apart as the projections to be machined in the large hole, thus insuring rigidity and obviating chattering. The large hole is 5.505 inches in diameter and the small hole ¾ inch in diameter. The casting is faced off with the turning tool *K* held on the cross-slide, this operation being accomplished while the boring-tool *G* is at work. The time to complete one case is thirteen minutes, including clamping the work and machining.

* * *

ANNUAL MEETING OF THE N. M. T. A.

The fourteenth annual meeting of the National Metal Trades Association was held in New York City, April 11, at the Hotel Astor. The meeting was remarkable for the despatch with which the business was transacted, the public program, including the reading of several papers of length, being carried through in one day. The banquet given to the members and guests in the evening, at which speakers of international fame spoke on the tariff, universal peace and education, was a notable affair, giving a member of the president's cabinet an opportunity to voice sentiments regarding protection and free trade of extraordinary public interest. F. C. Caldwell of H. W. Caldwell & Son Co., Chicago, the president of the association, presided, assisted by Robert Wuest of Cleveland, the commissioner, who has well demonstrated his ability to conduct the affairs of this association of over seven hundred manufacturers of metal products.

The program included the valuable reports: "Systematic Compensation for Industrial Accidents," presented by Henry D. Sharpe, president of Brown & Sharpe Mfg. Co., and "Industrial Education," presented by F. A. Geier, president of the Cincinnati Milling Machine Co.; the papers "Prevention of Industrial Accidents," by William H. Doolittle, the association's safety inspector; "Employer's Liability and Workmen's Compensation—What has been done to Date and is now doing in It," by Miles H. Dawson, attorney and consulting actuary, New York City; "How far must Business Yield to the Demands of Industrial Organizations?" by Hon. J. J. Feeley, of Boston; the reports of Commissioner Robert Wuest, and Assistant Commissioner H. E. Herrod, and other reports on the various activities of the association.

The report on industrial education comprised the Hartford, Cleveland, New Haven, St. Louis, Chicago, Springfield, New York and New Jersey and Cincinnati branches, all of which are doing effective work in educating boys. The cooperative course in engineering in Cincinnati has been in operation six years and three hundred are taking it. This year thirty-five will graduate and take positions as assistant engineers and foremen, and other executive positions. A new building has been added which will increase the capacity of the school to four hundred. The Cincinnati continuation school work has

been extended to include the apprentices employed in the allied printing trades. Notwithstanding the depression in business, the attendance has been two hundred.

Mr. C. A. Prosser, the recently appointed secretary of the National Society for the Promotion of Industrial Education, spoke on the Page education bill, which carries an appropriation of $14,000,000. This bill to extend Federal aid to industrial education was primarily intended to help agriculture, and Mr. Prosser pleaded that the bill might be given a scope that would comprehend industrial education generally. He argued that the moral effect of Federal aid would be to make young men generally look upon the industries in a more favorable light and thus reduce the crowding in the so-called "genteel" occupations.

The report on industrial accidents by Mr. Doolittle is a painstaking paper describing a large variety of conditions in shops, mills and factories likely to cause accidents to workmen. Stereopticon views showed practical protective devices for machine tools, presses, saws, elevators, etc., which have been provided in the plants of members of the association.

The paper by Mr. Dawson, of which a full abstract appears in another part of this number, is a summary of the changes made in the relation of employers and employes in the United States and abroad by legislative enactment of employers' liability and workmen's compensation laws. The progress of this movement during the past two years is remarkable, and it foreshadows the time, comparatively close at hand, when every industry will be required to directly bear the burden of workmen's disabilities resulting from their occupations.

Judge Feeley's paper on the relations of capital and labor, defines a strike and what constitutes an unjustifiable strike under the laws of Massachusetts; also a lawful strike, methods of enforcing a strike, the sympathetic strike and the boycott.

The speakers at the banquet were Hon. Franklin MacVeagh, secretary of the treasury who spoke on the tariff; Hon. W. Morgan Shuster, formerly treasurer of Persia, whose theme was international peace; and Dr. Arthur A. Hammerschlag, of Pittsburg, a noted exponent of industrial education.

The officers elected for the ensuing year are:

President, Henry D. Sharpe, of Brown & Sharpe Mfg. Co., Providence, R. I.

First vice-president, W. A. Layman of Wagner Electric Mfg. Co., St. Louis, Mo.

Second Vice-President, L. H. Kittredge of the Peerless Motor Car Co., Cleveland, Ohio.

Treasurer, Howard P. Eelles of the Bucyrus Co., Cleveland, Ohio.

* * *

SINKING OF THE TITANIC

The sinking of the White Star Steamship *Titanic* on her first voyage is the most appalling of the long roll of disasters on the sea. Though built with all the safeguards that human ingenuity could devise, collision with an iceberg off Cape Race, Newfoundland, just before midnight, April 14, so crushed the hull that in less than three hours she had sunk in one of the profound depths of the Atlantic, carrying down 1600 of the passengers and crew and millions in treasure. The boasted security of the modern steamship seems a hollow mockery in the face of this catastrophe—so great that it stuns the intelligence and sickens the imagination. A great vessel of 46,000 tons registered, the largest ever built, was lost by an accident that everyone familiar with the perils of the sea knew to be possible, but which few supposed could be so disastrous as this.

Out of this appalling disaster the wireless telegraph emerges triumphant. Without this wonderful means of communication few, if any, would have survived to tell the awful tale. Although but a few hours in the boats before they were picked up by the *Carpathia* of the Cunard line, several of the 700 died of shock and the intense cold. Had life boats been available for all and had there been time to embark in an orderly way, the loss of life even then would have been severe. Many more lifeboats are needed but will be futile unless both crew and passengers are drilled to act systematically in emergencies, each going to his appointed place on signal. But important as are lifeboats and lifeboat drill they are secondary. The business of steamship companies is transporting passengers from one port to another—not dumping them into small boats to perish in the open sea. Let us devote more thought to making vessels stronger and safer, to the construction of bulkheads that will stand the greatest water pressure that can be imposed on them, to the design of bulkhead doors that will promptly close in emergencies, to the personnel of the crews and finally to navigation laws that will stop this reckless trifling with death in taking the risks of the shorter route and running at full speed when icebergs are moving down from the North.

* * *

AN ACCESSION TO MACHINERY'S STAFF

We are glad to announce that Mr. William Ledyard Cathcart has become a member of MACHINERY's editorial staff in the capacity of consulting engineer. Mr. Cathcart will devote particular attention to problems in mechanics and machine design, and to the preparation of a series of reference books on machine shop practice and machine details, which he is especially qualified to edit.

Mr. Cathcart is a graduate of the University of Pennsylvania and the United States Naval Academy, and following his graduation served sixteen years as an officer of the engineering corps of the United States Navy. During the Spanish-American War he volunteered for service, was appointed chief engineer in the Navy and ordered to special duty at Washington on the staff of the late Admiral Melville, then engineer-in-chief. Mr. Cathcart spent two years as professor of marine engineering; four years as adjunct professor of mechanical engineering, Columbia University; seven years as treasurer of a textile manufacturing company; five years with the Babcock & Wilcox Co., New York, translating, collating and analyzing scientific data from French and German sources. Prof. Cathcart is the author of "Machine Design," "Fastenings" and co-author with Prof. J. Irvin Chaffee of "The Elements of Graphic Statics."

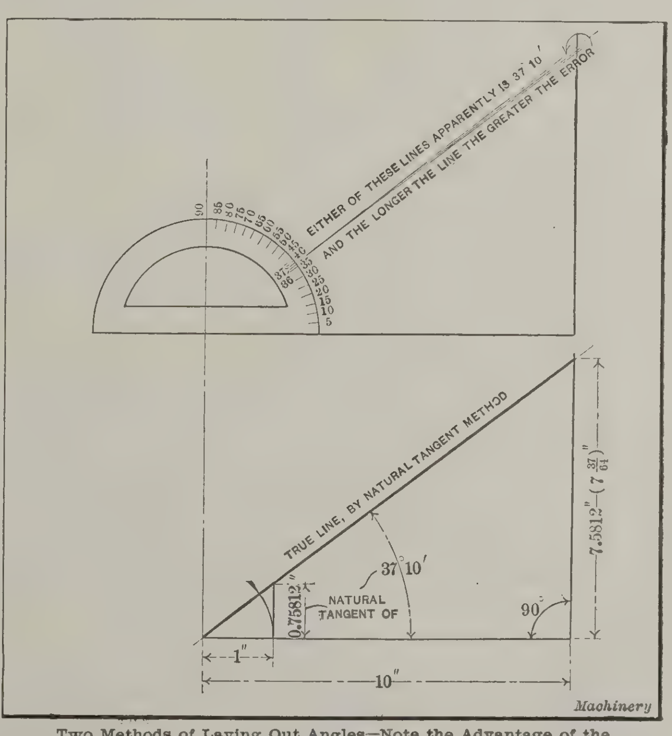
LAYING OUT ANGLES ACCURATELY

By HARRY B. WRIGLEY*

In laying out an angle by an ordinary circular protractor, it is evident that a slight error at the circumference of the protractor will be multiplied many times in plotting a long line. The angle can be laid out accurately by the "natural



Two Methods of Laying Out Angles—Note the Advantage of the "Natural Tangent" Method

tangent" method. To illustrate, assume that it is necessary to lay out an angle of 37 degrees, 10 minutes. The natural tangent is 0.75812, and as this represents the altitude in inches of a right angle triangle having a base 1 inch long, the alti-

* Address: Care of Y. M. C. A., Allentown, Pa.

tude having a base 10 inches long will be ten times the natural tangent or 7.5812 inches (7 37/64 inches). It is evident that it is only necessary to find the natural tangent of the angle and multiply it by 10 which is equivalent to moving the decimal point one place to the right, in order to obtain the altitude when the base is 10 inches. A 10-inch base is taken as a matter of convenience, as it simply means moving the decimal point as described. The two methods of laying out angles—by means of the protractor and natural tangent—are shown in the accompanying illustration, where it can be seen that the angle can be laid out much more accurately by the latter method.

[A similar method for laying out angles accurately, but which employed the use of the sine, was illustrated and described in MACHINERY, June, 1911. It is evident that any of the functions of a right angle triangle—sine, cosine, tangent, or cotangent—can be used for laying out angles. Some prefer the sine, as the sine of half the angle is equal to half the chord.—EDITOR.]

* * *

PERSONALS

J. C. Ward, director and general manager of Edgar Allen & Co., Ltd., Chicago, departed April 21 for a business trip in Japan. Mr. Ward expects to be gone for several months.

F. B. Jacobs, who for the past year has been traveling for the Carborundum Co., Niagara Falls, N. Y., gathering data on shop practice, has entered the company's store at Philadelphia as a salesman.

E. Hawkinson, foreman in the toolmaking department of the Canadian General Electric Co's. plant at Peterboro, Ont., for the last three years, has resigned his position to take the position of tool designer for the Russell Motor Car Co., of Toronto.

William W. Bishop, for six years manager of the machinery department of the Cincinnati Iron & Steel Co., Cincinnati, Ohio, has resigned his position to become associated with the sales department of the Shaw Electric Crane Co., with headquarters in Chicago.

George Langen, works manager of the Cincinnati Planer Co., who intended to start in March for an extended European trip, was stricken with appendicitis two days before his sailing date. Mr. Langen is recovering, but his trip has been indefinitely postponed.

Ralph E. Flanders, of the Fellows Gear Shaper Co., Springfield, Vt., formerly associate editor of MACHINERY, addressed the American Society of Swedish Engineers, Brooklyn, N. Y., April 20, on the subject: "Scientific Management from a Social and Economic Standpoint."

Selbert M. Connor, heretofore an engineering draftsman with one of the large railroads terminating in Chicago, has started in business for himself, having opened an office at 414 Sherman St. Mr. Connor will undertake drawing, mapping and the execution of commissions for patterns, model work or any work of a mechanical nature.

A. N. Goddard (W. P. I. '99), for thirteen years with the Morgan Construction Co., Worcester, Mass., as assistant superintendent, recently resigned his position to become superintendent with the Union Twist Drill Co., Athol, Mass. When leaving the Morgan Construction Co., the employes presented him with a solid gold watch and guard suitably engraved.

E. F. Lake, formerly steel editor of the *American Machinist*, who for the past year has been conducting a consulting metallurgical business in Bayonne, N. J., has been placed in charge of the laboratory of the Perfection Spring Co., Cleveland, Ohio. Mr. Lake has contributed a number of valuable articles on alloy steels, extrusion of metals and die-casting machines to MACHINERY.

R. S. Bryant has been appointed consulting engineer of the Standard Welding Co., Cleveland, Ohio. Mr. Bryant was formerly with the Bryant Rim Co., of Columbus, Ohio, and his long experience in the design and manufacture of automobile rims peculiarly fits him to carry out the company's policy of constantly improving its products and service, as well as keeping its automobile rim designs in every way up to the latest requirements of the trade.

George Sherwood Hodgins, a well-known writer on railway topics, at one time editor of the *Railway Digest* and later of *Railway and Locomotive Engineering*, has been engaged by the commissioners of the Trans-Continental Railway of Canada to make a special report concerning the shop equipment of the various roundhouses, terminal shops, etc., now built or being constructed on that line. Mr. Hodgins will be engaged for several months on this work.

Frederick A. Hall, engineer, 5-9 Beekman St., New York, announces that Mr. Mancius S. Hutton is associated with him in the management of the office and conduct of the business. Mr. Hutton, who is the son of Prof. F. R. Hutton, honorary secretary and past president of the American Society of Mechanical Engineers, will have general charge of correspondence regarding the business, and will give special attention to the departments of boilers, engines and power equipment in which Mr. Hall acts as the direct representative of manufacturers.

Dr. Rudolf Diesel of Munich, Germany, director of the Busch-Sulzer Bros.-Diesel Engine Co., St. Louis, Mo., came to New York April 6 on the steamer *Amerika*. He will make a tour of the United States, lecturing before engineering societies and other bodies on the possibilities of the internal combustion engine. He is the inventor of the Diesel engine which is displacing steam engines in Europe for industrial purposes, and is being applied as the motive power of marine vessels with success. Dr. Diesel predicts that the internal combustion locomotive will eventually displace the steam locomotive because of its superior economy and simplicity. He was made an honorary member of the American Society of Mechanical Engineers, April 30, at the meeting of the gas power section. The conferring of honorary membership was followed by an illustrated lecture by Dr. Diesel on the development of the Diesel engine.

OBITUARIES

Frank B. Manville, an inventor of automatic machinery for making wire goods, and one of the organizers of the E. J. Manville Machine Co., Waterbury, Conn., died at his home in Waterville, Conn., March 29, aged sixty-two years. Mr. Manville invented machinery for making hooks and eyes, threading bicycle spokes by the rolling process, and forming rims for bicycle wheels. He also invented a brass shoe lace hook. He had worked in the Winchester, Colt, Whitney and Ames armories, and at the Elgin watch factory. Although one of the organizers of the E. J. Manville Machine Co., he was no longer connected with that concern. A widow and three brothers survive him.

Stanley K. Fox, machine demonstrator for the Gleason Works, Rochester, N. Y., was lost in the wreck of the *Titanic*, April 15. He helped the women and children into the life boats until the last one was filled and then calmly awaited his fate. Mr. Fox was thirty-eight years old, and was twenty-eight when he made his start with the Gleason Works without mechanical training. He soon became an expert machine operator, excelling all others in setting up work rapidly. Soon he was sent out to demonstrate machines and made many friends by his enthusiasm and kindly nature. He made his first European trip four years ago and was abroad last year from June to October and went again on the last trip in January. A memorial service was held in St. Andrew's Episcopal Church, Rochester, April 20, in which Rev. Dr. Thomas paid a high tribute to Mr. Fox's sterling qualities.

* * *

COMING EVENTS

May 9-18.—First Annual Aeronautical Exhibition held in the Grand Central Palace, New York City, under the auspices of the Aero Club of America.

May 13-15.—Triple joint convention at Norfolk, Va., of the American Supply and Machinery Manufacturers' Association, National Supply and Machinery Dealers' Association, and Southern Supply and Machinery Dealers' Association. The program includes papers on "Workmen's Compensation"; "Motion Study"; "The National Banking and Currency Problem"; and "The American Merchant Marine." F. D. Mitchell, secretary-treasurer, 309 Broadway, New York.

May 13-25.—Newark industrial exposition under the auspices of the Board of Trade of Newark, N. J., in the First Regiment Armory. It is claimed that one hundred thousand different articles are manufactured in the three thousand shops of the Newark industrial district, the diversity being proportionately greater than that of any other manufacturing district in the country. William G. Rose, manager, Newark, N. J.

May 14-17.—Sixth annual convention of the Master Boiler Makers' Association at the Fort Pitt Hotel, Pittsburg, Pa. J. R. Flannery, of the Flannery Bolt Co., Frick Building, Pittsburg, Pa., secretary and treasurer of the general committee of arrangements.

May 16-17.—Semi-annual convention of the National Machine Tool Builders' Association at Atlantic City, N. J., Hotel Chalfonte headquarters. E. P. Bullard, Jr., president, Bridgeport, Conn.; James H. Herron, secretary, Cleveland, Ohio.

May 20-22.—Railway Storekeepers Association's convention in Buffalo, N. Y. Hotel Statler, headquarters. Wm. E. Kelley, secretary-treasurer, 825 Wabash Ave., Chicago, Ill.

May 27-31.—International Safety Congress to be held at Milan, Italy. Dr. W. H. Tolman, director of the American Museum of Safety, 29 W. 39th St., New York City, is a delegate to the congress from the United States.

May 28-31.—Spring meeting of the American Society of Mechanical Engineers in Cleveland, Ohio. Hotel Hollenden, headquarters. Calvin W. Rice, secretary, 29 W. 39th St., New York.

June 12-14.—Annual convention of the American Railway Master Mechanics' Association at Atlantic City, N. J.

June 17-19.—Annual convention of the Master Car Builders' Association at Atlantic City, N. J.

June 17-22.—First annual gas engine show under the auspices of the National Gas Engine Association in the Auditorium, Cleveland, Ohio. Albert Stritmatter, secretary, Cincinnati, Ohio.

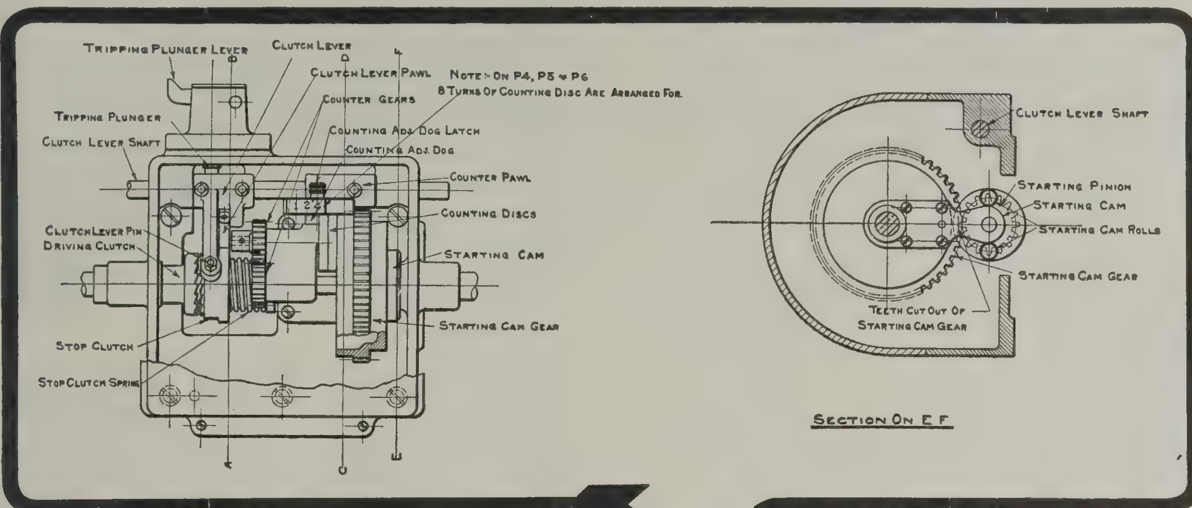
July 9.—Annual convention of the American Railway Tool Foremen's Association in Chicago. H. L. Miller, secretary of the supply association, 835 Monadnock Bldg., Chicago, Ill.

August 20.—Annual convention of the International Railroad Master Blacksmith's Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7.—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

Study these Diagrams of the Mechanism that Indexes Gears so Accurately and Quickly

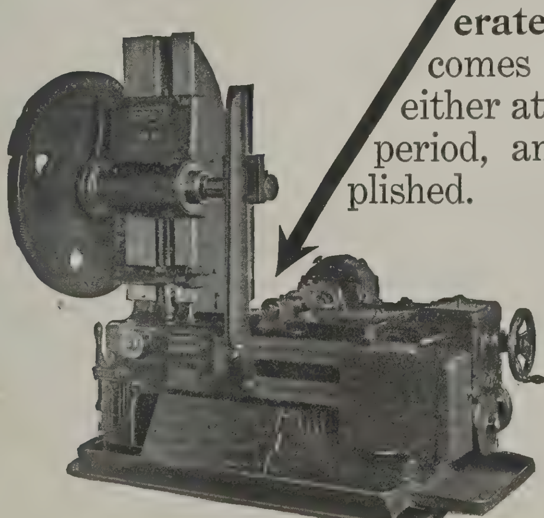


The indexing mechanism on a gear cutting machine is a feature of great importance.

It should not operate with a shock, for that will cause the spacing of the gear teeth to be inaccurate. Neither should it operate too slowly, for that will impair the production of the machine.

The indexing mechanism on B. & S. Automatic Gear Cutting Machines overcomes both of these difficulties because of certain exclusive features in its design.

At each indexing, the mechanism **starts slowly, is accelerated and then retarded** just before it comes to a stop. Hence there is no shock either at the beginning or end of the indexing period, and the operation is quickly accomplished.



Rapid, accurate indexing, together with other excellent features in design, enable a high rate of production to be obtained with B. & S. machines.

Write for special circulars of these machines.

BROWN & SHARPE MFG. CO.

PROVIDENCE, R. I., U. S. A.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

COLUMBIA UNIVERSITY, New York, has issued an announcement for the Summer session for 1912, beginning July 8 and continuing until April 16.

AMERICAN SOCIETY OF ENGINEER DRAFTSMEN, 116 Nassau St., New York City. Year book containing the constitution and by-laws governing the society; also list of members.

BELOIT COLLEGE, Beloit, Wis. Sixty-fifth annual catalogue of the college, containing information relating to the faculty and students, the courses, admission requirements, scholarships, etc.

VIRGINIA POLYTECHNIC INSTITUTE, Blacksburg, Va. Bulletin, April, 1912, covering 172, 6 by 9-inch pages, giving courses of instruction, and general information useful to prospective students, as well as a list of students for the year 1911-1912.

LOUISIANA STATE UNIVERSITY, Baton Rouge, La. Bulletin giving information relative to the summer school of the university. The term of this summer school begins June 3 and ends August 2. The courses of instruction, admission requirements, fees, etc., are dealt with in this bulletin.

MODERN SYSTEMS CORRESPONDENCE SCHOOL, 6 Beacon St., Boston, Mass. Booklet entitled, "As Others See Us," being an extract from an article in *Castings* on specialized correspondence schools. This school, of which Mr. Oscar E. Perrigo is director, specializes its courses to meet the needs of individuals.

SOCIETY OF AUTOMOBILE ENGINEERS removed its New York office from No. 1451 Broadway to the U. S. Rubber Bldg., Broadway and 58th St., May 1. The growth in membership and activities of the society made necessary the removal to larger quarters. The new location will be appreciated by out-of-town members, being close to the Columbus Circle subway station and on the route of the Broadway surface car lines.

NORTHWESTERN UNIVERSITY, Evanston and Chicago, Ill. Annual catalogue 1911-1912, covering 515, 6 by 9-inch pages, containing complete information of the various departments of the University, including the College of Liberal Arts, the College of Engineering, and the School of Commerce, and information relating to fraternities, university societies, alumni association, register of students, and general information relating to expenses, fees, etc.

AMERICAN ASSOCIATION FOR LABOR LEGISLATION, Metropolitan Tower, New York City, is entitled to much credit for the enactment of the phosphorus match bill signed by President Taft, April 9. Investigation of "phossy jaw," the occupational disease of match factory workers, led to the introduction of the bill in June, 1910, immediately after the publication of the report on phosphorus poisoning by John B. Andrews, secretary of the association. Public sentiment demanded the prohibition of the death-dealing match. Through this legislation one of the most terrible of occupational diseases will be abolished.

NEW BOOKS AND PAMPHLETS

ELECTRIC POWER ON THE FARM. By Adolph Shane. 62 pages, 6 by 9 inches. 31 illustrations. Bulletin No. 25 of the Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa.

SECOND ANNUAL REPORT ON THE STATISTICS OF EXPRESS COMPANIES IN THE UNITED STATES, for the year ending June 30, 1910. 38 pages, 8 by 10 inches. Published by the Interstate Commerce Commission, Washington, D. C.

KERRAWALLA'S TEXTILE AND ENGINEERING DIRECTORY AND YEAR BOOK. 10 by 13 inches, 111 pages. Published by C. D. Kerrawalla, Kalachowki Road, Parel, Bombay, India.

The Textile and Engineering Directory and Year Book for 1912 is the seventh issue. Among the useful information contained are complete lists of cotton ginning and pressing factories, jute presses, cotton jute, woolen and silk mills, iron works, gold, copper, iron, lead, manganese, ruby, salt and coal mines, flour, sugar, oil, rice, saw, bone and paper mills, quarries, coil works, roperies, mica works in India, cotton mills in China and Japan together with a number of useful tables for mill and factory owners, managers, engineers, carding, spinning and weaving masters, hardware and mill store merchants, etc. The directory is freely circulated among the users of textile and engineering machinery in India and is, therefore, of special interest to manufacturing concerns who wish to reach this trade.

TRANSPORTATION RATES. By A. M. Fisher. 16 pages, 5 by 7½ inches. Published by the author, New York. Price 50 cents.

This comment upon transportation rates, it is stated, has been written with particular reference to the section of the Interstate Commerce Act which is properly known as the "long and short haul" clause. The booklet is written from an extremely one-sided point of view, in which the opinions of the old-time "stand-pat" railway managers' ideas only are considered. As an example of the spirit of the booklet the following statement may be quoted: "It need not be anticipated that there will be a general revival of business with the present Interstate Commerce Act in effect and enforced." Digressing somewhat from the avowed purpose of the book, the author mentions that "it is hardly to be expected that profitable methods can be devised for the operation of the subways and other urban transportation service." It is difficult to understand on what basis this statement is made, in view of the fact that financiers seem to be extremely anxious to obtain monopolies in transportation services in cities, subways included. Another example of the peculiar mental processes by means of which the conclusions in this booklet are arrived at is the statement that the result of a parcels post would be "a very decided influence toward increasing the cost of living." The author finally advocates the introduction of scientific transportation rates. Just what he means by "scientific" is not entirely clear, but may perhaps be surmised from the few quotations given above.

NEW CATALOGUES AND CIRCULARS

CROCKER-WHEELER CO., Ampere, N. J. Bulletin No. 147 on Crocker-Wheeler electric fans.

DETROIT FUSE & MFG. CO., Detroit, Mich. Revised bulletin No. 23 on the "Detroit" three-phase motor starter.

STUDEBAKER AUTOMOBILE CO., South Bend, Ind. Bulletin No. 1023 on electric commercial motor vehicles for all purposes.

DAMASCUS BRONZE CO., Pittsburg, Pa. Pamphlet on "Damascus" bronze products with special reference to bearings.

DETROIT FUSE & MFG. CO., Detroit, Mich. Catalogue of the "Detroit" ironclad fused switches and the "Arkless" indicating fuses.

HANNIFIN MFG. CO., Chicago, Ill. Catalogue of air-operated chucks, countershafts, gate valve seating chucks, special tools and machinery.

ROCKFORD IRON WORKS, Rockford, Ill. Circular and specifications of the Rockford inclinable open-back foot press, size A; also No. 4 flywheel press.

GENERAL FIRE EXTINGUISHER CO., Providence, R. I. Bulletin on the "Grinnell" automatic sprinklers for the protection of shops, mills and factories from fire.

J. H. WILLIAMS & CO., 61 Richards St., Brooklyn, N. Y. Catalogue of lathe dogs, C-clamps, machinists' clamps, planer strap clamps, drop-forged wrenches, drop forgings, etc.

F. O. WEYDELL, 224 S. Jefferson St., Chicago, Ill. Circular of the "Hi-Low" drawing table which can be quickly changed in height from 36 to 44 inches to suit the convenience of the draftsman.

AMERICAN TAP & DIE CO., Greenfield, Mass. Catalogue No. 4 of "Adamantine" screw plates; "Eagle" brand taps, dies, stocks and tap wrenches; and pipe tools, comprising stocks, dies, taps and reamers.

AUTOCALL CO., 100-110 Franklin Ave., Shelby, Ohio. Card illustrating the "Autocall" and its application in the manufacturing establishments for locating foremen, superintendents and others without loss of time.

FRANCIS REED CO., Worcester, Mass. Circular of the No. 20 Stanley sensitive drill having six spindle speeds, detachable countershaft, ball thrust bearing for spindle, ample power for one-half-inch drill and which sells for $50.

BROWN HOISTING MACHINERY CO., Cleveland, Ohio. Pamphlet illustrating and describing "Brownhoist" suspended bins for coal, ore, ashes, etc., and catalogue of the "Brownhoist" tramrail systems, trolleys and electric hoists.

ELECTRIC CONTROLLER & MFG. CO., Cleveland, Ohio. Bulletins, Nos. 1009 on push buttons; 1016 on automatic motor starters for non-reversing direct-current motors; 1025 on lifting magnets; and 1027 on current limit panels for direct-current motors.

UNIVERSAL STAMPING CO., Buffalo, N. Y. Bulletin illustrating safety devices made to prevent the flying of chips from shaper tools, lathe tools and other cutting tools, emery wheel guards, safety belt hanger, snap-on reflectors, lamp shades, lamp stands, etc.

CHICAGO PNEUMATIC TOOL CO., Chicago, Ill. Bulletins, E-19, E-20, E-21 and E-22 on universal electric drills, operating on direct or alternating current; electric drills for heavy work; Duntley track drill; and air-cooled direct current drills, respectively.

PAWLING & HARNISCHFEGER CO., Milwaukee, Wis. Booklet entitled, "Cutting the Cost of Lumber Production," illustrating handling and transporting apparatus built by the company, comprising monorail systems, traveling electric cranes and hoists and electric transfer cars for handling lumber in bulk.

WATSON-STILLMAN CO., 192 Fulton St., New York, has just issued catalogue No. 85 "Hydro-Pneumatic Wheel Presses," which describes and lists the company's line of full hydro-pneumatic wheel presses. Seventy-six types and sizes of hydraulic tools exclusively of Watson-Stillman designs are also listed.

SCULLY JONES & CO., 316 Railway Exchange, Chicago, Ill. Circular of the "Wear-ever" sockets for drills. The sockets are made of special steel, heat-treated, and reinforced at the bottom by a solid ring of metal of increased diameter having a drift groove which saves time in separating nested sockets.

BAUSCH & LOMB OPTICAL CO., Rochester, N. Y. Circular of the "Balopticon" for the projection of large opaque objects on a screen. This instrument is designed for educational purposes and enables a lecturer to project drawings, photographs, working models, mechanisms, etc., directly on the screen without previous preparation.

EUREKA CO., North East, Pa. Price-list of copper hammers for machine shop use, furnished in sizes from ¼ pound to 16 pounds, with or without handles. Copper hammers are more durable than babbitt hammers and have the characteristic of not seriously marring steel or cast iron when employed for driving or hammering work.

INDUSTRIAL INSTRUMENT CO., Foxboro, Mass. Bulletin No. 60 on indicating gages for all purposes comprising pressure and vacuum gages, compound, ammonia, pyrometer, test, hydraulic, electric alarm, altitude, sulphite, illuminated dial, standard duplex and triplex, and recording gages, thermographs, marine and locomotive clocks, etc.

WATSON-STILLMAN CO., 192 Fulton St., New York. Bulletin J describing a filling liquid, called "Jackohol," developed for hydraulic tools such as jacks, presses, punches, benders, etc. This liquid does not freeze, thicken, gum or change chemical composition. It is invariably protective to the metal surfaces and packings with which it comes in contact.

W. P. DAVIS MACHINE CO., Rochester, N. Y. Treatise on keyseating and keyways compiled for American machine shop practice. This interesting and valuable little booklet contains a fund of useful information on a very practical subject affecting everyone having to do with the design and construction of machinery. The booklet also illustrates the Davis keyseater made in two sizes.

PRATT & WHITNEY CO., Hartford, Conn. Wall hanger of machinists' handy tables comprising U. S. standard screw threads, standard dimensions of wrought iron, welded tubes, table of cutting speeds and feed per minute, metric standard screw threads, pitch or angle diameters of hand taps, U. S. and Whitworth standard and A. S. M. E. standard screw threads for machine screws.

FURNACE GAS CONSUMER CO., Matteawan, N. Y. Pamphlet entitled "Smokeless Chimneys," describing a furnace gas consumer for the prevention of smoke, consisting of a bank of fire clay tubes installed back of the bridge-wall underneath the boiler which becomes incandescent and thus promotes complete combustion of the gases before they are cooled by contact with the water-backed surfaces.

KEUFFEL & ESSER CO., Adams and Third Sts., Hoboken, N. J. Descriptive circular of an improved farm transit with and without compass for the use of builders, architects, instructors, farmers, etc. This instrument, which without compass sells for $30, has a 10-inch telescope, one-inch aperture. The same instrument with compass sells for $38. The circular also illustrates farm levels selling for $16 and $25.

GENERAL ELECTRIC CO., Schenectady, N. Y. Booklet No. 4926 on the application of electricity to marine service. The publication is printed in colors and describes the various pieces manufactured and supplied by the company for marine use. The data given are of general interest to motor boat owners and among these data will be found reproductions of the flags of the principal yacht clubs throughout the country.

J. M. CARPENTER TAP & DIE CO., Pawtucket, R. I. Catalogue No. 19 on tools for cutting screw threads comprising taps, dies, screw plates, die-stocks, tap wrenches, etc. The catalogue also contains useful tables on U. S. Standard threads, V threads, International, and French standard threads, Whitworth standard threads, British Association standard, Acme standard and A. S. M. E. standard for machine screws, etc.

RAHN-LARMON CO., Cincinnati, Ohio. Catalogue of Rahn-Larmon engine, turret and gap lathes built in the following series and sizes: Series A, 16-, 18- and 20-inch engine lathes; series A, 16-, 18- and 20-inch gap lathes; series B, 18-, 20- and 22-inch engine lathes; series D, 22-, 24- and 26-inch engine lathes; series G, 24- and 48-inch extension bed gap lathes; and series F, 26-, 28-, 30- and 32-inch engine lathes.

HALE-MCADAMS WHEEL CO., 224 High Avenue, Cleveland, Ohio. Circular of the Cleveland friction clutch which is made in nine sizes,

Inspection and Routing Department.

Department for Assembling and Testing Feed and Drive Boxes.

Department for Testing the Completed Machines.

EVERY DETAIL OF CINCINNATI MILLERS

is inspected after every operation. Some of them pass through this department as many as twenty times before they are finished. Hardened gears, clutches, and similar parts are also tested with the scleroscope and must meet definite standards of hardness set for each piece.

The drive box, feed box, etc., each form a complete unit of mechanism. They are assembled by skilled men who are expert on this work because they do nothing else.

Every unit when assembled, is given a running test under working conditions before passing into stock.

The completed machine must pass an exacting inspection for alignment; must run continuously for a given period; and must also do a variety of milling successfully.

These running and working tests are a final check on each unit of mechanism, and are a guarantee that every detail is fully up to our high standard of excellence.

These are some of our Manufacturing Methods. Visit us and see them for yourself.

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

EUROPEAN AGENTS—Alfred H. Schutte, Cologne, Berlin, Brussels, Milan, Paris and Barcelona. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Sam Lagerlofs, Stockholm, Sweden. Axel Christiernsson, Abo, Finland. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow. CANADA AGENT—H. W. Petrie, Limited, Toronto, Montreal and Vancouver. AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne. JAPAN AGENTS—Andrews & George, Yokohama. CUBA AGENT—Krajewski-Pesant Co., Havana. ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Ayres.

CONTENTS FOR MAY

The first column of page numbers applies to the Engineering and Railway Editions: the second to the Shop Edition.

ranging from 8 inches diameter to 24 inches diameter and having capacities of 8 to 63 horsepower per hundred revolutions per minute. The clutch is self-oiling, has few parts, is easily adjusted, and has other advantages of interest to all those concerned with the installation of clutches.

INDUSTRIAL INSTRUMENT CO., Foxboro, Mass. Bulletin No. 61 on portable or hand tachometers, single-spindle multi-speed spring type made by Dr. Th. Horn of Leipzig, Germany. These instruments show at a glance the rate of rotation or peripheral speed and by means of the selective speed-changing mechanism a single instrument may have several scales. One of the forms of this instrument is a cut meter for showing the cutting speed of lathe and planer work.

NEW PROCESS TWIST DRILL CO., Taunton, Mass. Catalogue of carbon high-speed and "Reliance" high-speed twist drills. The regular carbon steel and high-speed drills are hot-forged and twisted instead of being milled from the solid as is the common practice. The "Reliance" high-speed twist drills are made from profile stock inserted in a carbon steel shank by a special process. The claim is made that the hot forging process gives the drill greater strength because the grain follows the spiral fluting.

HESS-BRIGHT MFG. CO., 2111 Fairmount Ave., Philadelphia, Pa. Data Sheets, Nos. 5-A, 52-I, 65-A, 68-A, 70-A, 75, 76 and 78 on mounting collar type ball thrust bearing to take thrust in one direction only; DWF adapter bearings; centrifugal basket mountings; application of floating bushes to grinding spindles; DWF adapter and method of assembling with bearings on a straight shaft; standard form of mounting for two-bearing four-cylinder crankshaft; built-up crankshaft and two-cylinder V type motor; and mountings for rolls.

ADAMS CO., 877 Market St., Dubuque, Iowa. Circular No. 812 illustrating and describing the No. 4 Farwell universal gear hobber which was illustrated and described in the March number of MACHINERY. This gear hobber cuts spur gears, worm-wheels, spiral and worm gears, herringbone gears, ratchet wheels, sprocket wheels, etc. It has a capacity for gear diameters up to 24 inches, and with arbor support removed, up to 28 inches. The vertical feed of the head is 12 inches and the coarsest diametral pitch cut in steel is 3½ pitch, and in cast iron or bronze, 3 pitch.

CRESCENT MACHINE CO., 56 Main St., Leetonia, Ohio. Catalogue for 1912 of "Crescent" wood-working machinery comprising band saws, "Crescent" angle band saws which may be tilted for bevel sawing, guards for band saws, setting and filing clamps, saw tables, saw guards, shaper fence, single and double spindle shapers, jointers, variety woodworker, planers and matchers, surfacers, swing cut-off saws, disk grinders, universal borers, post borers, etc. A valuable feature of the catalogue is the data on the horsepower required for machines, which enables a customer to estimate the probable power requirements of machines to be installed.

W. S. ROCKWELL CO., 50 Church St., New York. Specimen views from catalogue No. 14 showing installations of Rockwell oil and gas furnaces, among which are installations of single chamber and double chamber annealing furnaces, double-end underfired annealing furnaces for brass, copper, German silver, sterling silver, etc.; single-end underfired annealing furnaces for the same fuel and purposes are shown, also annealing and hardening furnaces, carbonizing furnaces, rotary annealing and hardening furnaces, rod heating furnaces, forge furnaces, brass melting furnaces, plate heating furnaces, and soft metal furnaces, all using oil or gas fuel.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletins Nos. 4915 on direct current motors; 4921 on electric heating and cooking; 4922 on electricity in metal mines; 4923 on modern electrical equipment for economical production of iron and steel; 4928 on searchlight projections for commercial use; 4929 on electrically operated brick plants; 4933 on small polyphase motors; 4934 on battery charging rheostats; 4935 on GE-201-A railway motor; 4940 on commutating pole motors; 4941 on water flow meters; 4942 on Thompson direct current test meter; 4943 on direct current motor starting panels for heavy service; and 4944 on isolated and small plant alternating current switchboard panels.

WESTINGHOUSE ELECTRIC & MFG. CO., East Pittsburg, Pa. Leaflets, Nos. 2362 on type CA alternating-current motors; 2409 on self-starting synchronous motors, ranging in capacity from 90 to 1500 horsepower and from 220 to 6600 volts; 2441 on the application of small motors; 2443 on motors for crane and hoist service; 2446 on type QK electrically-operated brakes for direct-current cranes and hoist motors; 2447 on type SP electrically-operated brakes designed especially for mill and crane service; 2449 on hand-operated controllers for light crane and hoist service; 2383 on alternating-current steel mill motors, type MA; and circulars Nos. 1088 on three-wire direct-current generators; 1522 on multiple unit trains and HL control; and 4049 on type F carbon circuit-breakers.

TRADE NOTES

DOEHLER DIE-CASTING CO., Court and Ninth Sts., Brooklyn, N. Y., has established a Detroit office in the Ford Bldg., Room 1313, in charge of the company's vice-president, Mr. H. B. Griffin.

E. L. ESSLEY MACHINERY CO., Chicago, Ill., has made Mr. James L. Gough sales manager and Mr. James J. Shanahan representative for Indiana and Michigan, replacing Mr. J. A. Richardson, resigned.

CANTON MACHINERY EXCHANGE, 624 N. Market St., Canton, Ohio, was recently organized to deal in machine tool specialties, and the catalogues and literature of manufacturers of machine tools and accessories are requested.

EDGAR ALLEN & CO., LTD., Chicago, Ill., formerly of 434 W. Randolph St., has moved to larger and more commodious quarters at 718-722 W. Lake St., where a full stock of all grades of Allen's tool steels will be carried.

ALLIS-CHALMERS CO., Milwaukee, Wis., which recently went into the hands of receivers, has been reorganized with a capital stock of $42,500,000. The stock consists of $26,000,000 common and $16,500,000 seven per cent accumulative preferred stock.

LUCAS MACHINE TOOL CO., Cleveland, Ohio, was awarded a gold medal and diploma at the Brussels Exposition in 1910 for the Lucas precision horizontal boring, drilling and milling machine which was exhibited by the company's representative, Mr. Alfred H. Schütte.

PAGE-STORMS DROP FORGE CO., Chicopee, Mass., has installed a thoroughly equipped chemical laboratory, modern in every respect. It is under the direction of an experienced chemist who was connected with the Halcomb Steel Co., Syracuse, N. Y., for about four years.

ANDREW C. CAMPBELL, Waterbury, Conn., will erect a factory on State St. for the manufacture of a patented self-spreading cotter-pin. The cotter-pin is so fashioned that when inserted in a hole and driven with a hammer, one part slips past the other, thus spreading their ends, and preventing the pin from falling out.

SUFFERN & SON certified public accountants, have established a branch at 1121 Newhouse Bldg., Salt Lake City, Utah, under the direction of Mr. Charles A. Secor, as resident partner. This office will have a staff of competent accountants and will also command the services and abilities of the entire organization.

JOSEPH T. RYERSON & SON, Chicago, Ill., have been appointed as sole agents for Chicago territory to represent the full line of multi-spindle drill presses manufactured by the Fox Machine Co., Grand Rapids, Mich., and a machine has been installed on the floor of the Chicago machine tool warehouse for demonstrating purposes.

HOSKINS MFG. CO., 459 Lawton Ave., Detroit, Mich., maker of Hoskins electric furnaces, pyrometers and heating appliances, and "International" electric heaters, has opened an office in the Oliver Bldg., Pittsburg. This office will enable the company to more adequately care for its rapidly growing business in the Pittsburg district.

RICKARD & SLOAN, 20 Vesey St., New York, is a newly organized advertising firm, composed of William L. Rickard and Clifford A. Sloan. The firm will give particular attention to the planning and management of advertising campaigns for firms engaged in the manufacture of mechanical and electrical apparatus and accessories.

BUFFALO FOUNDRY & MACHINE CO., 63 Winchester Ave., Buffalo, N. Y., was damaged by fire early in the morning of April 11 to the extent of about $10,000. Because of its steel and glass construction the building is practically fireproof, excepting the roof, where the greatest damage was done. The damage stopped business in the plant for only a few days.

MACHINERY

Railway Edition for Locomotive Construction and Repair Shops

June, 1912

MILLING MAIN-RODS AT THE JUNIATA SHOPS

By FRANKLIN D. JONES*

THE machining of locomotive main-rods at the Juniata Shops of the Pennsylvania R. R. was described in MACHINERY (railway edition) February, 1910. Since that time, however, the method of milling these rods has been improved considerably, which is saying a great deal, as the former practice was doubtless in advance of that found in the average shop. In connection with the milling operations, a large amount of stock is removed and, at first thought, it would seem more economical to forge closer to the finish size, but this superfluous metal is milled off so rapidly that any fancy forge work would cost more than the extra time required for milling. As the article previously referred to contained a complete description of the rod work, we shall deal more particularly with the milling operations, in order to show how quickly a large amount of stock can be removed by milling. when the machine itself is adapted to the work and the cutter is properly constructed.

The successive stages through which the main-rod passes while being transformed from a rough forging to the finished product, are illustrated in Fig. 1. The rough forging is shown at *A* just as it comes from the blacksmith shop. It is made of 50 point carbon steel, and the particular rod referred to in this article weighs approximately 1831 pounds before any milling operations have been performed. After it is milled, the weight is reduced to 1535 pounds. The first operation is that of planing the sides and edges of the enlarged ends. The sides are finished to the required width, but the top and bottom edges are simply rough-planed, as they have an irregular outline which cannot be machined to advantage by planing. A special double-head rod planer is used for this work. Each head of this planer has two tool-heads on the cross-rail and a similar number of side-heads, so that two forgings can be planed simultaneously. The object in planing the ends first is to provide finished surfaces for setting up the work while milling the sides and edges. The rod is next taken to the laying-out benches where the finished outline is transferred to it from a steel templet. Centers for the holes which have to be drilled in the ends are also located at this time.

The third operation is that of milling the edges. A group of six rods is placed on a horizontal milling machine and the edges of first one side and then the other are milled to the required outline, as will be described more in detail later on. The sides are then finished to the required width by milling, two rods being placed on the machine at a time. The shape of the work after the milling operation is shown at *B*. The rods are next placed on another milling machine of the horizontal type which cuts deep grooves or channels in the sides as shown at *C*. This channeling operation is performed on two rods simultaneously. The channel, which is $4\frac{1}{2}$ inches wide and $1\frac{3}{4}$ inch deep, is completed by taking two cuts, each of which is $\frac{7}{8}$ inch deep.

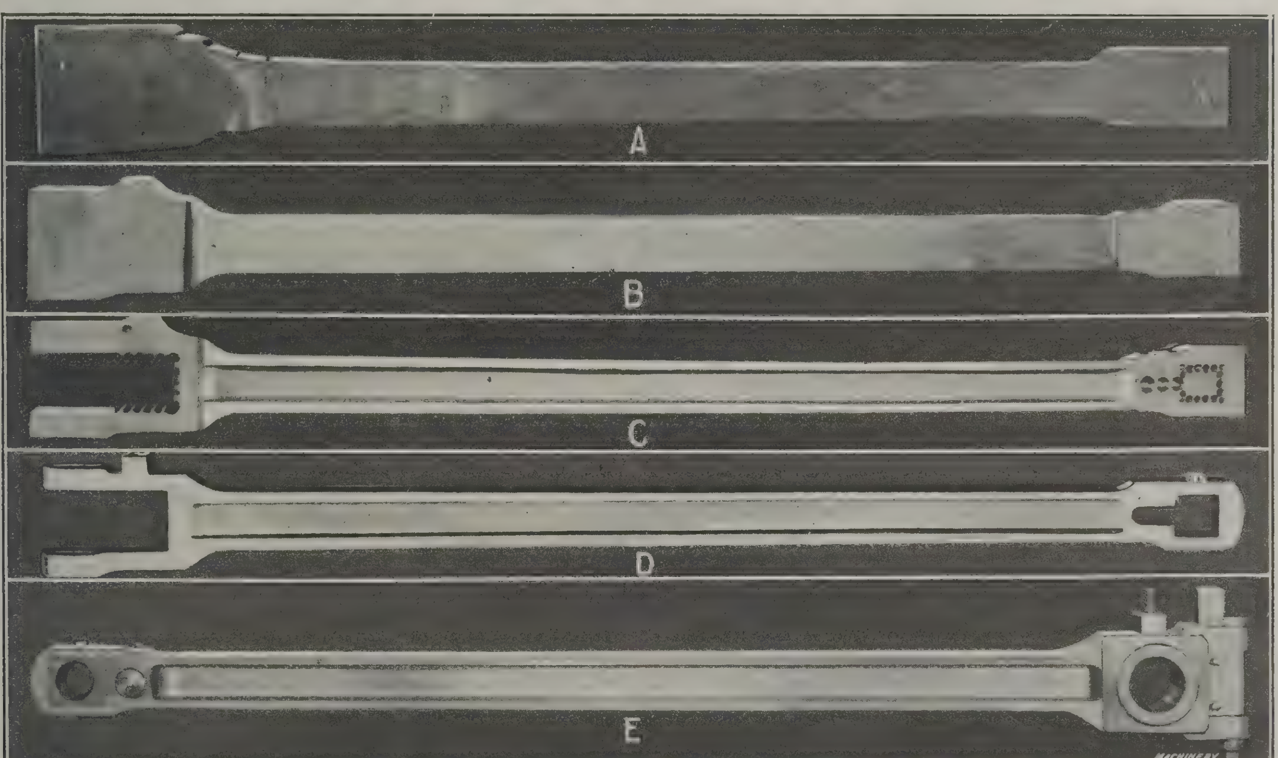


Fig. 1. The Evolution of a Locomotive Main-rod

After both sides have been channeled, thus forming an I-beam section, the drilling indicated at *C* is done, preparatory to forming openings at the ends for the bearing brasses. The small end is blocked out entirely by drilling, as the illustration shows, and the large end, after being drilled part way, is taken to a double-blade sawing machine which removes a solid block of metal from the center. These rough interior surfaces are next finished to the proper width in a slotter, the previously scribed lines serving as a guide for the workman. A view of the rod after the slotting operation is shown at *D*. The holes for the key-slot at the large end are next drilled and slotted and the oil holes are also drilled and counterbored, which completes the machining operations. The rod is now taken to the bench, where the sides and ends are finished and polished,

* Associate Editor of MACHINERY.

and finally, the brasses, keys and bolts are fitted in place, thus completing the rod as shown at *E*.

The milling of the sides and edges of these rods is done by the powerful horizontal milling machine shown in Figs. 2 and 3. The table of this machine is driven by a rack and spiral pinion, and power to the cutter arbor is transmitted through large worm-gears on each side, as indicated in the illustration. The milling cutter used is 33 inches wide and is composed of three units 11 inches long and 8¾ inches in diameter. It is equipped with inserted blades which are held in helical grooves. When the edges of the rods are being milled, this cutter covers a surface 30 inches wide and takes cuts ranging in depth from 1/4 inch to 1 3/16 inch. As previously stated, the edges of six rods are milled simultaneously. Fig. 2 illustrates how the work is set up for the first milling operation, and Fig. 4 is a view showing a group of rods after the edges have been machined. When the sides are being milled, two rods are clamped to the table as indicated in Fig. 3, and Fig. 5 shows the work after the sides have been milled.

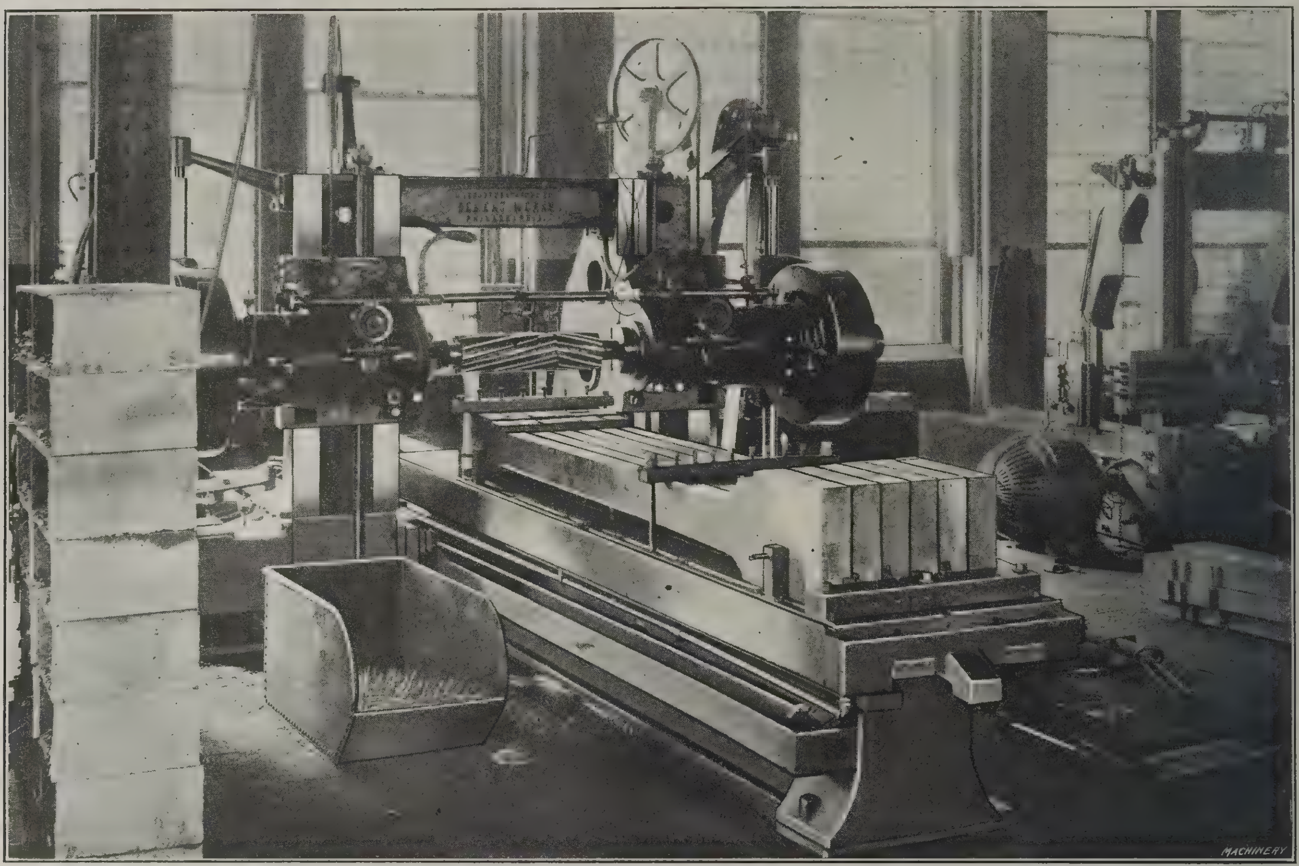

Fig. 2. Horizontal Milling Machine in which the Edges of Six Main-rods are milled simultaneously

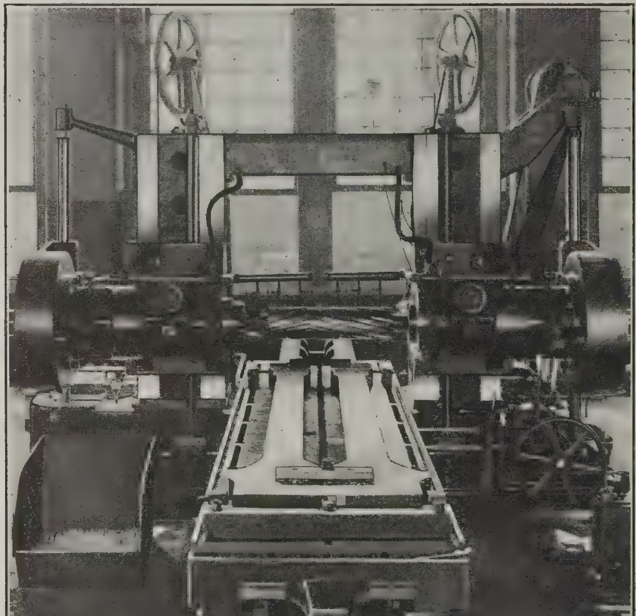

Fig. 3. Method of Holding the Rods while the Sides are being milled

The diagram, Fig. 6, shows the lengths of the different sections or surfaces on the sides and edges, which are milled. The time required for milling each of these sections, together with the average depth of cut, will be given in order to show exactly what is accomplished. Section *A*, the original outline of which is indicated in a general way by the dotted lines, is finished to the form shown in 55 minutes, two cuts, each having a depth of 1 3/16 inch, being required. Part *B*, the original form of which is also indicated by dotted lines, is milled in 1 hour, 40 minutes. Section *C* requires only 35 minutes, and the depth of cut varies from ⅜ to ⅝ inch. Section *D* takes 20 minutes, the cut being 1 inch deep part way and ¾ inch the remainder of the way. Section *E* is milled in 40 minutes, the time being increased for the length milled, because of the hand manipulation required for the irregular outline. The long cut

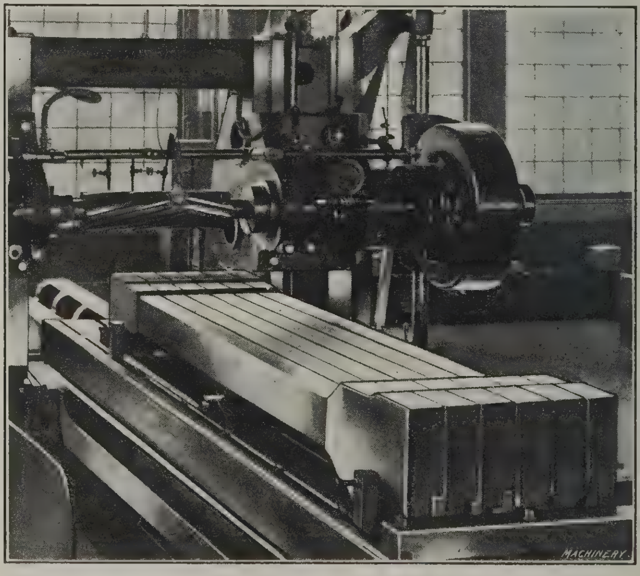

Fig. 4. View showing Group of Rods after Edges have been milled

F requires 45 minutes and varies in depth from ½ to ¾ inch. Section *G* is milled in 15 minutes and the depth of cut is ¾ inch. It should be remembered that the time given in each case is for six rods, whereas the following figures which refer to side milling operations are for two rods. Side *H* is milled in 22 minutes, the cut varying in depth from ¼ to ½ inch, and the opposite side *I* requires the same time, and approximately the same amount of metal is removed.

These figures were not taken from special tests, but represent everyday practice. After the edges and sides are milled the weight of a rod is reduced from 1831 pounds to 1535 pounds, as previously stated, 296 pounds of metal having been removed. The total time for milling the edges of six rods is 5 hours and 10 minutes, and both sides of six rods are finished in 2 hours and 12 minutes, making a total cutting time of 7 hours and 22 minutes. The average amount of stock removed per hour is 241 pounds, and the average time required for milling each rod is about 1 hour and 13 minutes. It will be seen that the figures given in the preceding sentence justify the great difference in weight between the rough forging and the milled rod; in other words, the milling is done so rapidly that it is not necessary to forge close to the finish size. By removing plenty of stock from the outside, a solid homogeneous rod, free from surface flaws or other imperfections, is obtained.

AUTOGENOUS WELDING IN GERMANY

According to a report by Consul General A. M. Thackara of Berlin, Germany, autogenous welding methods are used very extensively in Germany, and practically all of the larger manufacturers of metal products have their own welding plants. There are comparatively few independent welding plants, but there has been a notable increase in the number of small welding apparatus sold during the last year. It is estimated that about 12,000 plants in Germany are using autogenous welding apparatus at the present time. In both Berlin and Cologne courses in the manipulation of welding apparatus have been given. The "Handbuch für Carbid und Acetylene," by Prof. Vogel, published by Friedr. Vieweg & Sohn, Braunschweig, has been recommended to the American consul in Berlin as being the best work describing the different German welding apparatus. The price of this book is 15 marks (approximately $3.60). By far the greater number of German plants use acetylene instead of hydrogen gas, because, although the prices of acetylene and hydrogen are practically the same, the claim is made that a greater amount of hydrogen is required to do a given piece of work, and, furthermore, hydrogen is not suitable for welding comparatively thick pieces.

OLD DAYS IN AN EASTERN MACHINE SHOP

By R. H. G.

About thirty-five years ago the Pratt & Whitney Co. of Hartford, Conn., made all kinds of special machines to order, and it was only necessary for the customer to send a sample of the article that he wished made in large quantities to the firm; an automatic machine would then be designed and built for the work. At that time there were working in the drafting-room of the plant some of the best mechanics and inventors in this country. The machines designed always had novel features, and in this way the company obtained its prominent position. Mr. Frank Pratt, the president, was himself one of the best draftsmen and designers in his day, and had on his staff such men as J. Reynolds, John J. Grant, Charles Church, and others.

One day Mr. Pratt came into the drafting-room and asked if a certain special machine had been laid out; when nobody replied, he said: "Give me a drawing-table and I'll show you young fellows how to draw a machine in quick time." He was soon at work, and it did not take him long to outline the machine. He had, however, not done any work of this kind for several years, and the calculations of the various movements proved tedious to him. He was also anxious to finish the work, and started to ink in the drawing before it was quite completed. Then he was called away on business for a few days, and when he started drawing again, upon his return, he noticed several mistakes, so that it became necessary for him to do a good deal of erasing. When the erasing commenced, Mr. Reynolds spoke up and said: "Mr. Pratt, there's a new way out for making drawings quick and easy." Mr. Pratt, who always was interested in everything new, said: "What is it?" Mr. Reynolds replied, "You take a large sheet of drawing paper, and after carefully fastening it to your table, you cover the entire paper with lines and circles, and then you erase those which you do not wish to use."

Mr. Reynolds did not stay to see the effect of his explanation.

SAFETY GATES FOR SHOP DOORS OPENING ON RAILROAD TRACKS

The very frequent practice of running railroad tracks close to factory walls and having doors from the factory open directly upon the railroad track, has been the cause of many fatal accidents. A simple method of guarding against accidents of this kind has been adopted by a large western concern. Small gates are provided which ordinarily extend across the railroad track, but which are so arranged that when cars

are to pass along the track, they can be swung aside so as to close the entrance to the shop. The gates are cared for by the switching crew, who close them across the doors of the shop when a train approaches. This means of safety is very effective, because it cannot easily be neglected. Should the switchman not attend to his duties, however, the neglect would be apparent, as the gates extending across the tracks in front of the approaching train would be broken by it, and, hence, an indisputable evidence of the neglect to close the gates in front of the doors opening upon the tracks would be at hand.

FORCE-MAKING FOR EMBOSSING DIES

By CHESTER L. LUCAS*

THE term "force" is used in connection with die-sinking, but the words "force" and "hub" are often confused by those who are not familiar with this work. A hub is a hardened steel punch used to form an impression in a die. Usually the die is heated to facilitate this operation. Only a small percentage of dies require the use of a hub, but there are some designs that are more easily cut "on the hub." A die having flat panels with projecting lines, as illustrated in Fig. 9, would be very difficult to make without a hub, and so would one in which a number of letters or parts of the design had flat faces cut to the same depth, as shown in Fig. 10. After the dies are made, the work of the hub is done, unless duplicate dies are to be made at some future time.

A "force," or "forcer," is, as its name implies, a block of metal which *forces* sheet stock into every crevice in the impression of a die. A force is probably used with nine out of every ten embossing dies. The exceptions are dies in which the design is extremely shallow and the metal relatively thick, and dies for emblems, buttons or similar work in which the design is so intricate that a force would be of no advantage. "Strikings" to illustrate these cases are shown at *A*, *F*, *G*, *M*, *N*, *O*, and *R*, Fig. 1. In such cases the metal is simply driven into the impression by a flat steel block held in the hammer of the press. This block is often called a flat force, and is usually made by heating a piece of round bar steel, about two inches long, laying it on a plain hard die block in the press, and striking several blows upon it with the hammer of the press, in which has been mounted a "pick-up." One of these pick-ups is shown in Fig. 8. The flat force is hardened and tempered to a light straw color.

Fig. 2 illustrates four embossing dies for which forces would be required, and Fig. 3 shows a group of forces, those at *A* and *D* being made of copper and the rest of steel. Those at *B* and *C* show the reverse sides with the ridges formed by the pick-up. In Fig. 4 are shown, in place, the die *A*, the force *B*, and the pick-up *C*, keyed in the hammer of the press, which is illustrated at *D*.

Forces are made from different materials, depending upon the character of the work, the design of the die, and the thickness of the metal being stamped. In determining the material from which a force shall be made it is quite important that the number of impressions be taken into consideration. Thus, if only fifty or one hundred impressions are to be made, it would be inexpedient to make a steel force.

Tin or Lead Forces

Tin or lead forces are used for embossing dies where the designs are large and no small detail is required, and the material to be stamped is soft, like brittania metal or silver. Tin is, by far, the better of these two metals, but often lead is employed in its place. The stampings shown at *C* and *P*, Fig. 1, are easily made by means of tin forces. The metal is soft and thin and the detail is not too complicated. The method of making a tin or lead force is to surround the design on the die with a wall of putty. The molten tin or lead is then poured into this enclosure and allowed to set. This operation can often be performed without removing the die from the press. As soon as the metal has cooled, the putty is removed from the die and the hammer brought down upon the tin or lead casting. The blow thus struck imbeds the top side of the force into the pick-up of the hammer and sharpens the face of the force, leaving it ready for use.

A typical job upon which this class of force is employed is shown set up in the press in Fig. 5. The work being stamped is a silver hand-mirror mounting. The lead force for this job may be seen imbedded in the pick-up of the press, which has

Fig. 1. Stampings from Embossing Dies involving Use of Forces of Various Kinds

* Associate Editor of MACHINERY.

a series of parallel slots extending both ways across its face, enabling it to hold the large lead force firmly. In the stampings shown in front of the die, holes have been punched at the center of the impression. This is done to allow the metal to "pull" evenly in forming the design, thereby lessening the danger of cracking or causing thin spots in the work. Beside these stampings is shown a lead force that has just been removed from one of the other presses. Lead or tin forces are very short-lived, but as they are extremely easy to make, they are profitable to employ if the character of the work permits it.

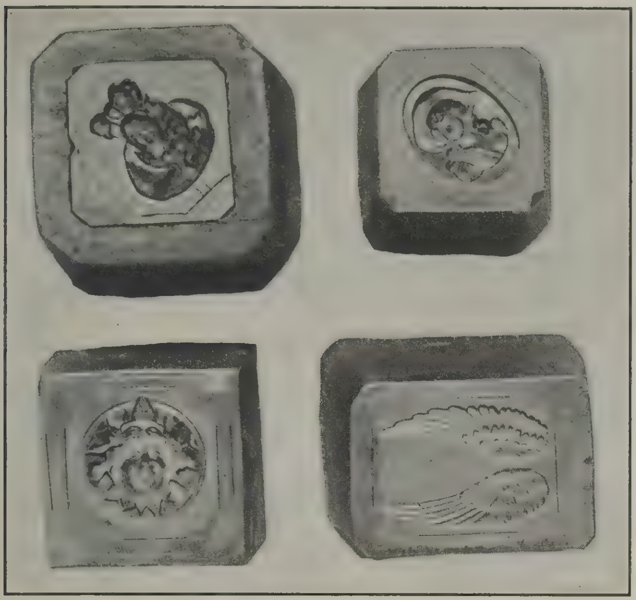

Fig. 2. Embossing Dies requiring Forces

Cast Brass Forces

On long runs of soft metal stamping, when it would be too slow to stop and renew the lead force many times, cast brass forces are made. A plaster of Paris pattern is first made, and after being cut away in certain places and built up at the ends to anticipate the loss from shrinkage of the brass, a casting is made. After filing up this casting, it is fitted to the pick-up and struck into the die to bring up the design. It is relieved where necessary, and is then ready for use. Fig. 6 shows a pattern for a brass force.

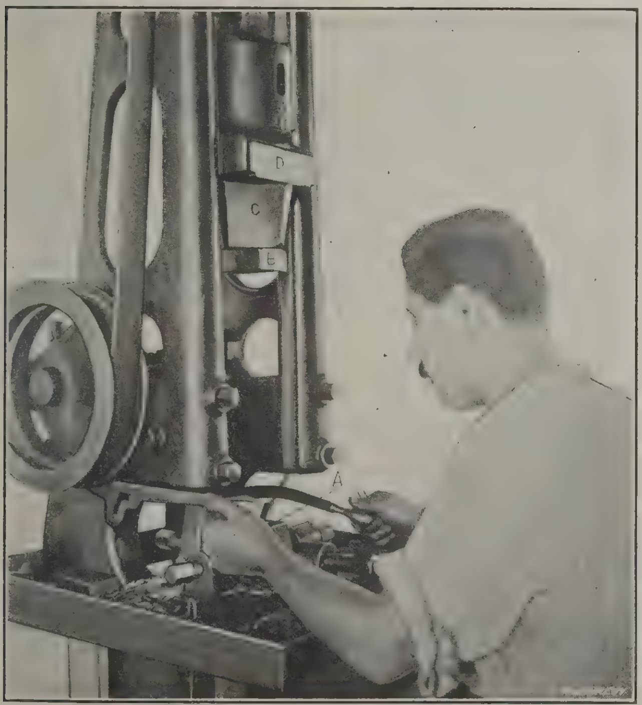

Fig. 4. Showing the Use of Embossing Die, Force and Pick-up

Copper Forces

For work in which the requirements are somewhat more severe than in the work just described, copper forces are generally used. They are especially useful in striking up small gold emblems which are too deep to be successfully made with a flat block for the top die. One of these designs is shown at *S*, Fig. 1. Copper forces are seldom used for work over one and one-half or two inches in diameter. They are made by taking a blank piece of sheet copper from 1/16 to 1/8 inch thick, placing it on the die, and striking it into the impression. This operation is performed without heating the metal. In order to get the force "full," it is often necessary to anneal it and restrike it several times. It is then finally placed in the die with a small piece of beeswax on top of it, and is "picked up" on the flat top die. The metal blanks are then struck up in the usual manner.

Fig. 3. Copper and Steel Forces

Difficult cases require that the blanks be run through a first operation consisting of striking them into the impression of the die; this being done, they are struck a second blow, which is often so severe that the copper force is loosened from the hammer at each blow. It is, however, an easy matter to lay the partly formed blanks in the die, place the copper force on top, seated in the impression in the partly formed blank, and proceed with the striking. Thus it is immaterial whether the force sticks to the top die or not.

Fig. 5. Lead Force in Use

Copper forces are also used for striking up deep articles in which the requirements are too severe for tin or lead forces, because of the metal being excessively hard or thick. The

samples shown at H and L, Fig. 1, should be made by using copper forces. A force for this class of work is made by heating a piece of bar copper to a red heat, placing it on the die which has been previously set up in position in the press with a pick-up in the hammer, and striking it repeatedly into the die impression until every detail of the design is plainly visible on the force. During this striking operation it is

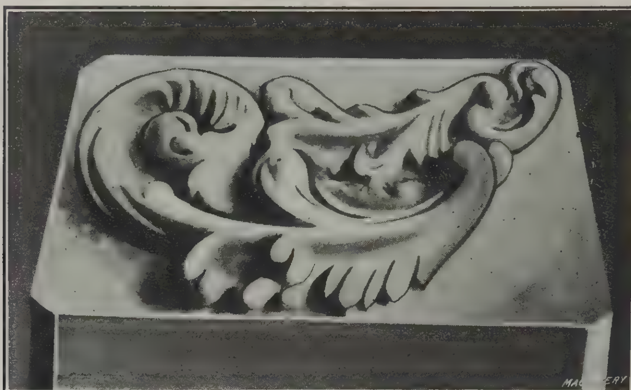

Fig. 6. Plaster of Paris Pattern for a Brass Force

necessary to clean out the die after each blow, either by an air blast or with a wire brush. The whole operation must be carried through as rapidly as possible in order to get the force "up" at the first heat, because a second heat produces an inferior force, on account of the softening of the metal on reheating. The copper force is left in the pick-up, and while cooling, is struck into the die at intervals to make up for the shrinkage. If the design is fairly symmetrical in all directions, the result of the shrinkage will be negligible, but if the design is long and narrow, trouble generally arises, a point which will be touched upon more fully in the following.

Soft Steel Forces

Soft steel forces are employed in many shops in preference to hardened tool-steel forces because there is less danger of

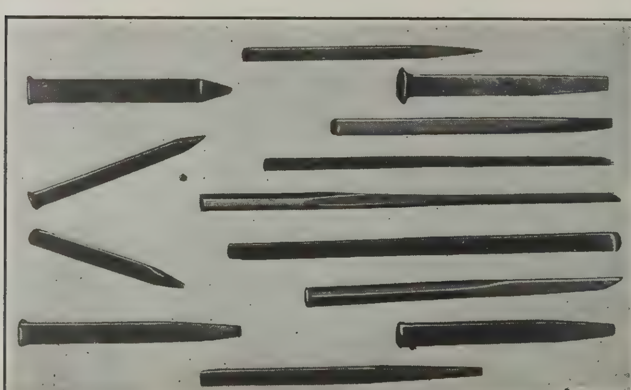

Fig. 7. Chisels and Punches used in Fitting and Relieving Forces

the die being injured by careless operators. If a hardened force, for instance, is struck into the die without any work being placed in it, the die will be injured. In general, soft steel forces are employed in cases where a lead, tin or copper force would not stand up to the requirements, and yet a tool-steel force is not required. A typical piece of work of this character is shown at K, Fig. 1.

Another case in which it is advantageous to use soft steel forces is where the trouble caused by shrinkage would be great, and it is, therefore, considered best to work up the force cold. This is especially true of forces for name-plate dies where the letters are weak and narrow. A force cannot be made cold, however, without a great deal of trouble, unless the design is fairly shallow and of even depth.

When working up a machine-steel force cold, the outline of the blank should first be machined to approximately match the impression of the die. The face of the force should then be covered with a thin coating of solder. This is best accomplished by flowing solder over the face of the force, afterwards wiping off the surplus with a piece of clean waste. In this condition the force is laid upon the die in the press, care being taken to have its face match that of the impression in the die, after which a fairly hard blow is struck upon the top side of the force. This will leave an impression upon the force-face; the steel may be chipped off from the parts of the force where it is not needed, as shown in Fig. 17, and the force refitted in the die and struck again. This process is repeated until every detail of the force comes up sharp. Sometimes it is advantageous to use punches to drive the metal down and out of the way rather than to try and chip it away with chisels. Some of these punches are shown in Fig. 7, and the method of doing the work is illustrated in Fig. 18.

The advantage of working up a force cold, as mentioned, is that the problem of shrinkage does not enter into the work. The shrinkage of a force is illustrated by Figs. 11, 12 and 13. Fig. 11 shows the face of a die with the impression of a long narrow scroll cut in it. In working up a force for this design, it should be done cold, if possible, and the force will then

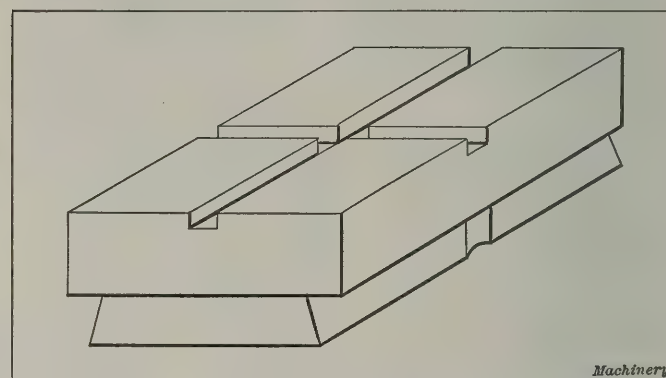

Fig. 8. One Form of Pick-up

fit as shown in Fig. 12. If, however, it is thought best to try to make the force hot, the result will generally be as shown in Fig. 13, in which the force, while a good fit for the die when hot, shrank in cooling. The shrinkage of the force may be evened up by distributing the poor fit in both directions and by favoring the worst places during the relieving. By doing a little driving over of the metal and with the aid of a few impressions struck cold, the force may be made passable. It takes, of course, a great deal more skill to make a

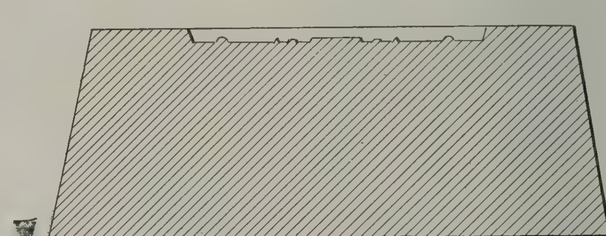

Fig. 9

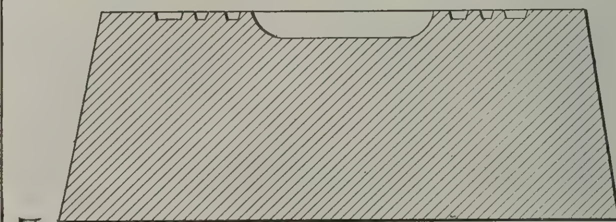

Fig. 10

Figs. 9 and 10. Types of Dies that can best be made by Use of Hubs

force cold than it does to fit it hot, but for designs resembling that in Fig. 11, the force should be made cold if possible.

Hardened Steel Forces

Without doubt, the majority of forces used for the ordinary run of brass and copper work are made of tool steel and hardened. This is necessary either on account of the toughness of the metal being worked, the thickness of the stock, or the large number of impressions to be produced.

For making a force of this character, Jessop's steel is considered the best. Other brands of steel on the market are,

however, used to good advantage, and no doubt the use of Jessop's steel may be traced to the fact that it has been a good, well-known steel for so many years back. In selecting the stock for a force of this kind, the shape of the blank piece of steel should depend upon the design of the die. While a good many force-makers simply cut off a piece of square or round steel from the bar, heat it, and strike it into the die,

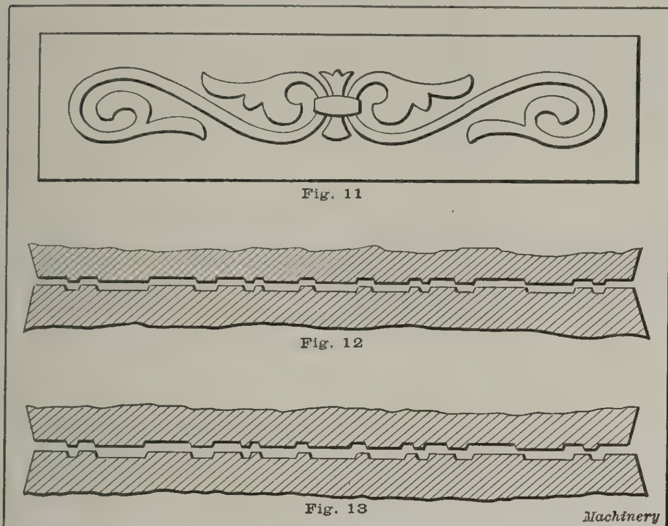

Fig. 11. Design of a Die whose Force can best be made Cold. Fig. 12. Illustrating the Way a Force must fit the Die. Fig. 13. Showing the Effect of Shrinkage

there are many cases when the force could be more quickly made by using a blank that had been carefully prepared by machining. Such an instance is illustrated in Figs. 14 and 15. In these two illustrations the impressions in the dies are alike. In Fig. 14, a flat block of steel is shown being struck into the die. The idea of this illustration is to bring out the fact that it is very difficult to get the center of the force "full" when using a blank of this shape, because the steel at the sides retards the central part of the blank from flowing into

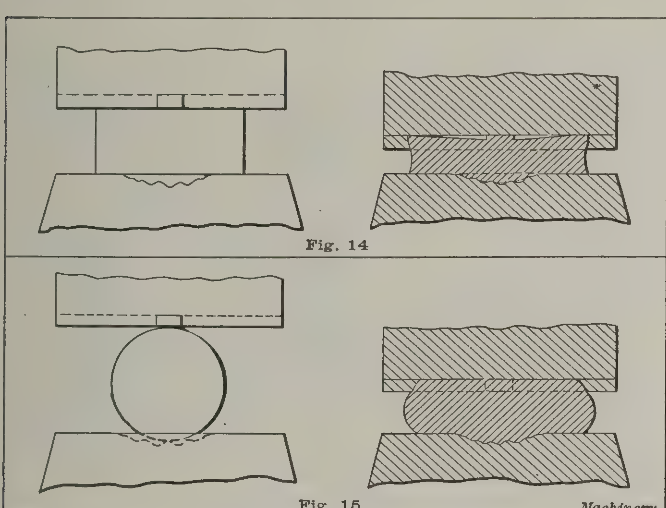

Fig. 14. Making a Force from a Flat Piece of Steel. Fig. 15. Making a Force from a Round Piece of Steel

the impression in the die. To overcome this tendency, the force-blank should be turned in a lathe so as to round the ends about as shown in Fig. 15. When a force-blank of this shape is struck into the die, the first part of the impression to be filled is the center. The last part of the impression to be filled, and the easiest, is the outside edge of the design.

In striking up a force, there are several essential points to be borne in mind. Among these the most important is to have the ways of the drop press adjusted so that there will be a minimum amount of shake to the hammer; the die should be solidly held in place by the poppet screws, care being taken to see that it rests on an even base on the bed of the press. The edges of the grooves in the pick-up should also be in good condition. After heating the blank to a bright red heat, it should at once be carried to the die and laid in the proper position and struck immediately. In striking, the heaviest blows should be struck at the beginning, picking the force up at the first blow if possible, as the hot steel should not be kept in contact with the face of the die any longer than possible. During the operation of striking up the force, the scale formed should be brushed off the die as rapidly as possible after each blow with a wire brush, or, better still, with an air blast. It is often necessary to use a second or even a third heat. If the design is fairly regular in outline and the impression does not have too much detail, the force may be struck into the die at short intervals while cooling in its position on

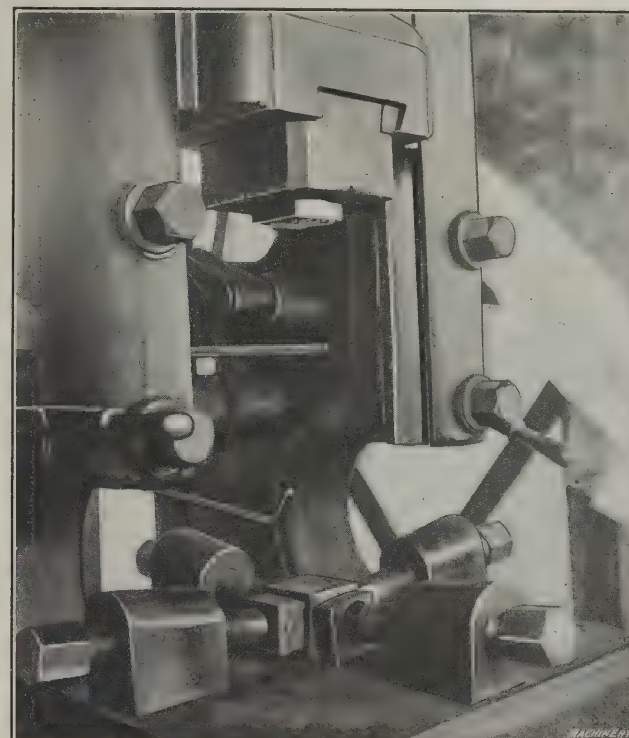

Fig. 16. Striking the Force in Cold

the pick-up, which will, in a measure, reduce the evils of shrinkage.

In order to make it possible to grip the force while working on the face, the first operation after striking consists in squaring up the edges in the shaper. It is usually necessary to anneal the force before it can be machined. At this time the machine work necessary for the relieving (which will be referred to later) can also be done. In addition, the ribs on the back of the force should be peened out to fit the slots in the pick-up, for, in cooling, these ribs have shrunk until they are a loose fit in the slots. In some shops forces are held in the

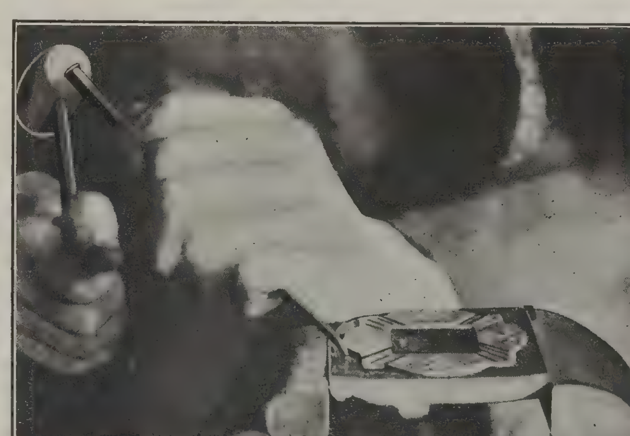

Fig. 17. Fitting and Relieving the Force—Chipping

pick-up from the back by means of screws engaging tapped holes in the force, but this is not good practice.

Fitting and Relieving the Force

The fitting of a force consists in overcoming the "misfit" caused by shrinkage. This is accomplished by "driving" over all necessary parts, "stretching" the design toward the ends, and chipping off at the inside of the design. When nearly

fitted, the force may be struck into the die cold a few times to properly shape the affected parts. Between these blows, it will usually be found that additional cutting or punching is necessary to facilitate the remainder of the work of fitting.

In order to produce good stampings from the force, certain parts of its face must be relieved. The amount of this relief depends upon the design, and especially upon the thickness of the metal being stamped. The first step in the relieving of the force consists in cutting away the metal from the background of the face of the force around the design to a depth slightly in excess of the thickness of the metal. This operation may be, and usually is, partly accomplished by machining in the shaper or lathe, going as close to the edge of the design as possible without running into it. In removing this metal, it is, of course, necessary to take the same depth from the interior of the design of a piece like that shown at *Q*, Fig. 1, as from the outside, so that the force will not strike hard at

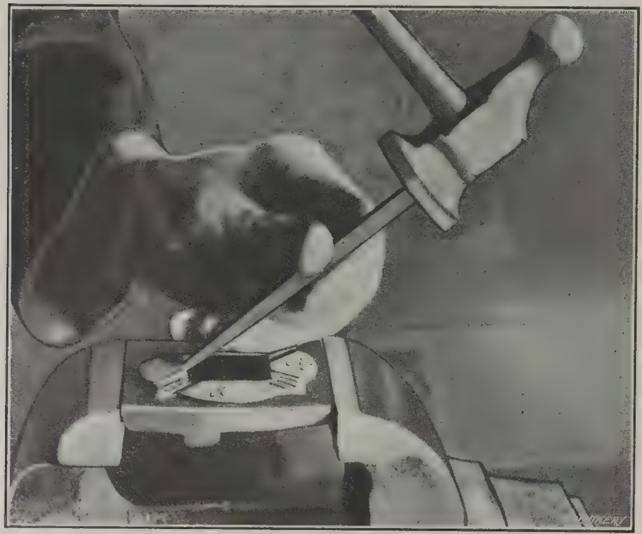

Fig. 18. Fitting and Relieving the Force—Driving up

the center. On large rings, etc., the interior of the design can best be relieved in the lathe.

The next step consists in chipping away the remainder of the metal up to the edge of the design as illustrated in Fig. 17. This being done, the metal must be removed from any straight portions of the design of the force. This will be more clearly understood by referring to Fig. 19—especially the section shown at *B*. If, on a design of this character, the force is not relieved on the sides, which in this case are very nearly straight, the effect of the blow upon the metal will thin the stock at the points *F*, *G*, *H*, and *I*, in the manner shown. To overcome such troubles, the force must be relieved at these and similar portions so as to produce a stamping of even thickness

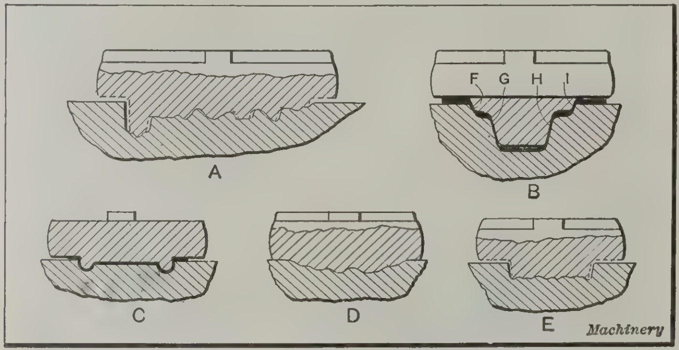

Fig. 19. Illustrating Points about Relieving Forces

as shown at *C*. In this view it will be seen that the two ribs on the force are very much thinner than the corresponding impressions in the die, due to the fact that they have been relieved. At *A* is shown a force set into the impression of the die after having been properly relieved. It may be thought strange that the face of the force is not also relieved, but it must be remembered that it is the face of the design that receives the full effect of the blow, and all stock possible should be left on this part of the force. In order to leave the face of the force as high as possible, the stock is often punched or driven up from the sides, thereby forcing the face of the force higher than it formerly was. Occasionally there is a force which requires no relieving. Such an instance is shown at *D*, in which the design could be struck up without relieving the force at all, unless it be very slightly around the background outside of the design. At *E* is shown another instance where the sides must be relieved to permit the force to push the metal into the bottom of the design and act with the full blow upon the impression at this part of the die.

The most difficult parts of a force to bring up are "matted" backgrounds, like those shown on parts *I* and *J*, Fig. 1. The detail is here too fine to be brought up by punches. The best way to take care of such places is to clean all scale from the surface and strike the force into the die, cold, several times. In stamping thin metal, the matted portions will not "come up" unless the force is perfectly fitted at these points. Moreover, it is seldom advisable to lower a matted background in relieving, for all possible pressure is needed to bring up the matting to the best advantage.

Hardening the Force

After the force had been fitted and relieved and a few stampings struck up to make sure that the work has been done right, the force may be hardened. The temper of the force should be drawn to a dark straw color. If there is little detail to the design it will be best to draw the temper to a purple color, especially if the metal being worked is hard, thereby lessening the risk of breaking the force while in use.

All of the presses shown were made by the Standard Machinery Co., Providence, R. I., and were photographed through the courtesy of Philip Vester & Brother, and George Parks Co., both of Providence, R. I.

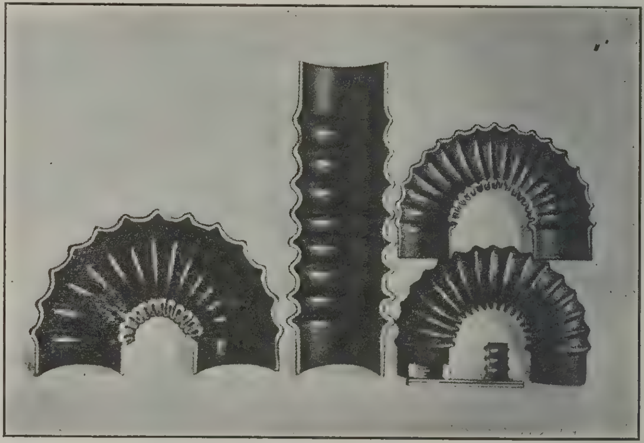
ELASTIC CORRUGATED TUBES

The accompanying illustration from *Engineering* shows a form of corrugated tube which has been designed for expansion joints, heating- and smoke-tubes, superheaters, condensers, etc., where the tubes are subjected to wide ranges of temperature. These tubes, instead of having a spiral corrugation, frequently seen in tubes made in the past, have corrugations parallel to one another. This method of construction is adapted to tubes



Some Examples of Elastic Corrugated Tubes

made in a great range of sizes. Owing to the construction the tubes can be bent to a very small radius. They are manufactured with an inside diameter of from 1⅜ to 18 inches. The process of manufacture is claimed to be such that after pressing out the corrugations, the pipe retains its exact original internal diameter, and there is an absolute uniform thickness of the metal in all the parts.

The chief advantages claimed for these pipes are: That they are of great utility in all cases where the expansion or vibration of pipes has to be taken into consideration; that they are valuable as boiler tubes because of the increased heating surface and because they relieve the strain due to expansion and contraction; that they are well adapted for superheaters owing to the whirling motion given to the steam; that they are exceedingly well fitted for expansion joints; that they take up much less space than bends of ordinary piping, because the bends can be made much shorter; and that the stress on the flanges and connections is greatly reduced.

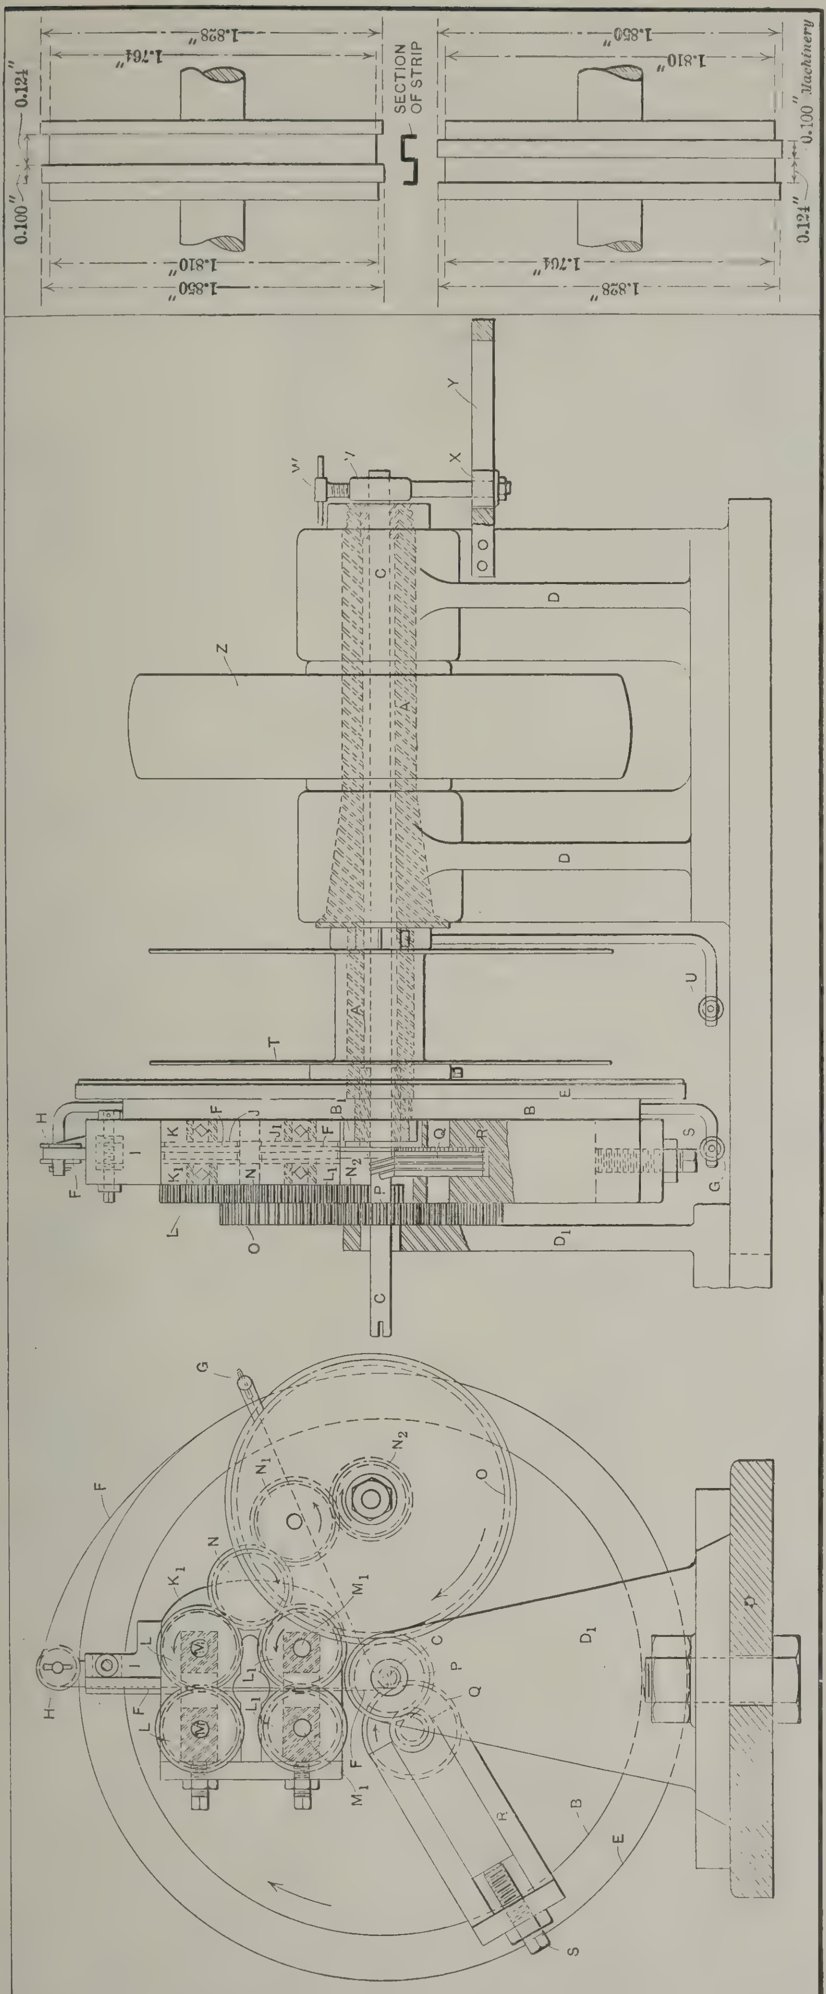


Fig. 2. Forming Rolls

Fig. 1. Details of the Tube Forming Machine

MACHINE FOR FORMING FLEXIBLE TUBING

By RICHARD TOEPLITZ*

Flexible tubing is extensively used in the automobile industry in connection with horns and speedometers, etc. The usual method of making this tubing is to form a length of ribbon stock and turn it over a revolving mandrel, at the same time making it airproof by running an asbestos cord between the single turns. This method has several disadvantages, the most prominent of which are the difficulty of freeing the finished tubing from the mandrel and the starting of a new piece of stock.

Briefly stated, the machine to be described in the following consists of a stationary mandrel supported by the frame of the machine, and a faceplate, which carries the forming rolls and the ribbon stock for the tubing, and which revolves on the mandrel. The formed tubing is pushed from the end of the mandrel as soon as formed, and is received by a special pair of rolls whose purpose it is to prevent the tubing from twisting. Referring to the illustrations, Fig. 1 shows the details of the tube forming machine; Fig. 2 shows the forming rolls together with a section of the formed stock; Fig. 3 shows a length of flexible tubing; and Fig. 4, the rolls which receive the tubing as it leaves the forming machine.

The construction of the forming machine, Fig. 1, is as follows: On the main-shaft *A* of the machine is mounted the faceplate *B*. The main-shaft is hollow throughout its entire length to receive the mandrel *C*, which is supported by bushings at both ends. Shaft *A* runs in suitable bearings located in the main casting or frame *D* of the machine. On the reverse side of faceplate *B* is located a case *E*, which contains the ribbon stock from which the tubing is formed. This ribbon stock comes in the form of rolls and provision is made for readily replacing these rolls as they are used up. The ribbon stock *F* leaves case *E*, and running over roller *H* passes through bracket *I* to the forming rolls *J* and J_1. These forming rolls are an important factor in the operation of tube making, and are shown in detail in Fig. 2. Referring to this latter illustration, in which the rolls are shown approximately full size, it will be seen that the rolls are in reality dies, running together so that the projections on the one roll push the stock into depressions on the corresponding roll. The brass for which this set of rolls was made was 0.012 inch thick and 19/64 inch wide. The rolls are made of tool steel and hardened.

Returning to Fig. 1, the shafts *M* and M_1, upon which the forming rolls run, are mounted in suitable boxes which, in turn, are fitted in slides in the side plates *K* and K_1. By means of adjusting screws and check nuts, the rolls are kept in proper relation to each other, varying, of course, with the thickness of metal being formed. Keyed to the outer ends of shafts *M* and M_1 are gears *L* and L_1. These gears are cut with 29 teeth of 16 pitch, and both pairs are driven by means of gears *N*, N_1 and N_2, which also have 29 teeth. Gear N_2 is permanently attached to gear *O*, which

*Address: 416 East 83rd St., New York City.

has 105 teeth of 16 pitch. Gear O is mounted, together with the other mechanism previously described, upon faceplate B, and is driven by contact with the stationary gear P held upon the frame of the machine.

The face of the grooved roller Q, which corresponds exactly with the shape of the strip, is mounted in fixture R which is located on faceplate B, and is adjusted with relation to the center mandrel C by means of set-screw S. The function of this roller is to roll the stock into its circular form after it has left the forming rolls. Reel T is mounted on shaft A behind case E which carries the ribbon stock. A supply of asbestos cord is contained on this reel, the free end of which passes over guide roller U to guide roller G, from which it runs to the mandrel as may be seen in the front elevation view of Fig. 1. This cord is wound between the single turns of the metal and its function is to make the joints of the tubing air- and liquid-tight.

As before stated, mandrel C runs completely through the main shaft A. At the rear end of the machine a holder V is clamped to it by clamping screw W. At the lower end of this holder is mounted roll X which is free to turn. This roll engages a slot in bracket Y that is bolted to the machine at this point. The object of this holder is to prevent the mandrel from turning while the tubing is being formed, but it does not interfere with the longitudinal travel of the arbor within the limits of the slot in bracket Y.

Operation of the Machine

The machine is operated by starting a coil of brass ribbon over pulley H down through the forming rolls J and J_1. At the same time, the end of the asbestos cord is run over rolls U and G down to the mandrel C. Mandrel C is moved to its extreme "in" position, and the end of the formed ribbon is passed through the slot in the end of the mandrel. The end of the asbestos cord is also caught in this slot. The machine is turned about two revolutions by hand and care taken that the brass ribbon and asbestos cord are properly coiled; then the grooved roller Q, the right-hand side of which feeds into the formed strip of stock, is pressed against the tube and locked by the tension screw. The extreme right-hand ridge on this roll is very finely corrugated to assist in driving the brass strip, and, moreover, this roll is keyed to the same shaft as a gear which meshes with the stationary gear P. The action of this

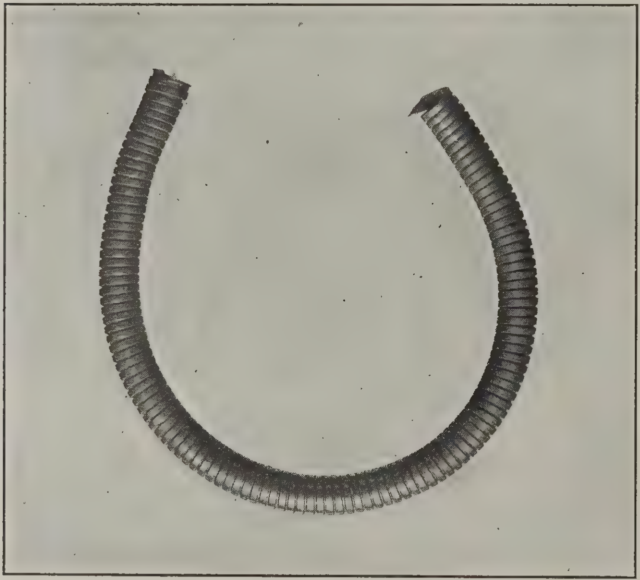

Fig. 3. Flexible Tubing

roller moves the tubing and mandrel forward until the holder V on the rear end of the mandrel touches the end of the slot in Y; then the machine is stopped and the end of the strip is removed from the slot in the mandrel; the mandrel is then pulled back, it being held from turning by means of holder V. The machine can now be run continuously, as long as the coil of stock in case E lasts. As the faceplate and shaft turn about the mandrel C, it is obvious that the entire chain of gearing, forming rolls and grooved roll Q revolve with the shaft about the stationary gear P.

It is very important that the stock should be drawn through the forming rolls just fast enough to be taken up completely as it turns about the mandrel C; thus it will be very apparent that if stock which is thicker or thinner than 0.012 inch be used, or if the diameter of the tubing being formed is larger or smaller than in this instance, the gearing must be changed by substituting larger or smaller gears.

It has been found advantageous to guide the tube around the pulley A, Fig. 4, and to hold the tubing in place by roller B so that it cannot twist as it leaves the machine. This pulley A, being mounted on a shaft C upon the outer end of which is a

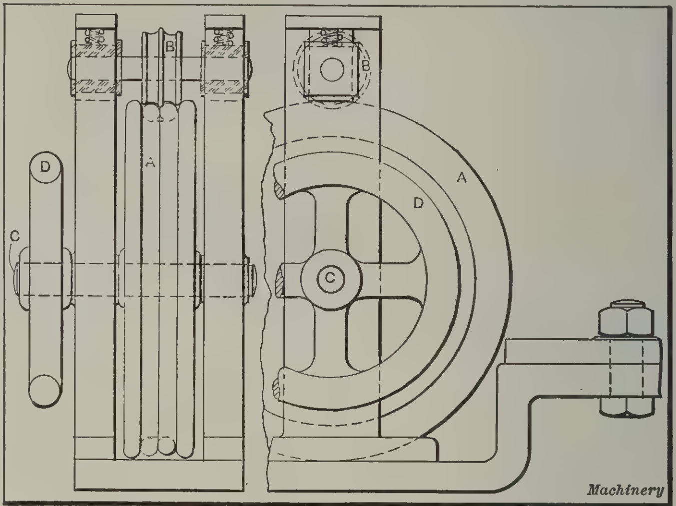

Fig. 4. Roller for receiving the Tubing after it leaves the Machine

handwheel D, enables the operator to coil up the tube as it is being formed.

After the supply of ribbon in case E has been exhausted, it may be replenished by moving back stand D_1, Fig. 1, and withdrawing the grooved roller Q. But B_1, on the end of main-shaft A, is then removed and plate B lifted off, thus making it possible to slip in a new coil of brass ribbon. The asbestos will last for several coils of brass. Should tubing of smaller or greater diameter be required, it is only necessary to remove the tube bushings at the ends of mandrel C, put the proper size mandrel and corresponding bushings in place, and change the gearing so that the speed at which the brass strip travels is equal to one turn around the mandrel for each revolution of the machine.

This machine, which is in successful operation, has required no repairs and is turning out an average of 225 pounds of tubing per day. A roll of ribbon weighing in the vicinity of 12 pounds will produce a continuous length of tubing about 70 feet long. The machine is run at a rate of 225 R. P. M. and at this speed will produce 30 inches of tubing per minute.

HEAT TREATMENT FOR VANADIUM TOOL STEEL

The George Hamilton Co., Providence, R. I., maker of figured rolls for rings, galleries, hubs, dies and tools, recommends the following treatment for vanadium tool steel in *American Vanadium Facts.* The brand "Hawk H" hardens very well in oil, water, brine, or sulphuric acid, but oil is preferred for the best results. In oil hardening, heat to between 1450 and 1550 degrees F. (dull cherry red) and then quench in oil. In hardening for toughness, draw to about 425 degrees F. (very faint yellow). In water hardening, heat to about 1400 degrees F. to get the best results.

* * *

TIME LOST WAITING FOR TRAINS

The traveler in the West who would go from town to town on local railway trains should count on wasting about one hour waiting for each train—but not always. If he could be sure that the trains would always be late he could allow for it and conserve his time, but, of course, if he does so the train he wants to take is likely to be on time. The annual loss of time of the traveling public through defective train service is enormous, and it is a serious indictment of railway management that such conditions generally prevail.

LOCATING JIG BUTTONS

By H. P. FAIRFIELD*

The use of jig buttons for accurately locating centers in the body or frame of drill jigs is not a new method, but perhaps some of the readers of MACHINERY have never seen it applied. It is for these that the accompanying halftones are presented. The reasons for using jig buttons and the general subject of jig and fixture making are excellently treated in MACHINERY'S Reference Books Nos. 3, 41, 42, and 43, and these are freely used by the classes in jig and fixture construction at the Worcester Polytechnic Institute. It is probable that by no other method used in the average shop, can centers for jig

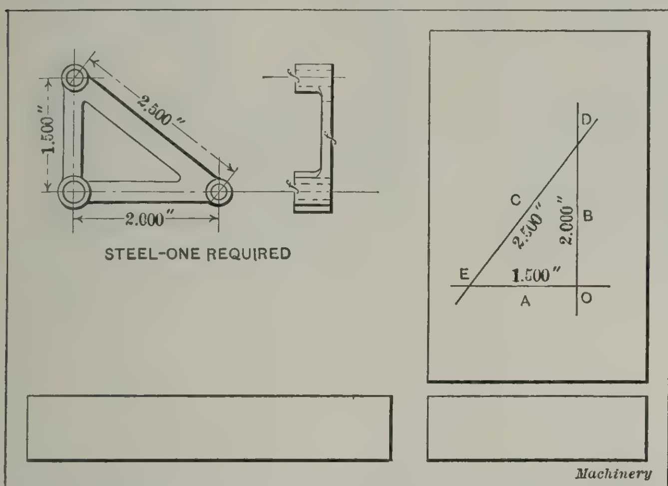

Fig. 1. Piece to be drilled, and Jig Plate to be laid out

bushings be so accurately located as by means of these jig buttons.† The buttons can be placed so accurately to the true location that the ordinary shop measuring and testing instruments can detect no errors; and expert jig-makers can bore the holes and can place the drill bushings so nicely that the inspection department can find no errors. In the shops of one firm with which the writer is familiar certain jigs are invariably rejected by the inspector if any error can be found. In most jig construction, however, certain tolerances are allowed.

The method of setting jig buttons described in the following, is typical of the common practice of toolmakers. To

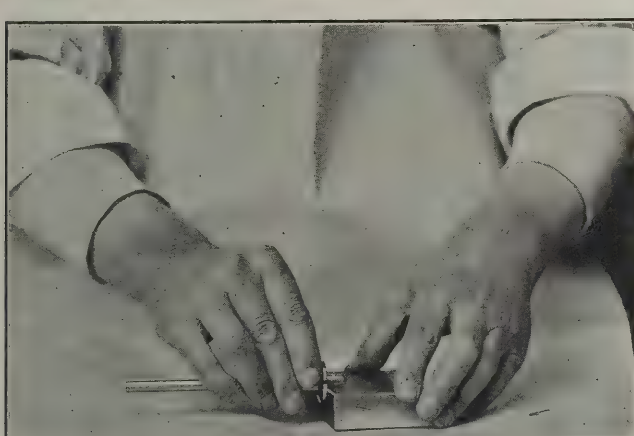

Fig. 2. First Step in Laying-out the Jig Plate

illustrate the operation it was thought best to choose as simple an example as possible, and, therefore, the buttons are located upon the cover plate of a simple drill jig used to drill the holes in the piece shown in the line-engraving Fig. 1. The lay-out of the length of the sides to insure a right angle at *O* is very simple, as the sides *A*, *B*, and *C* must be to each other as 3, 4, and 5; or, in other words, if the relations of the sides to each other are as 3, 4, and 5, angle *O* will be a right angle; because the square of the base plus the square of the perpendicular in a right-angled triangle is equal to the square of the hypotenuse. The halftones show, step by step, how to locate the buttons at the exact points desired. In the problem selected not only must the buttons be at the points shown, but those at *O* and *D* must be in a line exactly parallel to the side of the plate on which they are to be set.

* Address: Worcester Polytechnic Institute, Worcester, Mass.
† See MACHINERY, April, 1912: "A New System for Locating Holes to be Bored on the Milling Machine."

While different toolmakers may proceed in different ways, the order of progression here followed represents good average practice. Assume that the cover plate is planed to shape.

Fig. 3. Second Step in Laying-out Jig Plate

The portion upon which the buttons are to be located can be prepared for a lay-out by wetting with a solution of copper sulphate (blue vitriol). As this evaporates, a thin deposit of copper is left upon the surface of the plate; the finest line scratched through this upon the surface of the plate is very distinct, and the points of intersection of the lines can also

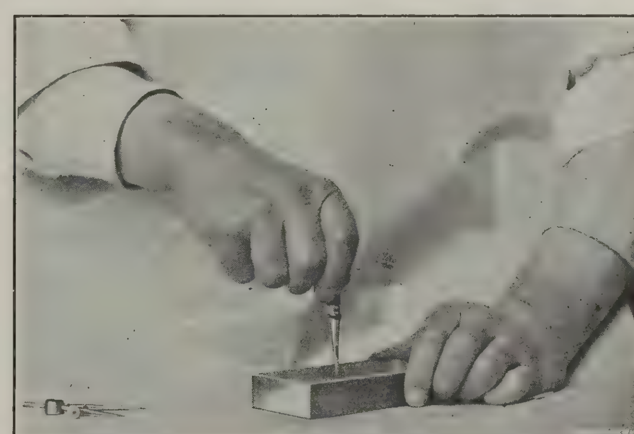

Fig. 4. Prick-punching the Intersections of the Lines

be easily noted. Now, set the scratch-gage to the distance that the line *OD*, Fig. 1, is to be from the edge of the plate, and gage or scribe a fine line parallel to the working edge of the plate with the tool held as shown in Fig. 2. This line is the line *OD* of the triangle. Next, place the beam of a square firmly against the base side of the plate and slide the blade

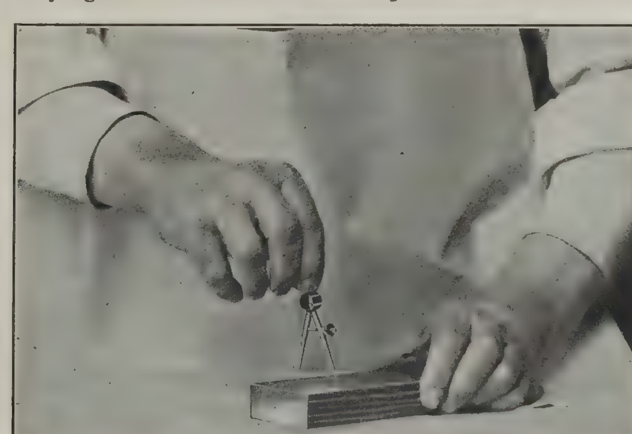

Fig. 5. Laying-out Location of Center by the Aid of Dividers

along the plate until it coincides with the center *O*. Using a fine pointed scriber, scribe a line at right angles to *OD*, as shown in Fig. 3. This is the line *OE* of our right-angled triangle. At the intersection of *OD* and *OE*, at point *O*, locate a light center-punch mark as shown in Fig. 4. If a magnifier

such as jewelers employ is used, this light prick-punch mark can be located very accurately, but as the buttons are subsequently located by independent means any high degree of accuracy in the preliminary location is not necessary. The writer uses the automatic center-punch shown in Fig. 4 for all lay-outs.

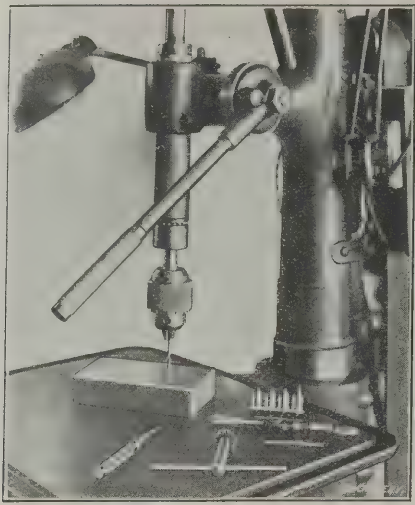

Fig. 6. Drilling for the Button Screw

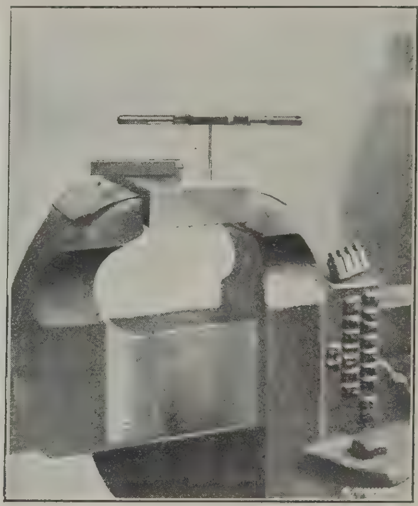

Fig. 7. Tapping for the Button Screw

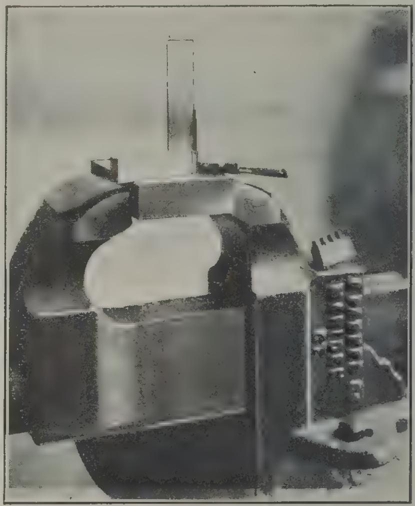

Fig. 8. "Squaring-up" the Tap

Next, set a pair of toolmakers' dividers to the length of line *OE*, and with *O* as a center scribe a short arc across *OE*, as shown in Fig. 5. If the points of the dividers are kept sharp, this line, like the preceding ones, will show sharply against the copper coating. With the center-punch lightly prick a center at the point of intersection of line *OE* and the short arc just scribed, as shown in Fig. 4. If an adjustable automatic center-punch is used, the center points can be as lightly pricked as the toolmaker wishes. The location of point *D* on the line *OD* is prick-punched in a manner similar to that of the location of *E*. Deepen and enlarge the prick-punched centers sufficiently to enter the point of the tap drill, and drill for the button screws as shown in Fig. 6. Tap the drilled hole for the button screws (see Fig. 7), carefully testing to insure perfect "squareness" with the surface upon which the buttons are to be clamped, as shown in Fig. 8. If this is not carefully done, the buttons cannot be so easily and accurately adjusted.

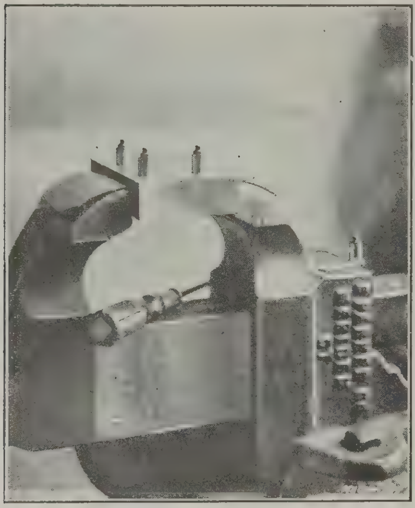

Fig. 9. The Buttons in Place

Fig. 10. Accurately Adjusting the Buttons with relation to the Side of the Plate

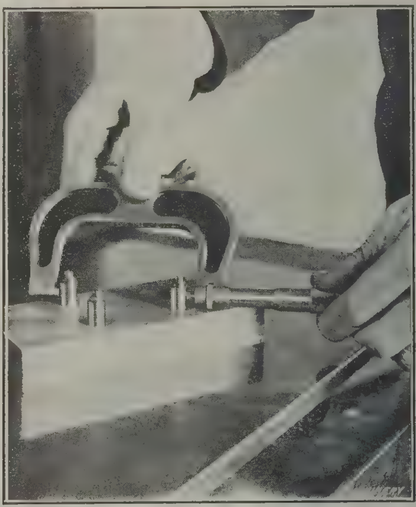

Fig. 11. Using a Micrometer for the Adjustment of the Buttons

Clamp the buttons in their approximate positions by means of the button screws, as in Fig. 9. In doing this, remember that at this stage these positions are only approximate, and that the tension placed upon the screws must admit of further adjustment. Adjust the buttons by micrometer to the desired distance from the edge or side of the plate, as shown in Fig. 10. Note that the micrometer reading from the edge of the plate, when made as shown in this halftone, is as much greater than

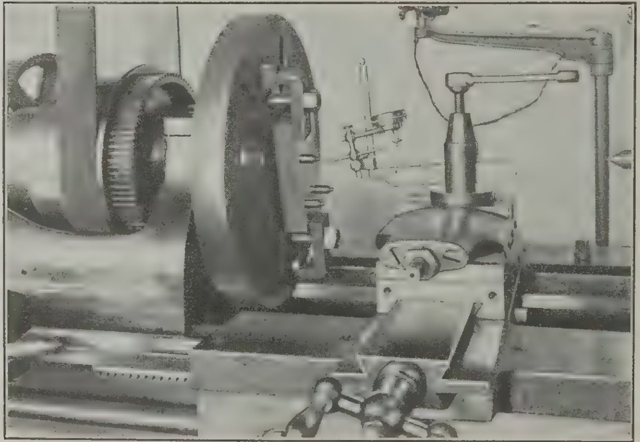

Fig. 12. Indicating the Buttons on the Lathe

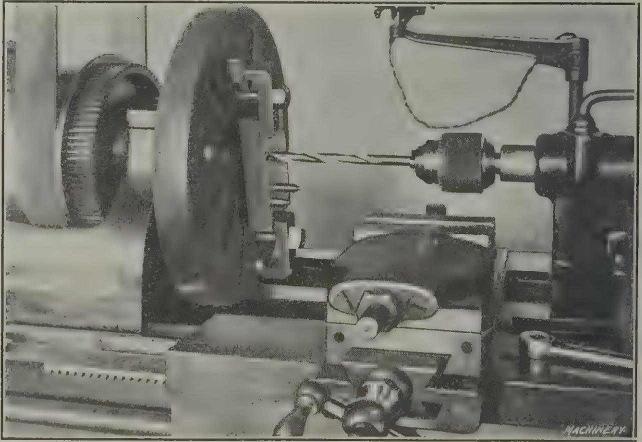

Fig. 13. Drilling the Bushing Holes

the distance from the center of the hole to be bored to the edge of the plate, as the sum of the thickness of the straightedge and the radius of the button. Adjust the buttons correctly with regard to the distance *OD* by micrometer and shift the button at *E* until the center to center distances *OE* and *DE* are those designated. It is possible, in this manner, to locate the buttons where desired within an error too small for the micrometer to indicate. If the holes to be bushed can be bored concentric with the buttons as located, the greatest accuracy can be obtained by this method. While the writer uses micrometers for all possible measurements, the proper use of a high-grade height-gage will assist the toolmaker in many cases. The surface plate used must then have an especially smooth surface, and it is a delicate job to determine just when contact between the surface of the button and the feeler is made.

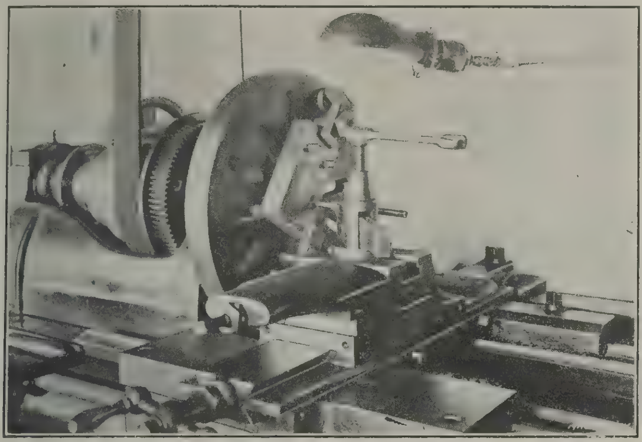

Fig. 14. Boring the Bushing Holes

Instead of depending upon "feel," the toolmaker often uses some thin pigment on either surface, and indicates contact by sight rather than by "feel."

Next, clamp the cover plate, which carries the buttons previously located, upon a lathe faceplate. The clamping should be sufficiently firm to retain the position and yet allow adjustment. Using a copper or lead hammer, adjust the cover plate upon the faceplate until one of the buttons indicates "dead true." Fig. 12 shows one of several indicators designed for this purpose. After the faceplate is screwed firmly upon the nose of the spindle, and before mounting the work upon it, its face surface should be indicated, and if appreciably out of true, a light finish cut with a lathe tool should be made, starting at the center and feeding to the outer edge. This is commonly known as "truing up the faceplate."

Fig. 15. Tools used by the Jig-maker

After the button is indicated dead true, it is removed and the bushing hole drilled to approximately the desired size, as in Fig. 13. Where a suitable milling machine is accessible, the plate can be drilled and bored in that machine. In fact, this job can be done upon any machine in which it is possible to indicate the button concentric with the center line of the spindle. Then, for boring the hole (see Fig. 14), use an inside boring tool with a keen cutting edge to avoid error due to its springing. An inside boring tool ground to correct clearance and cutting angles, properly set and run at the correct speed, will turn out a hole that will indicate dead true. If the work when clamped to the faceplate throws it out of balance, a weight should be clamped to the "light" side, sufficient to restore the balance. Fig. 15 shows some of the tools needed by the toolmaker. In closing, the writer offers no defense for the button method of locating holes for drill bushings, as none is needed, but submits it to young toolmakers as probably the most accurate method for the purpose.

* * *

STRENGTH OF STEEL TUBES UNDER INTERNAL FLUID PRESSURE*

In order to arrive at some definite conclusion as to the formulas which ought to be used for calculating the strength of tubes, pipes, and cylinders subjected to internal fluid pressure, a number of different formulas were investigated and compared. These formulas were the so-called "common" formulas generally found in books on mechanics and based directly on the tensile strength of the material, and the formulas given by Barlow, Lamé, Clavarino and Birnie. It was found that of the five formulas considered, that of Barlow is the best suited for all ordinary calculations pertaining to the bursting strength of commercial tubes, pipes, and cylinders. The theoretical error on the side of safety resulting from its use will generally not exceed the actual combined error on the side of danger resulting from the use of either Birnie's or Clavarino's formulas. This is true, at least up to the yield point of the material, for any ratio of thickness of wall to outside diameter less than 0.3. In this respect, Barlow's formula is superior to the common approximate formula which gives errors that are entirely too large on the side of danger for very thick walls.

Barlow's formula assumes that because of the elasticity of the material, the different circumferential fibers will have their diameters increased in such a manner as to keep the area of cross-section constant, and that the length of the tube is unaltered by the internal fluid pressure. As neither of these assumptions is theoretically correct, the formula, of course, gives only approximate results; but, as already mentioned, the errors are on the side of safety.

Assume that

D = outside diameter in inches,

t = average thickness of wall in inches,

p = internal fluid pressure in pounds per square inch,

f = working or safe fiber stress in pounds per square inch.

The Barlow formula is then as follows:

$$\frac{p}{f} = \frac{2t}{D}, \text{ from which}$$

$$p = \frac{2ft}{D};\ t = \frac{Dp}{2f};\ f = \frac{Dp}{2t}$$

It should be observed that while the Barlow formula is similar in form to the common formula, it gives results quite different when applied to tubes and pipes having walls of considerable thickness. This is due to the fact that the Barlow formula is expressed in terms of the outside diameter, whereas the common formula is expressed in terms of the inside diameter.

The average ultimate tensile strength of seamless steel tubes may be assumed at 60,000 pounds per square inch; that for butt-welded steel pipe at 40,000; that for lap-welded steel pipe at 50,000; and that for wrought-iron pipe at 28,000 pounds per square inch.

The investigations undertaken also indicated that if seamless steel tubes are assumed to have a strength of 100 per cent, butt-welded steel pipe has a comparative strength of 73 per cent, and lap-welded steel pipe of 92 per cent. From this it will be seen that the strength of a butt-weld is only about 80 per cent of that of a lap-weld. The relative strengths of wrought-iron and steel pipe are as follows: Butt-welded wrought-iron pipe has 70 per cent of the strength of similar butt-welded steel pipe, and lap-welded wrought-iron pipe has 57 per cent of the strength of similar lap-welded steel pipe.

* Abstract of a paper by Mr. Reid T. Stewart, of Pittsburg, Pa., read before the American Society of Mechanical Engineers.

TURNING CHILLED IRON ROLLS*

By F. B. JACOBS†

Ordinary soft steel which contains 0.25 per cent carbon and up is rolled from a steel billet in a mill generally called a finishing mill. Different rolling mills have different methods of "setting-up" finishing mills; the following method is often used for small mills, say twelve-inch mills, or those where the rolls are twelve inches in diameter. First there are three roughing rolls. These are set one above another and are made from steel castings with 0.70 to 1.20 per cent carbon. Next there are three pony rolls set the same as the roughing rolls and made from the same quality of steel. The next set consists of the so-called "strand rolls," which are set "three high" in the same manner as the roughing and pony rolls. Strand rolls are made of ordinary cast iron for rolling flat stock, and of chilled iron for rolling rounds and squares. After the strand rolls come two edging rolls, set one above the other, these being made of chilled iron, and finally come the two finishing rolls which are relied upon to finish the bar stock to the correct dimensions. These rolls are also made of chilled iron.

All the rolls have grooves turned in them termed "passes," the passes in the roughing rolls being a little smaller than the billet to be rolled. Down through the mill the passes decrease in size to the finishing rolls, where the passes are just a trifle larger than the size of the finished bar. The frames or housings that carry the rolls are set side by side, the wobblers or ends of the rolls being connected in the same manner as the two rolls shown in the roll lathe in Fig. 1. The mill is generally driven by a direct-connected steam engine, steam being considered the most economical means of driving the mill, as it is generated by the waste heat from the furnaces.

The process of rolling steel is quite simple and can be briefly described as follows: One roller starts the billet of white-hot steel through the roughing rolls; a roller on the opposite side of the mill grabs it with a pair of heavy tongs and starts it back. In this manner it is sent through all the sets of rolls, and after coming from the finishing rolls it is laid out flat to cool. As may be imagined, rolling is a dangerous occupation; it calls for a sure hand, a rapid eye, and great strength. In spite of reasonable precautions, serious accidents sometimes happen. Rolling is, without a doubt, the best paying of all the mechanical pursuits, good rollers earning from eight to fifteen dollars* a day, depending on the locality, and the quality of the material worked on. It takes at least six years of hard work and close attention to become an expert roller.

The constant rolling of hot metal soon wears the passes of the rolls, which makes it necessary to re-finish them. The turning of new rolls and the re-dressing of worn ones is, in itself, a trade calling for skill and, especially, patience. A roll lathe, as shown in Fig. 1, differs widely from the ordinary engine lathe, as it has neither carriage, ways nor cross-slide, the tools being clamped securely to the tool bed, directly in front of the roll to be turned. The tools are set up to the work by means of screws working through blocks set in the tool bed. Roll lathes are generally triple-geared, and the roll is always located from its necks or journals while turning the face and passes, this being necessary to avoid chattering.

In Fig. 2 are shown several roll turning tools. These are made of a good quality of tool steel, hardened in brine and drawn only enough to relieve the internal strains. The tools marked *A* are used in turning passes for square stock. The tools used for roughing and finishing the face of rolls are shown at *B*. The tools marked *C* are used in turning passes for angle-iron rolling. The shape of these tools is worked out by hand to fit the templets shown at *D*. The shape of tool generally used in roughing cast-iron rolls is shown at *E*. When the tools require grinding it is done by hand as shown in Fig. 3, the wheel used in this case being "Aloxite," 16 inches in diameter, 3-inch face, 24 grit, H grade, D 333 bond.

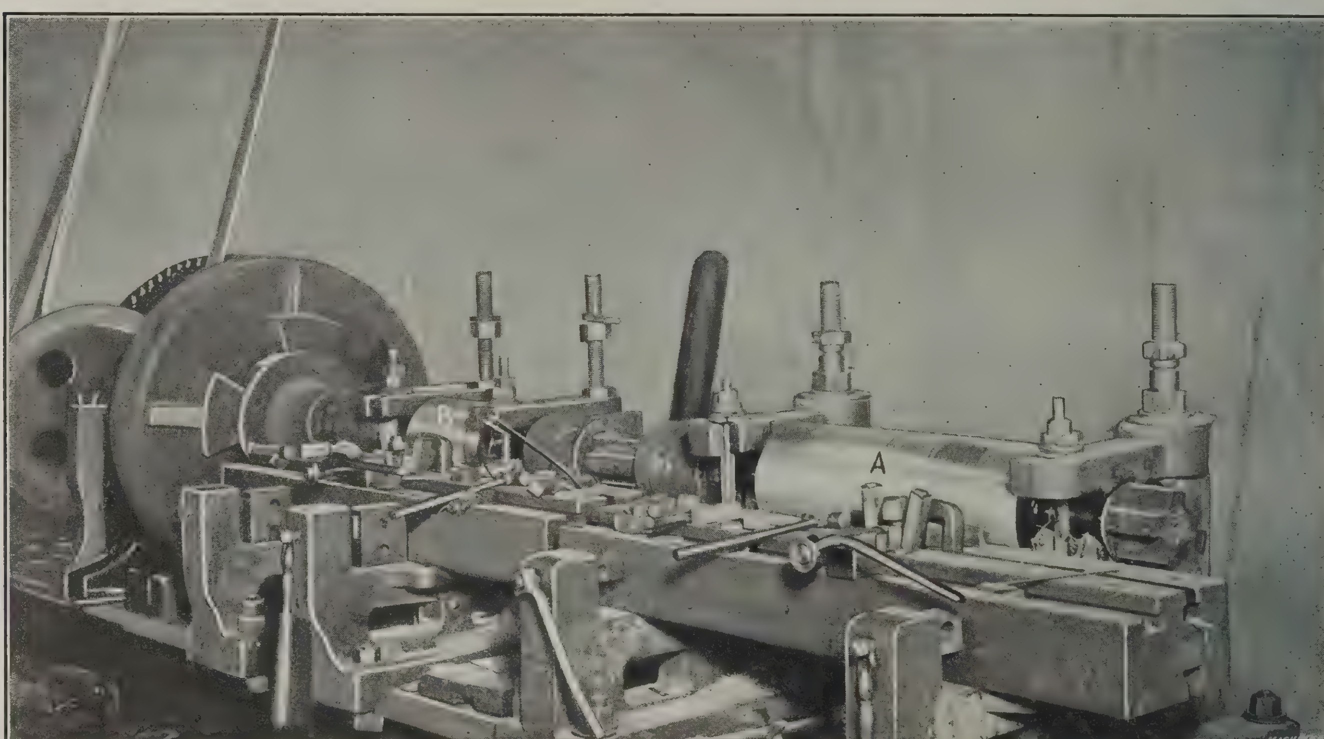

Fig. 1. A Roll Turning Lathe with Work in Place

The operation of roughing a strand roll is shown at *A*, Fig. 1. This roll is 26 inches long and 9½ inches in diameter. A chip 6 inches long is taken at a time, the tool being fed directly to the work. The time for roughing this roll, removing ⅝ inch of stock, is ten hours. To many this may seem rather slow work; however, it must be taken into consideration that the material is chilled iron, which is extremely hard and therefore calls for a slow speed—in this case one revolution in 55 seconds.

The roll shown at *B*, Fig. 1, is a small finishing roll for T-iron. The grooves or passes being turned are 3/16 inch wide and ¾ inch deep. The tool used in this case has the appearance

* See MACHINERY, September, 1895. "Roll Lathes and Roll Turning."

† Address: Care of Carborundum Co., 826 Arch St., Philadelphia, Pa.

* Wages paid rollers in the Pittsburg district run from $8 to $15 a day depending on the material rolled. The rollers are paid according to the tonnage they turn out, the $15 rate being earned in the large plate mills where the tonnage production is heavy. In sheet mills, tin-plate mills and bar mills, the rollers get from $10 to $12 a day. In hoop mills and other mills rolling light materials the rollers make from $8 to $10 a day. In union mills the wage scale is set on all materials by the Amalgamated Association and in the non-union mills the wage scale runs closely parallel to the union scale. Of course the stated wages are earned only when the day or night run is made without interruption from breakdowns or other causes.—EDITOR.

of an ordinary cutting-off tool. Let the average machinist consider for a moment what it means to cut grooves of the above dimensions in chilled iron, and he will realize why the roll turner has to have plenty of patience. It is quite necessary that the passes in all finishing rolls be of the required dimensions, and that the corners be square. In Fig. 4 is shown a large chilled iron strand roll, 48 inches long and 18½ inches in diameter. The time for roughing this roll, removing ¼ inch, was ten hours, the roll being revolved at one revolution in one minute and forty seconds. Another ten hours was consumed in turning five passes for 1¼ inch square stock. The photographs and data for this article were obtained in one of the smaller rolling mills that are to be found scattered all over the Middle West, and give a fair idea of the time required to turn chilled iron rolls under ordinary conditions.

When we stop to consider the fact that in the majority of the industries using chilled rolls they are invariably finished by grinding, either on a regular roll grinding machine, or on a heavy plain grinding machine of the type embodying a stationary platen and a traveling wheel carriage, the question naturally arises, why do not the rolling mills rough and finish the straight portions of their rolls by grinding? There are several reasons why they do not, one being that the roll turner who has had no experience at grinding is prejudiced against any method of finishing rolls other than the time-honored method of turning. He also argues that as it is necessary to have a roll lathe for turning the passes, it is more economical to finish the face of the roll by turning, the face and passes thus being finished at one setting of the roll. With the roll shown in Fig. 4 the time for roughing the body, as before stated, was ten hours, the amount of stock removed being approximately 384 cubic inches, or 38.4 cubic inches per hour.

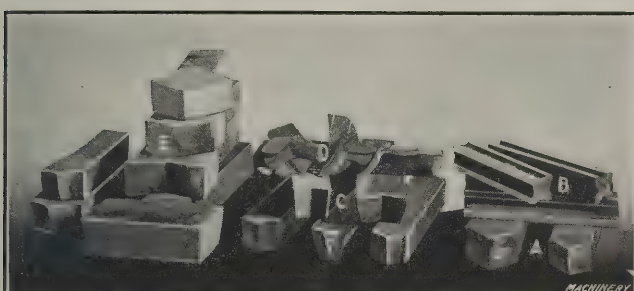

Fig. 2. Tools used in Turning Chilled Cast-iron Rolls

Some time ago the writer witnessed a very interesting roll-grinding operation on a heavy plain cylindrical grinding machine. The roll in this case was of chilled iron 32 inches long and 32⅛ inches in diameter. The grinding time for removing ⅛ inch from this roll was four hours. As approximately 192 cubic inches was removed, this equalled 48 cubic inches per hour. This work was done with a carborundum wheel 24 inches in diameter, 2-inch face, 403 grit, P grade, run at a speed of 950 R. P. M. The work speed was 6 R. P. M., and the advance of the traverse feed 1¼ inch for each revolution of the work. The finish left was superior to the finish left by the process of turning.

Fig. 3. Grinding the Tools for Roll Turning

From these data it is evident that the grinding machine shows an increase of 25 per cent in the amount of stock removed in a given time. Another point in favor of the grinding machine is that the wages of a skilled roll turner are about 30 per cent higher than the wages of a grinding machine operator. From this it would appear that the most economical method of finishing the straight portions of rolls used in rolling bar stock would be by the use of a grinding machine equipped with the proper wheels.

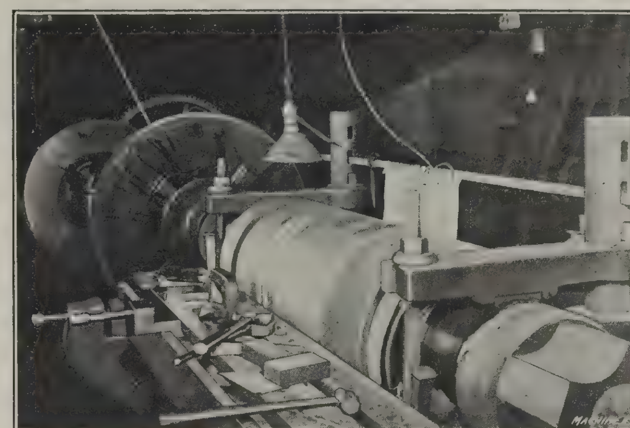

Fig. 4. Turning a Roll 48 Inches Long, and 18 1/2 Inches in Diameter. The Rough-turning removing 1/4 Inch, requires Ten Hours

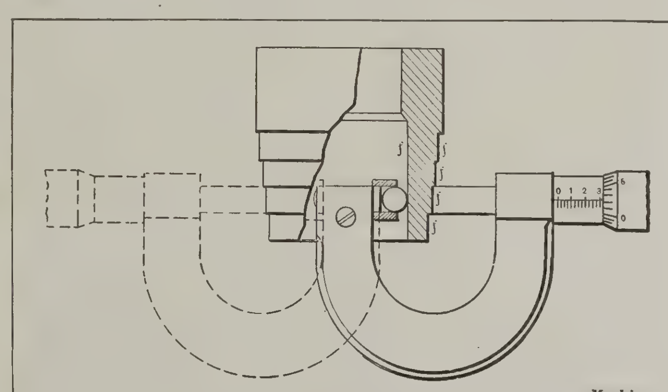
* * *

METHOD OF TESTING LATHE SPINDLE ALIGNMENT

The accompanying line engraving shows a convenient and accurate method of testing the spindle alignment of New Britain-Prentice turret lathes. This method is used in the trying-out department of the New Britain Machine Co., New Britain, Conn., but is equally applicable to testing machines in use in manufacturing departments.



Method of Testing Spindle Alignment

A brass bushing is held in the chuck and bored out to any convenient internal diameter by means of the No. 1 spindle. With the same spindle a shoulder is turned on the outside for a distance of approximately ¼ inch. With the No. 2 spindle a second shoulder is turned of about the same width but of a slightly larger diameter. Likewise, with the No. 3 and No. 4 spindles, similar shoulders are turned, leaving the bushing, when finished, about as shown in the engraving.

By means of a micrometer, arranged as shown in the engraving, the variations in thickness at different points of each shoulder may be ascertained, and by taking readings of the diametrically opposite thick and thin portions of any one shoulder, the amount of spindle error for that particular spindle may be determined, bearing in mind that the difference in the two readings will be *twice* the amount of spindle error.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

JUNE, 1912

PAID CIRCULATION FOR MAY, 1912, 24,980 COPIES

MACHINERY is published in four editions The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

INVENTIONS THAT REVOLUTIONIZE WORKING CONDITIONS

Few of the younger generation realize the change wrought by electric lighting in the working condition of shops and factories. Some fifty years ago it was necessary to so arrange the working hours that no artificial light need be employed. In order to average a ten-hour day for the whole year, the working hours in the summer had to be made unusually long, to make up for the short winter days. In New England shops the average length of the working day was about eight and one-half hours in December, while the men worked eleven hours a day in May, June, July and August.

Now conditions are in many cases reversed. The men in the shop are willing to work overtime, if necessary, during the winter months, but when summer comes they prefer as short a working day as possible in order to have an opportunity for outdoor recreation. This change has been made possible by the invention of effective artificial light—electric light, principally —which makes it easy to light a shop at night almost as well as it is lighted in the daytime. The advantages gained in improved working conditions from this source alone are manifold, and have added not only to the comfort and safety of the work in the shop, but to the rational enjoyment of the leisure hours as well.

* * *

COMPLAINTS DUE TO IGNORANCE

Manufacturers of machinery and tools are often put to considerable inconvenience and expense attending to unfounded complaints about their products. Often these complaints are due to the "fussy" or "cranky" disposition of the customer, but frequently they are simply due to the buyer's ignorance of the proper use of the machine or tool bought. As a rather extreme example, perhaps, may be mentioned the following case: A customer ordered a number of die hobs from a firm manufacturing small tools. In a few weeks complaints were received stating that the hobs were practically useless, that they would not cut freely, and that a great many had been broken while in use. An investigation showed that the purchaser had used the hobs to cut the threads in the die blanks without previous rough-threading by a die tap. As the hob is intended for a light finishing and sizing cut only, and consequently is fluted in a manner that gives very little chip room, it was a foregone conclusion that the chips would clog and the tools break when used in the manner mentioned.

Similar cases are not unusual. It is to the interest of every manufacturer to educate the users of machinery and tools in the proper and efficient use of his product. The best medium for this education is the mechanical journal. Special articles of general interest containing information of permanent value do more to increase the knowledge of the users of machinery than any other agency. The manufacturer who never cooperates with the technical journal in its work of education, and who then complains of the ignorance of his customers and the users of his machines and tools, has really little just cause for complaint. The more that is done to educate mechanics through the medium of mechanical journals, the fewer will be these exasperating complaints which are due purely to ignorance.

* * *

NEW FACTORS IN MACHINE TOOL DESIGN

There are many things to be taken into consideration by the designer of machine tools—too many to be properly enumerated here—but a few new ones have come into the designer's realm since the advent of the automobile which are of special interest now to users and builders of machine tools.

First are ball bearings. Whatever prejudice still exists against the use of reputable makes of ball bearings on all revolving parts of machine tools, other than the main spindles, is disappearing. The chief objection is the cost, and that is not very serious. In the case of a machine tool lately put on the market having ball bearings throughout excepting the work spindle, and costing about $750, the cost of the ball bearings is about $75, or ten per cent of the whole. An offset is about $40 for the plain bronze bearings displaced, which brings the net cost of the ball bearings down to about $35 more than plain bearings.

Second are hardened gears. These, also taken from automobile practice, are one of the latest refinements in tool design. The advantage of hardened gears is that they can be run at pitch line speeds considerably higher than 1000 or 1100 feet per minute, the practical limit of soft steel gears. The cost is more than unhardened steel gears and considerably more than cast-iron gears. In some machines built to order steel gears may have been specified without good reason, but that is not the case in the designs required to transmit heavy torques at high speeds efficiently.

Third is flood lubrication on the principal gears and important plain bearings carrying heavy thrusts. Whether it be of the splash or circulatory type, the essential requirement is to provide an amount of oil that will reduce friction to a minimum and carry away the excess heat generated without retarding effect. This is especially important in gear boxes, where, as has been demonstrated, too much oil has the effect of converting the gears into circulating pumps and thus wasting much power.

Why are ball bearings and hardened gears worthy of the serious attention of machine tool designers? The answer is because of the difficulty of conveying to the tool point sufficient power to utilize the best steels to the highest capacity when plain bearings and ordinary materials are used in the construction. Take, for instance, the case of a high-power drilling machine built to drive the best high-speed drills to the limit of their capacity, in which twenty-two horsepower is absorbed driving a one-inch drill. The machine is built with ball bearings, hardened gears and splash lubrication. Had plain bearings, cast-iron gears and common oil cup lubricators been used, the power required would have been considerably greater. But of more importance is the fact that belt widths and speeds, and face widths of gears, and lengths of bearings would have been so great as to be practically prohibitive. Ball bearings, hardened gears and flood lubrication may be regarded as essentials in the design of machine tools that are required to work the best high-speed steels to the limit of their capacities.

LEARNING BY TEACHING

There is no better way to acquire a thorough knowledge of a subject than to try to teach it to somebody else. In doing this, one will realize one's own shortcomings and find out that there are many points on which it is necessary to acquire more information. If this teaching of others is done in writing, one's own deficiencies will become all the more apparent, and that is the reason why writing for the technical press is, in itself, an excellent means of education. A man writing upon any subject usually digs up a number of questions that he cannot answer, and as he proceeds with the work he is thus impelled to acquire the information necessary to perfect the article. It is surprising how many details are involved in the preparation of even a simple but thorough treatise on machine shop work, and how necessary it becomes to study each one in order to acceptably present the subject to the readers of a mechanical journal.

Nystrom advised the mechanical engineer to collect the data for his own handbook. In giving this advice he probably did not consider every man capable of collecting the data he requires and putting it in better shape than could a trained compiler of handbooks. He thought, rather, that the educational advantages resulting from such a course are so great that, even in this day, with the large number of handbooks available, it would be of great educational value for any young man to collect for himself the data on his work which he considers especially useful to him. Should he then, in addition, try to put this data into form for publication, it would become his own mental property to a greater extent than if studied in any other way.

* * *

SPECIALIZATION IN LUBRICATION

The efficiency and working life of most machines are vitally affected by the lubricant provided for their bearings. If oil of poor quality or of insufficient quantity is supplied, the life will be short and the power wasted will be relatively great as compared with the friction loss under proper lubrication. The theory of friction between sliding surfaces is based on the fact that the smoothest metallic surfaces are relatively rough, and that the opposing inequalities interlock and shear off when rubbed together. The resistance to motion, known as friction, converts power into heat; and if the surfaces in contact are under considerable pressure and in rapid motion they will be quickly destroyed by the resulting attrition and high temperature. To prevent wear and reduce friction, an intermediary or lubricant is introduced which separates the opposing surfaces with a film that fills the inequalities of journal and bearing surfaces, making them smooth and supplying countless numbers of balls or rollers that support the load and move under heavy pressure with little resistance. There are many oils and greases and some mineral solids that have marked lubricating qualities, but which vary greatly in the characteristics necessary for the best results under certain conditions.

Years ago when machinery was generally run at comparatively slow speeds, the bearings being subjected to low unit pressures, the choice of lubricants was not of such great importance as now when high speeds and heavy unit bearing pressures are common. Specialization in lubrication has become necessary, and is carried out to a marked degree in textile mills, railway cars, locomotives, steam engines, gas engines, rolling mills, etc. Everyone knows, instinctively, that a lubricant which is satisfactory for watch pivots is not suitable for a rolling mill journal, but few are aware of the extent to which specialization in lubrication has been carried.

For example, take the automobile, which is essentially a road locomotive with an internal combustion motor. A natural inference is that a cylinder oil suitable for one make of car would be practically all right for all cars having gasoline engines, but the experts in lubrication say not. They claim that it is necessary for the highest efficiency to provide different oils for different makes of cars, and that even the various models of the same maker's cars may require different oils. "The correct oil for a Fiat, for instance, is absolutely wrong for a Packard. The spring strength of the piston rings must be considered, the fit of the piston ring in its recess, the length of the crankshaft and connecting-rod bearings, the feed systems and the length of the vacuum period while intake and exhaust valves are both closed, must be known and studied before the correct lubrication can be determined."

The users of all machinery, and especially automobiles, are advised to care for the bearings with the idea of reducing the friction loss to a minimum. While a car may have ample power when indifferently oiled, it should be remembered that the power wasted in overcoming friction is surely wearing it out. When it is considered that with indifferent lubrication the cylinder and bearing wear or general deterioration in mechanical fitness of a car may be as great in one season as it should be perhaps in three seasons with the best lubrication, the importance of proper attention to this feature can be better realized.

* * *

DEFINITIONS OF ENGINEERING

The public in general has a rather vague idea of the meaning of the word engineering, and of the work and duties of an engineer. Many definitions have been given, some of which have become classical, while others are quoted merely on account of the terse way in which the meaning the author intended to convey has been expressed. Thomas Tredgold's definition is well known. In 1828 he defined engineering as "the art of directing the great sources of power in nature for the use and convenience of man." This definition has been incorporated in the constitution of the Institution of Civil Engineers of Great Britain. There is a deeper meaning in this definition than is ordinarily appreciated at the present. The words "for the use and convenience of man" are especially intended to draw a distinction between the civil engineer and what was at that time termed the "military" engineer, whose work was confined mainly to the building of forts and the design of means for destruction. Tredgold aimed in his definition to show how the civil engineer was one who used the power in nature for the good of mankind and for the progress of civilization.

In 1885, A. M. Wellington, who was for many years editor of the *Engineering News*, defined engineering as "the art of doing that well with one dollar which any bungler can do with two, after a fashion." This definition differentiates the trained engineer who has specialized in any one particular line and devoted time and study to ascertaining the best methods of doing certain work, from the man who may be able to accomplish the same results, but on account of his lack of training, at an excessive cost.

A third definition by an unknown author, quoted in Ernest McCullough's book, "Engineering as a Vocation," defines an engineer as "a compound of common sense and mathematics. If he has not enough mathematics his lot in life will be hard. If he has not enough common sense, God pity him." This last definition brings up the importance of the theoretical training of the engineer. While there is not a great deal of mathematics used in the ordinary routine work in engineering, and while there are many "rule-of-thumb" and "pocketbook" engineers who advise that theoretical training is by no means as important as the college professors would want us to believe, yet it remains a fact that, as a rule, the men who have received the broadest training in mathematics and similar theoretical subjects, afterwards, when they have acquired the requisite practical training, become the most reliable, and frequently the most successful men, in the engineering field.

* * *

An engineering education is not only an introduction to strictly engineering work but is also becoming recognized as a useful preparation for numerous lines of business. More and more, technically educated men are making good in administrative and executive positions, because, along with business ability, their engineering knowledge, even though it has been fixed by only a very brief practical experience, gives them an advantage over those who are without such information. A knowledge of men is needed for even moderate success, but when it is coupled with a knowledge of rational construction, the two make a most forceful combination for getting many things done well.—*Engineering Record.*

SCIENTIFIC MANAGEMENT FROM A SOCIAL AND ECONOMIC STANDPOINT*†

The author of this paper wishes it to be understood that he is not an authority on "scientific management." His viewpoint is that of an outside observer with an investigating turn of mind. This position of outside observer is often a very advantageous one. An inside view alone gives us no perspective or sense of distance.

To be strictly scientific we should begin with definitions, but it is difficult for an outsider to attempt to define this new movement. In a general way, one might say, however, that the scientific management of a manufacturing concern involves the direct control by the management of every detail, and of every, even the smallest, move of every person employed, and the management of every piece of equipment or apparatus—all in accordance with thoroughly investigated and applied standards—to the end that the profits of the employers and employes alike may be increased to the highest degree possible.

Capable men all through the country are striving to put into actual working form the ideal roughly stated above. They are meeting with a large measure of success in their work, and in their enthusiasm they are making claims that look forward to great social reforms and the permanent betterment of industrial conditions. Among the things hoped for are: the permanent increase of profits and wages; the decrease of unemployment; and the growth in character and intelligence of those now classed under the general term "unskilled labor." These are the claims it is now proposed to investigate.

Comparison between Scientific Management and Labor-saving Machinery

We cannot reason about a thing whose qualities are unknown. The object must be thoroughly studied, and almost invariably when this is carefully done we find that the particular object of our study is in no sense unique, but belongs to some clearly defined class. By studying the past history and the recognized present effects of that class, we can form a clear idea of the future history and the effects of the new object or movement under consideration. This is the way in which we can investigate scientific management. The more we analyze and study its nature the more clearly do we see that it belongs to the class of labor saving machinery. All that labor saving machinery has done for the world, scientific management will do; that which labor saving machinery has failed to do, scientific management will fail to do. It should do as much—it can do no more.

Let us first ask what is the effect of scientific management on the worker. As with almost any labor-saving machine the effect is that of specialization. In place of broad, general skill and a wide range of activities, the work is confined to a few regulated motions, the necessary information for which is presented to the worker in blueprinted, typewritten or printed form. This complete specialization has aroused opposition of workers everywhere, especially where scientific management has never been tried, or is just about to be tried, or has been only half tried, or has been unwisely and clumsily tried. Where the scheme has been worked out with scientific thoroughness, the workmen have finally received it in a friendly spirit.

The reasons for this are plain: In the first place, the goal should be, and usually is, more work with the same effort; that is, easier work—not harder—but more of it. In the second place, the vast increase of the so-called "non-productive" labor, foremen, clerks, etc., necessitates in the end a change of employment throughout the whole force. The man with brains and experience enough to be a skilled mechanic, and who would object to minute supervision, is too valuable to waste on the mere mechanical machine work. He becomes a functional foreman or a productive specialist of some other kind. The unskilled man is raised from his lowly position to that of a trained machine operator, and the still less experienced man takes his former place as a helper. Of course, there are some skilled and intelligent men—but not many—who are unable to adapt themselves to the change. That has always been the case when new labor saving machines or processes have been introduced. These men may be assisted individually until they have re-adapted themselves, but, since the beginning of things, it has never been possible nor wise to stop the course of improvement for their sake.

When we consider the effect of scientific management on the profits of the employer, the analogy with labor saving machinery is especially striking. This analogy has been fully developed by Mr. Fred J. Miller, of the Union Typewriter Co. A few of his analogies are as follows:

Scientific management, like labor saving machinery, is best adapted to shops manufacturing in large quantities where the separate operations are comparatively simple, or may be made so.

Like the machine, it must be specially and skillfully adapted to the particular work in hand. An adjustable machine, supposed to be adaptable to a wide range of conditions, is likely to prove a failure. The expert designer must construct his machine or system for some particular work and for no other.

The first cost and operating cost of the machine or system must not be greater than any possible saving to be made by its use.

The most important analogy, however, is that from the business or financial point of view. The likeness between scientific management and labor saving machinery in its effect on wages and profits is absolute. Says Mr. Miller:

"When a labor saving machine has been designed for certain work and put in operation in a certain factory, which factory is only one of a number of factories doing similar work, the profits from the use of the machine may be very large because the price obtainable for the work done by it will be based upon the cost of doing the work by the least efficient of the older machines still necessary to be employed on that work in order to supply the demand. But when all the manufacturers have similar machines at work, competition will lower the price to the ordinary return on capital invested in that general line of manufacturing.

"Similarly, those who first successfully install a system of management materially better than that possessed by their competitors, may make higher profits until such efficient systems become the regular thing—and no longer. Those who are among the last to adopt a labor saving machine do not make more than regular profits. They simply are obliged to take the forward step in order to make any profit at all, or to remain in business. It is the same with systems of factory management.

"Workmen who operate new labor saving machines may receive more than the ruling rate of wages, one of the reasons for this being the lowered cost of production and greater relative ability to pay higher rates; but in the end, sooner or later, the law of supply and demand will regulate this as it does all other competing or unmonopolized businesses. When the use of the labor saving machine has become general, an owner of such a machine can no longer continue to pay materially higher wages than other and competing users of similar machines.

"In every way, so far as I can see, the effect upon factory employes of the use of labor saving machines and of labor saving systems of management is exactly the same, and their attitude toward them should be the same."

So we see that a system, wisely planned and carried out, may effect a substantial though temporary increase in the earnings of employer and employe alike, and it should be welcomed by both at its face value. Least of all should the workman in the engineering trades—machinery building and the like—place himself on record against it. His business in life is the building of labor saving devices for others to use; and can he object when an improvement of the same type is introduced into his own field?

Some Difficulties of Scientific Management

We have seen that substantial benefits, even though of a temporary kind, may be expected from the introduction of scientific management. We have found no logical reason for the objection of either employer or employe to a wise use of this new labor saving device. Are there any positive dangers in the idea itself or in the operations of those who are promulgating it? That there are such dangers and errors, is beyond question.

The first error is a purely commercial one, born of the zeal of the organizer. The system is not in itself the end, but only the means to an end. The true object is the simultaneous increase of the profits, wages, and good-will for all concerned, but a few organizers have mistaken this goal and have focussed

* Abstract of paper read by Mr. Ralph E. Flanders, of Springfield, Vt., before the American Society of Swedish Engineers, Brooklyn, N. Y., April 20, 1912.

† For information previously published on this subject, see "Industrial Efficiency," May, 1912, and articles there referred to.

their eyes on their pet system, instead of on the results to be obtained.

The second danger is that of obstructing invention and development along new lines. Two tendencies are constantly opposed to each other in management—the tendency toward new invention and the tendency toward standardization. Each is profitable in its place, but it takes ability and courage to balance the two properly. Consider the conditions. An immense mass of data collected at great cost is at hand. This data relates to the most efficient performance of certain operations which have been standardized for years. A new machine or process is then developed which attacks the problem in an entirely new way and with superior results. It is then difficult for the organizer to see his years of standardizing overthrown without making a struggle to save the system.

The introduction of a new system must not tend to block the development of automatic machinery by the desire to preserve the costly data for older processes. The improvement of mechanisms, after all, should be the larger vision of industrial management. With the increase of skill in our designs, the reign of the automatic machine will become supreme. With the hand-fed machine, the workman is like a slave to a master of steel and iron; but not so with the fully automatic, self-feeding mechanism. More and more will our shops approach the ideal shop of the future where the workman, as master, shall move among his servant machines, adjusting this one, changing the work of that one. In such a shop the system organizer would find his work reduced to the minimum, but progress is in that direction and the system must not stand in the way.

The third possible source of weakness in the work of the systematizer, if he has not a clear conception of the fundamentals of his work, is the misunderstanding of the most important element in his problem—the human element. Some fifteen or twenty years ago, during the height of what might be called the "biological period" of philosophy, an engineer might have been pardoned for believing that man is a machine, subject to invariable action under the laws of cause and effect, but we are now beginning to perceive that the laws governing man's actions are infinitely more complex and far beyond the powers of his own intellect to comprehend in their fullness.

There are two sources of trouble from the human factor. One is misunderstanding on the part of the workman. To overcome this requires first of all that the systematizer shall have firm assurance of the justice of his position; and then he must have tact, determination, and a real liking for the men he deals with. Confidence, willingness and enthusiasm must be built up on the solid foundation of square dealing. The second source of trouble from the human factor is a corollary of the first. The organizer must have the right attitude toward the men under him. The cause of scientific management has suffered much in this matter from some of its chief exponents. Originating as it did in the steel mills, with their vast armies of ignorant and unskilled workmen, it is natural that the system in its origin should have treated these men as so many machines, but even these men are mighty reservoirs of spiritual forces, before which laws of averages and tables of motion study are mere straws in the wind; and when the same attitude is carried into dealings with skilled and intelligent men, the scheme becomes hopelessly unworkable. It would have been better for the cause if some pages of its most authoritative tracts had never been written. There breathes through them, in spite of their protests, the feeling that the mission left to the workman is the mission of a machine—that his effectiveness to himself, his country, and the world, is measured accurately and absolutely by his output per hour in the factory. Such a view is false. The aim of the existence of the meanest laborer and the greatest captain of industry are alike—growth in individuality, character and social service. Scientific management may and sometimes does include all of these; where it does not, it is doomed to failure and deserves it.

Does Scientific Management solve the So-called Industrial Problem?

Scientific management, so far as its social and economic effects are concerned, stands, as we have seen, in exactly the same category as labor saving machinery. For a century or more the labor saving machine has been infinitely multiplying the efficiency of the individual workman. Even with the old systems of haphazard management, the labor saving machine has raised the individual efficiency to an exceptional degree. This new labor saving machine — scientific management—again multiplies this efficiency by a new factor. But does it solve the industrial problem—the labor problem? As stated, scientific management will do all that labor saving machinery has done to solve our problem—it can do as much; it can do no more.

What then has labor saving machinery done? It has multiplied the capacity to produce wealth. It has given to the workman comforts and conveniences of which the most wealthy were ignorant a century ago. So far it has done well; but it has done vastly more for the few than for the many. The difference between the wealth of the highest and the lowest has been vastly accentuated. The number of those who reap where they did not sow has been increased, and the sense of injustice in the breasts of those who are allowed to sow but not to reap is rendered keener by the greater intelligence of the present age. Hence, the doctrine of efficiency solves no problems—it makes them; it has never leveled inequalities and injustice—they have kept pace with its growth.

We will, therefore, have to look elsewhere for the solution of the industrial problem. Fortunately, the world is beginning to look elsewhere, and is beginning to see the outlines of monopolies and special privileges which have used the blessings of efficiency for their own satisfaction. We are beginning to understand that the problems that cause industrial disturbances are not the problems of production, but problems of just distribution. The immediate need of our age is not more efficiency, but better distribution of the products of the efficiency already at hand and here the engineer meets with a new responsibility. He has made the modern world what it is, but he does not ride the creature he has formed. His logical brain, his executive hand, his sympathetic heart, are all needed in the work of changing conditions for the better—in introducing greater efficiency in the distribution of wealth as well as in production. The management of society has been left long enough to the lawyers, merchants and financiers. They are good enough in their way, but the time has come when we must also call upon the engineer to take his part in the work of social service.

LIFE SAVING AT SEA

The American Museum of Safety has just made public the fact that Judge Elbert H. Gary, on behalf of the United States Steel Corporation, has presented the museum with $5000 toward obtaining a collection of the best devices for saving life at sea, as a permanent exhibit for demonstration and study, free to the public. Dr. W. H. Tolman, director of the museum, and its safety inspector, have gone abroad to attend the International Congress of Accident Prevention at Milan, and to study the best European methods for life saving at sea, and the prevention of injurious effects of occupational diseases. The policy of the museum is now being guided by Arthur Williams, who has just assumed the presidency, succeeding Philip T. Dodge, who felt obliged to withdraw on account of ill-health and absence from the country. President Williams announces another gift of $5000 from an "unknown friend" for research work in connection with industrial poisons. Dr. Charles A. Doremus is chairman of this section of the museum's activities. The public is not only invited to visit the museum, at 29 W. 39th St., between 9 A. M. and 5 P. M. every day to study its collections, but in addition, its jury on exhibits, requests inventors and anyone else with practical ideas for life saving at sea, to submit them at the museum.

* * *

The executive committee of the American Brass Founders' Association decided at a recent meeting to propose changing the name of the organization to the American Institute of Metals. It is stated that the reason for the proposed change is that the present name does not adequately describe the scope of the association.

MACHINE HANDLES—1

A STUDY OF THE VARIOUS TYPES OF HANDLES AND HANDWHEELS USED ON MACHINE TOOLS

By FRED HORNER*

Handles and handwheels constitute important elements in the design of machine tools and machinery in general. Many different types and modifications are met with. Different types are required according to the particular function of the handle or wheel, and sometimes the differences are due to the individual ideas of the designer. In order to facilitate manufacture, however, the variations in the forms of handles should be limited whenever possible.

Certain types of handles, one might say, are almost national in character, as, for example, the ball handle, which was first introduced in America on account of the convenience with which it could be turned from the bar. At one time it was seldom found on English or Continental machines, although at the present time it is frequently found in Europe. On the other hand, there are many English firms which have not been influenced by American or Continental practice, and which use forged handles of a particular type on practically all machines. This peculiarity is specially noticeable in the Manchester and Glasgow districts. The size of a machine tool also has an influence on the type of the operating handles, because the conditions of work are essentially different in a large and small machine. In small machines there are many hand movements for which convenient ball handles are suitable, while in large machines the power feeds eliminate most of the hand operations, and star handles are better suited for the less frequent movements required. Frequently some kind of a wrench or ratchet lever is all that is necessary for the occasional movements or adjustments to be made.

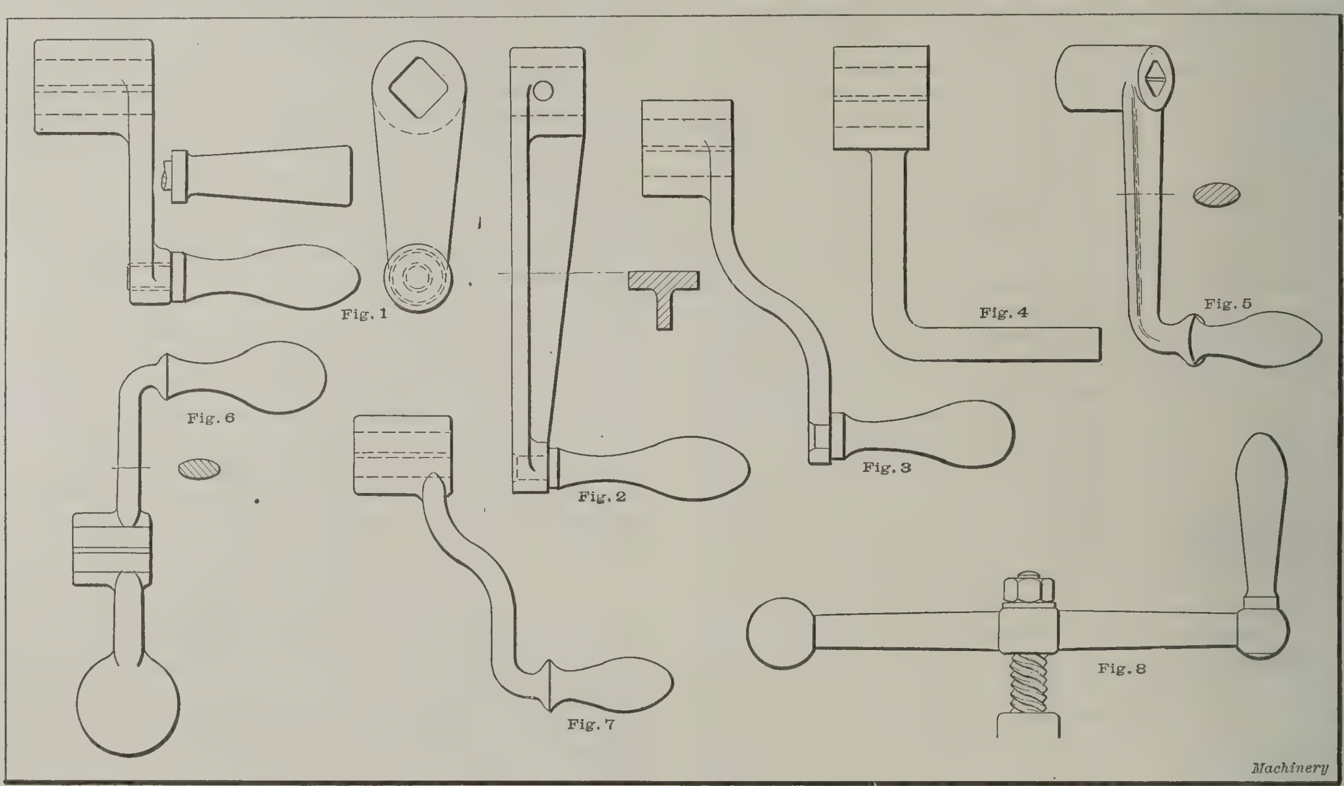
The question of whether or not a handle should be loose on its shaft or fixed to it is sometimes settled by the conditions of service, while sometimes it is a question that can be decided according to the designer's fancy. If it is impossible or inconvenient to give a complete revolution to a handle it should be fitted loosely, or a ratchet employed. Occasionally, when a number of screws or shafts are adjusted at infrequent intervals, it is the practice to supply but a single handle for their manipulation. A combination of a fixed and a loose arrangement is sometimes desirable, and is accomplished by a friction or other clutch arrangement, so that the handle or wheel can be coupled to the shaft or disconnected from it at will.

*Address: 13 Forester Ave., Bath, England.

Sometimes, when the ends of two or more of the shafts come close together, a single handle must be used, which is slipped onto either shaft as required. The waste of time involved in this has caused some designers to so modify the arrangement as to eliminate this proximity of the shafts, and to place them so that the distance between them is sufficient to permit a fixed handle or handwheel to be attached to each. When adjustments are required frequently, it is more convenient to have individual handles on every shaft.

In the following is given a selection of the more typical designs of handles. It should be understood that these are intended to illustrate types only, and that slight differences in design are frequently met with. However, it is believed that this collection of handles shows practically all of the types that are in more or less common use.

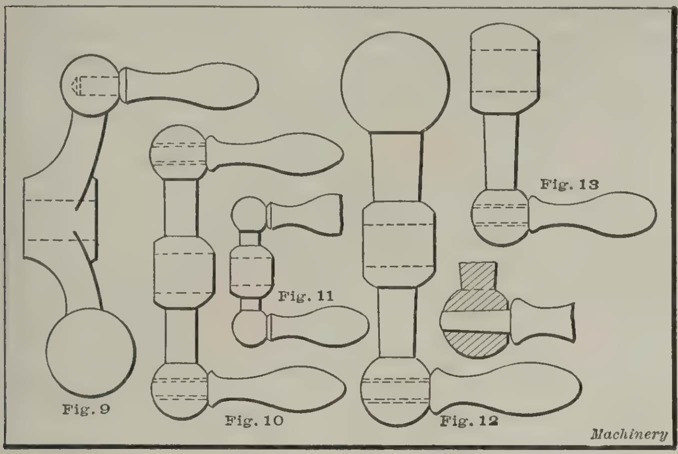
Perhaps the simplest, and, at one time certainly the most commonly used handle, is that shown in Fig. 1. The lever part was in the past usually made of an iron casting, but is, at the present time, often cast in gun-metal. It is used generally for small lathes and other small machines. The handle is either riveted or screwed in. The plain straight handle also shown in the illustration is not as comfortable to the hand as the rounded shape. The cast-iron handle shown in Fig. 2 is occasionally used, but does not present a very neat appearance. In Fig. 3 is shown a handle with a bent lever. This form is necessary when the handle comes inconveniently close to projecting parts, such as nuts and adjacent bearings, etc. Long handles are occasionally bent out in a straight line and then bent just at the tip where the handle portion is screwed in. A handle or "screw-key" frequently used in English designs is shown in Fig. 4. This is forged in one piece with the handle portion formed simply by bending the circular stem. It is not a very good looking handle, but seems to be a favorite among many machine-tool makers, particularly in the Manchester and Glasgow districts.



Figs. 1 to 8. Types of Handles used on the Machine Tools

The solid drop-forged handle, with a shaped portion for the hand, shown in Fig. 5, is probably employed to a greater extent in America than elsewhere, although, with the spread of drop-forging practice, its use is continually extending. The type shown in Fig. 7 is necessary in designs where on account of clearance, or for other reasons, the straight shape is impracticable or at least inconvenient. The most popular style of handle for ordinary use on slides and other parts that have to be frequently adjusted or manipulated is the balanced ball handle shown in Fig. 12. This is turned out of solid stock with forming tools and provided with a screwed-in handle, as

shown. Sometimes the handle is fitted with a taper, as indicated in the detail view. Ball handles with much longer arms, as in Fig. 8, are used to a moderate extent where greater leverage is required. French makers are particularly fond of using them, the example shown being taken from a French screw machine. The drop-forged style, shown in Fig. 6, has the handle formed in one with the body. This handle has a pleasing appearance, and the choice between this and the turned type depends entirely upon manufacturing conditions.



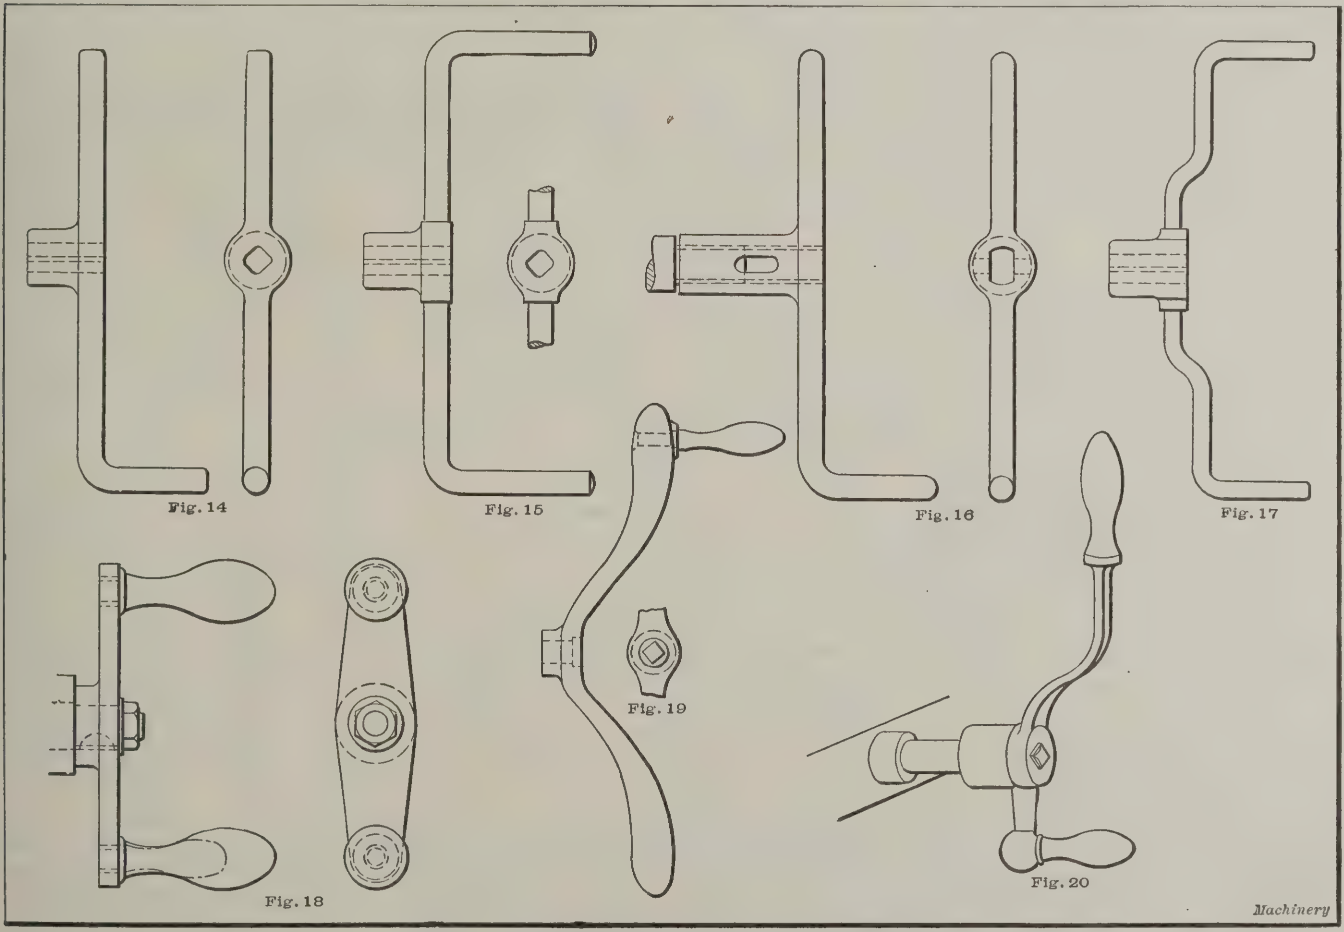
Figs. 9 to 13. Types of Handles used on Machine Tools

Ball handles are seldom used in cases where the unbalanced action is of no consequence, as, for instance, when the screw to be operated stands in a vertical position, as the feed-screw of a shaper tool-box. The handle shown in Fig. 13 would, however, be objectionable where the extra weight on the one side would tend to let the handle gradually drop under the influence of vibration, so as to move a screw or other portion and thus alter the adjustment. The balanced ball handle, if accurately designed, obviates this tendency. Ball handles with the balls on the ends in line with the center of the hub cannot always be used where the clearance space is limited, and the forged type shown in Fig. 9 is then employed.

The double-ended ball handles, shown in Figs. 10 and 11, give a more perfect control over the movements of a slide, and the handle is always within easier reach than in the case of the single-handled form. A type of double-ended handle much used in certain English and Scotch machine tools is that shown in Fig. 14, which is forged with round bar ends, one being bent as indicated. The type shown in Fig. 15 is also employed to a large extent; in this, both ends are bent. It is sometimes made in the shape shown in Fig. 17, when the clearance is limited. Handles of this type are sometimes fitted upon flatted spindles, as indicated in Fig. 16, and are also made with a cotter-way cut through it as illustrated. The object of this is to enable a cotter to be driven in to draw the handle off, if it should be jammed in place.

A frequently used type of double handle, having a web or plate body with the handles screwed or riveted in place, is shown in Fig. 18. The handles are either of equal size as shown, or one is made smaller than the other, as indicated by the dotted lines, so as to leave the hand and wrist less encumbered for rapid rotation. A different type intended for the same purpose is shown in Fig. 20. This is used on a hand milling machine; the leverage for one handle is long and is intended to give the required power for feeding, while the leverage of the other is short for rapid turning when making quick adjustments. A similar principle is embodied in the handle shown in Fig. 19, intended for turning a chuck, in which the ends are alike, but one has a transverse handle riveted to it for rapid rotation.

In Fig. 21 is shown how the movement of a handle is conveyed to a vise on a Lincoln milling machine, where the square on the vise screw happens to come over the table, thus preventing the full rotation of the handle were it attached directly to the end of the screw. A supplementary spindle is, therefore, provided for rapid manipulation, this spindle being supported in a bracket bolted to the table, and the handle applied to it.



Figs. 14 to 20. Types of Handles used on Machine Tools

Loose handles which turn on a stem or central spindle are used to a considerable extent. These can be rapidly operated with less friction and fatigue to the hand. Either steel, glass, horn, wood or other similar substances are employed for the loose part; horn is more durable than wood, and is a very

popular material for this purpose. A steel or brass handle, as shown in Fig. 22, fits directly on the pin fastened to the handle or wheel, but wood and horn handles require a bushing, as indicated in Fig. 23. In Fig. 22, it will be noticed that an oil groove is provided for lubrication.

The two-ended type of handle, shown in the previous illustrations, and also illustrated in Figs. 24 and 25, does not meet with all requirements in machine-tool operation, particularly when rapid movements are desired, and where considerable power must be exerted, as, for example, in the operation of turret lathe slides, lathe carriages, drilling and boring machine slides and spindles, etc. Star handles or "spiders" are then employed for this purpose. The simplest type of star handle is shown in Fig. 34. It is made of a steel forging with flat handles, which are either straight or bent as shown in the alternative design in the upper part of the right-hand view. A more neatly designed type, forged with round tapered handles, either straight or bent, is shown in Fig. 33. In Figs. 27 and 29, other forms are indicated.

In very large spiders, such as those sometimes used on boring mills and large turret lathes, the four or more star handles are screwed into the short arms of the central cast-iron boss. This type is used on account of the simplicity in making. As these star handles grow larger, however, the usual design takes the form of a central boss of cast iron into which forged or turned steel handles are screwed or pinned or held with nuts, making a graceful and light design, and one that is easy to manufacture and assemble. Handles of this type are shown in Figs. 30 and 32, the one having four and the other three handles. The handles are tapered or formed to prevent the hands from slipping off too easily, or are sometimes knurled.

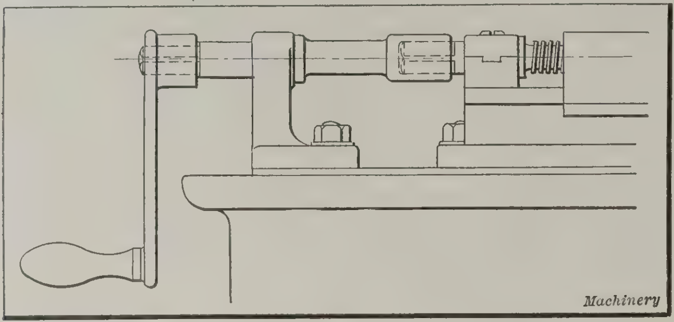


Fig. 21. Extension Spindle and Handle on Lincoln Milling Machine

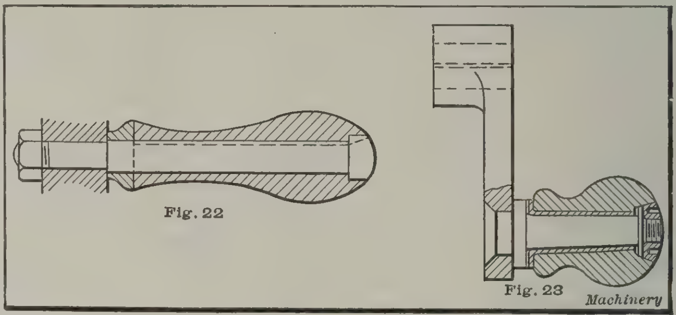
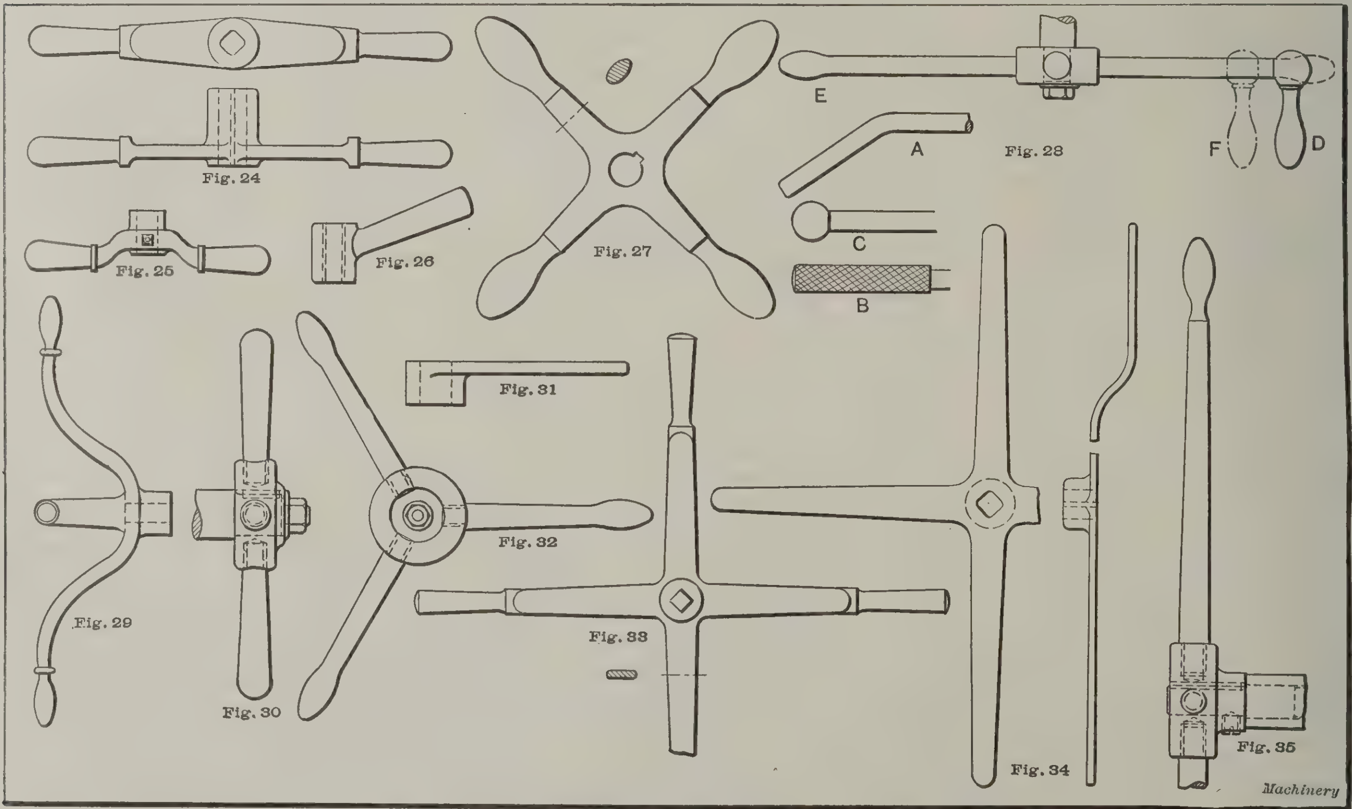


Figs. 22 and 23. Examples of Loose Revolving Handles

In Fig. 35 is shown a large "spider" for a chucking-lathe turret slide where the bearing of the spindle is brought out so as to avoid the necessity for bending the star handles outward. When it is necessary to bend these handles, however, this is done either as indicated at *A* in Fig. 28, or by putting them in at an angle as indicated in Fig. 36, the dotted lines showing a case where the angularity is considerable. Returning to Fig. 28, this figure shows the alternative designs *B* and *C* for the handle ends, the first being knurled for a certain distance, and the second having a knob or ball end. All these handles are used on turret lathes and for similar purposes. The handle shown at *D*, Fig. 28, provides a means for rapidly rotating the spider. This handle is attached to but one of the star spokes. This arrangement is varied by leaving all the handles as indicated at *E* and putting handle *D* further in on the spoke, as shown by the dotted lines at *F*. This leaves the star for feeding and provides a handle for rapid rotation.

A practice still more common is that of fitting handles *D* or *F* loosely, so that *D* can be attached to any plain bar and also adjusted for radius, to suit the throw which each particular operator prefers. The usual method for designing such a handle is with a split and a set-screw, as shown at *A*, Fig. 40. Occasionally a plain set-screw bearing on the bar is used. Another method is to use a grip-bolt as shown at *B*, drawn up by its nut to press on the bar and thus lock the handle.

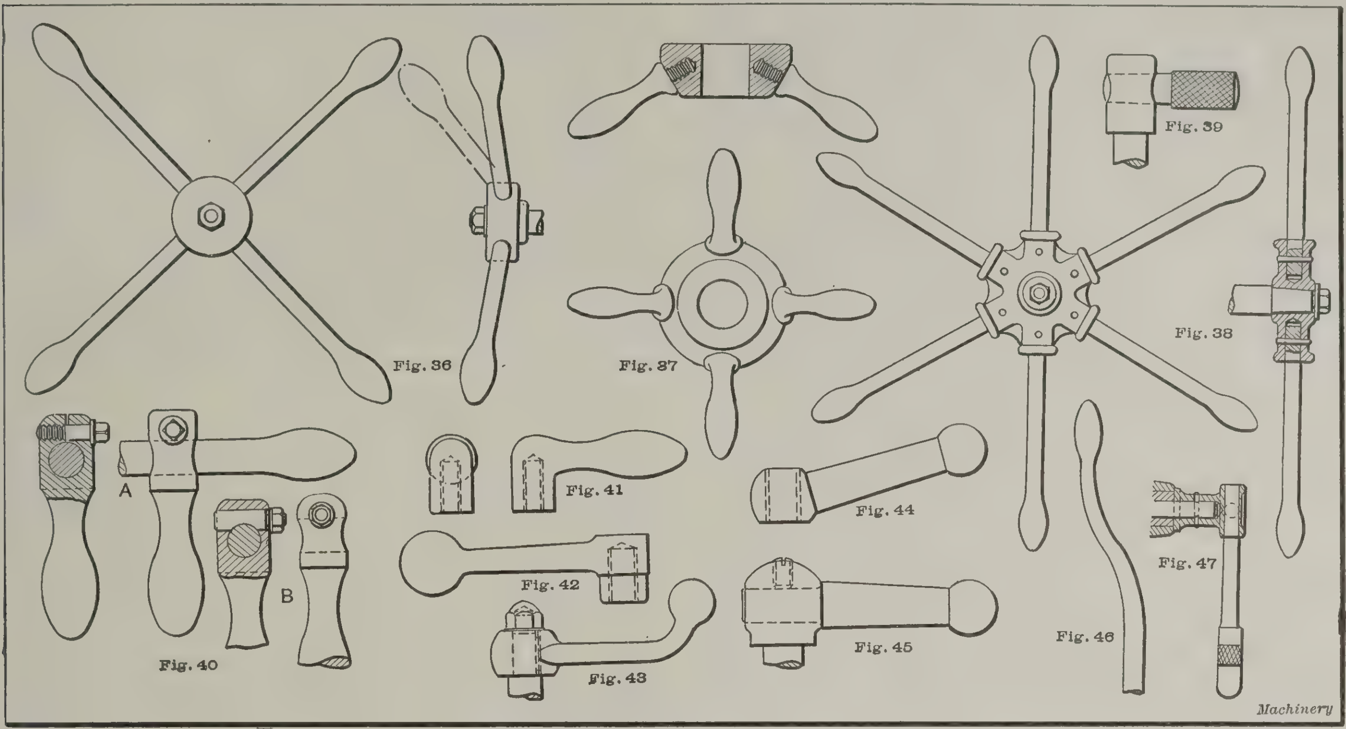
Other types of star handles are illustrated in Figs. 36, 37 and 38. The first is a simple design of star handle with a cast-iron boss, the handles being screwed in at an angle. This type is largely used in connection with certain feed motions. That in Fig. 38 is used for large turret lathes, the handles fitted having plain or slightly tapered ends and being fastened by taper



Figs. 24 to 35. Types of Handles and Star Wheels used on Machine Tools

pins. Star or pilot handles of this design are provided with up to eight or ten handles, and when two of them are placed adjacent, one in front of the other, on a shaft and a sleeve, respectively, the number of handles in each is occasionally varied, and the outer handle is provided with shorter arms than the inner, for convenience in manipulation.

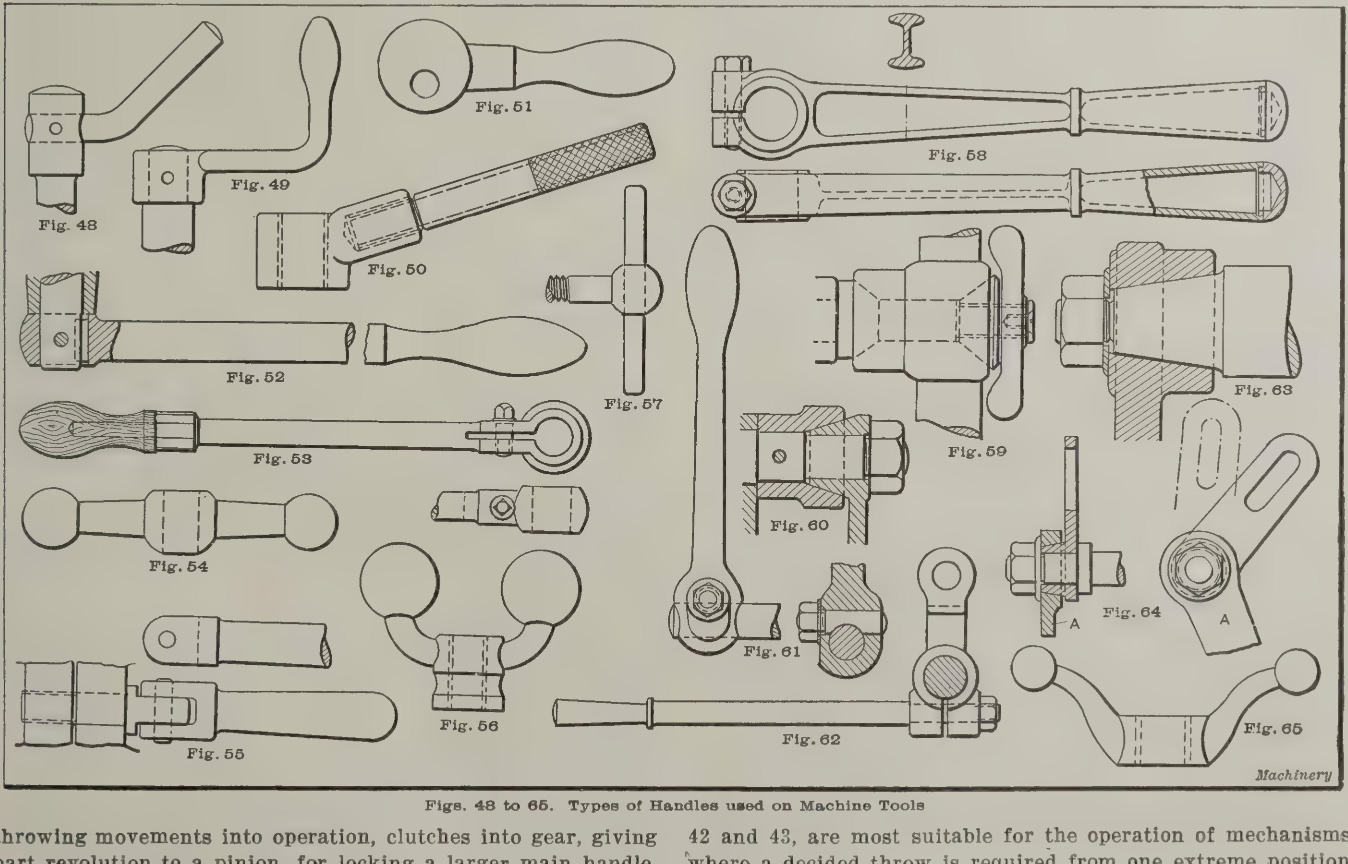
cation of a loose wrench. Others are wrenches, pure and simple, with a square or hexagonal hole, and with the usual handle portion of a different type from that of the ordinary wrench. Others, again, are nothing but nuts, with some kind of handle, wing, or ear. One of the plainest kind of handle of this type is shown in Fig. 31, and consists of a boss with a



Figs. 36 to 47. Types of Handles and Star Wheels used on Machine Tools

The handles so far illustrated have been principally intended for operating screws, pinions or other parts requiring a complete revolution, but there is a large and more varied class employed chiefly for partly rotative movements of a fraction of a circle. These are for such functions as locking or for

threaded, square, or hexagonal hole and a flat handle. Sometimes the handle is circular and tapered as shown in Fig. 26; this type of handle is more convenient to manipulate and is used when it is frequently operated. A drop-forged type with a nut portion is shown in Fig. 41. Ball-ended handles, Figs.



Figs. 48 to 65. Types of Handles used on Machine Tools

throwing movements into operation, clutches into gear, giving part revolution to a pinion, for locking a larger main handle, a slide, or a quadrant, feeding a slide, operating a chuck, and many similar functions. Some of these are really wrenches in the forms of handles, and are used to avoid the frequent appli-

42 and 43, are most suitable for the operation of mechanisms where a decided throw is required from one extreme position to the other, as for clutches, clasp-nuts, and similar mechanisms. The ball end is also well suited for larger handles or levers in places where a belt-shipper or clutch or similar strik-

ing gear is thrown in very suddenly. Figs. 44 and 45 show two variations of turned ball-handles, the one made solid and the other fitted into the head of the screw or spindle, and locked with a headless set-screw.

When but a small leverage is required, an arrangement like that in Fig. 39 is often adopted; or like that in Fig. 48, if the space for the hand is obstructed at the surface of the slide or other part of the machine, by nuts or other outstanding objects. Not only nuts, but other details are frequently made solid with their handles, pinions or quadrant teeth, or eccentric or cam portions, as indicated in Fig. 51. This makes a solid construction and eliminates the key or other fastening required.

Lightness is not usually a point in handle designs except when the handles are used in portable machines, and for certain devices, as opening dies. In certain instances, however, a piped form of handle may be provided, as shown in Fig. 50. In Figs. 47 and 49 two types of handles are shown, one for operating the tailstock spindle of a bench lathe, and the other for turning a vertical feed-screw, where occasional rapid complete revolutions are alternated with slight adjustments. A handle long familiar on certain designs of upright drilling machines, is shown in Fig. 46. This handle is forged directly to an extension of an adjusting screw. It is, of course, nothing but a bent forging, but illustrates that in certain instances even long handles may be made in one piece with the part being operated.

Longer levers for operating movements requiring considerable power are either of the plain type shown in Fig. 52, which is simply keyed or pinned onto the spindle or screw, or they are attached by a split boss and set-screw, as shown in Fig. 53. This latter design permits of adjustment in radial position to suit the convenience of the operator, and is met with in the feed lever of cross-slides and vertical forming slides on hand-milling machines, etc. The wooden handle on the end of the lever is used because it is more comfortable than a steel handle for constant operation. Fig. 58 illustrates a cast handle with a web of H-section, and a hollow handle portion with a cap screwed onto it. Instead of using a split boss for clamping, the draw- or grip-bolt method, as shown in Fig. 61, may be utilized.

The adjustment of the radial position of the handle is provided for in other ways besides those just illustrated. A favorite method is that of utilizing a cone as shown in Fig. 63, the handle being forced on by the nut. Another method is shown in Fig. 60, where the cone is fitted inside a collar which is pinned on the spindle. In Fig. 64 an arrangement is shown which is adopted for a turret lathe cross-slide. The handle *A* is locked to a slotted link (which moves the slide) by a cone and nut, so that the relative angular setting can be varied to bring the handle *A* into a higher or lower position, according to the setting of the tools and the diameter of the work. Another method for making a handle adjustable, or for allowing it to swing freely, is by a friction clutch device, as shown in Fig. 59.

The shapes of double-ended handles for the same purposes as those just mentioned depend chiefly on the size and the function of the handle. For simply tightening a plain cross-handle, the type shown in Fig. 57 is sufficient, or a more comfortable ball-handle, Fig. 54, may be employed. Two varieties of ball-ended handles are shown in Figs. 56 and 65. The ball ends give a flywheel effect that helps in rapid tightening and loosening, which is a feature of value when these operations are repeated at frequent intervals.

A handle attached to the end of the spindle, for operating a belt-shifting mechanism for a small countershaft, is shown in Fig. 62. When it is necessary to hinge handles so that they may be folded back out of the way after use, the type illustrated in Fig. 55 is used.

* * *

One of the few available materials that will stand the high heat of the blow-pipe used for melting platinum, is lime, and this material is almost exclusively used for crucibles for melting platinum. The lime used is regular burnt lime and not limestone. Large pieces free from fissures and foreign matter should be selected.

SOCIETY OF AUTOMOBILE ENGINEERS SPECIFICATIONS FOR STEEL*†

In a report by the Iron and Steel Division of the Society of Automobile Engineers, January, 1912, very complete specifications for the composition, heat treatment and properties of various kinds of steel, are given. In the following article the most important parts of these specifications will be reviewed. Tables relating to the composition, heat treatment, etc., of carbon, nickel, nickel-chromium and chromium-vanadium steels are given in the accompanying Data Sheet Supplement.

The steels specified may be of open hearth, crucible or electric manufacture, and must be homogeneous, sound and free from physical defects, such as pipes, seams, heavy scale or scabs, and surface and internal defects visible to the naked eye. The figures given in the tables for physical characteristics or properties of the various steels refer to sections common in automobile construction that is, to bars from 1 to 1½ inch round. The high elastic limits can be obtained only on small sections with very careful heat treatment, while the low elastic limits can be expected on heavy sections with less refined or severe heat treatment.

Carbon Steels

The 0.10 per cent carbon steel is usually known to the trade as soft, basic open hearth steel, and is commonly used for seamless tubing, pressed steel frames and brake-drums, sheet steel brake-bands, etc. It is soft and ductile and will stand a great deal of deformation without cracking. In its natural or annealed condition it should not be used where a great deal of strength is required. The quality of this material, however, is improved by cold drawing or rolling. An important fact to remember is that this steel when cold drawn or rolled is returned to the characteristics of the annealed material by heating. This remark also applies to all materials the elastic limit of which has been increased by cold working.

The 0.10 per cent carbon steel in its natural or annealed state cannot be easily machined. It will tear badly in turning, threading and broaching operations. Heat treatment has little effect upon it, and does not increase its strength but only the toughness. The heat treatment which will produce some stiffness is to quench it in oil or water at a temperature of 1500 degrees F. No drawing is required. This steel will caseharden but is not as suitable for this purpose as 0.20 per cent carbon steel. This latter steel is often known to the trade as machine steel and is intended primarily for casehardening. It forges well and machines well, but is not suitable for screw machine work. Its particular use is for forged, machined and casehardened parts, where strength is not of especial importance. It can also be drawn into tubes and rolled into cold rolled forms and is a good frame material. It can be interchanged with 0.10 per cent carbon steel for cold pressed shapes.

Heat treatment of 0.20 per cent carbon steel does not increase its strength to any degree, but causes a refinement of the grain after forging and increases the toughness; all that is necessary is to quench it in oil at 1500 degrees F. The casehardening treatment specified in the accompanying Data Sheet Supplement is the most important treatment for this quality of steel. The heat treatment specified as "A" is for parts which do not need to carry a great deal of load or withstand shock, but simply must have a hard surface. Heat treatment "B" is for the parts which must not only be hard on the surface but also must possess strength, as, for example, gears, cam rollers, steering-wheel pivot-pins, etc.

The 0.30 per cent carbon steel is primarily a structural steel. It forges well, machines well, and responds to heat treatment in regard to strength as well as toughness. It is used for such forgings as axles, driving-shafts, steering pivots and other structural parts. This quality of steel is not intended for casehardening, but, by careful treatment, it may be safely casehardened, although it is used for this purpose only as an emergency. In that case, it should be given a double heat treatment, followed by a drawing operation.

The 0.40 per cent carbon steel is a structural steel of greater strength than that previously mentioned. Its uses are more

* With Data Sheet Supplement.
† See MACHINERY, September, 1911, "Composition and Heat Treatment of Carbon and Alloy Steels."

limited and generally confined to such parts as demand a high degree of strength and a considerable degree of toughness. It is commonly used for crankshafts, driving shafts and propeller shafts. It has also been used for transmission gears, but is not quite hard enough for casehardening, and when casehardened, not tough enough to make safe transmission gears. When properly annealed it machines well, but is not suitable for screw machine work. The 0.50 per cent carbon steel differs but little from that just described, although owing to its higher carbon content, it is somewhat harder to machine and also somewhat stronger.

The 0.80 per cent carbon steel is ordinarily known to the trade as spring steel, and is generally used for springs of light sections. The 0.95 per cent carbon steel is also generally used for springs. When properly heat treated extremely good results are possible. The quenching temperature, as specified in heat treatment "F" in the Data Sheet Supplement, should, if anything, be lower than that specified. Because of the high carbon content, the steel is used considerably for heavier types of springs.

Screw Stock

The composition of ordinary screw stock is not given in the accompanying Data Sheet Supplement, but should, in general, be about as follows: Carbon from 0.08 to 0.20 per cent; manganese, 0.30 to 0.80 per cent; phosphorus, not to exceed 0.12 per cent; sulphur, 0.06 to 0.12 per cent. The characteristics and heat treatment of this steel were given in an article on "Composition and Heat Treatment of Carbon and Alloy Steels," published in MACHINERY, September, 1911, engineering edition.

Nickel Steels

With regard to the use of all alloy steels it should be borne in mind that such steels must be heat treated and not used in the annealed or natural condition. In the latter condition they are but slightly superior to plain carbon steels. In the heat-treated condition, however, a marked improvement in physical characteristics is shown.

The 0.15 per cent carbon nickel steel, the analysis of which is given in the accompanying Data Sheet Supplement, is suitable for carbonizing purposes. Steel of this character properly carbonized and heat treated will produce a part with an exceedingly tough and strong core and a hard exterior. This steel can be used for structural purposes, but is not especially suitable for this purpose. It is intended for casehardened gears and for such other casehardened parts as require both strength and hardness. The 0.20 per cent carbon nickel steel may be used interchangeably with that just described. It is intended primarily for casehardening purposes, but may, with suitable heat treatment, also be used for structural parts. The 0.25 per cent carbon nickel steel may also be casehardened successfully and is satisfactory for gears—either of the transmission or the rear axle bevel type. The treatment for carbonizing must be slightly modified to meet the increase in carbon content. It can also be used for many structural parts if subjected to heat treatment "H" or "K."

The 0.30 per cent carbon nickel steel is primarily used for structural parts where strength and toughness are required, for example, such parts as axles, crankshafts, driving-shafts and transmission shafts. Wide variations as to elastic limits are possible by varying the quenching mediums—oil, water or brine—and by variations in the drawing temperatures. This material may be casehardened, but is not suitable for that purpose. The 0.35 per cent carbon nickel steel is very similar to that just described.

The 0.40, 0.45 and 0.50 per cent carbon nickel steels are not widely used, but are available for certain purposes. A greater hardness is obtainable in these steels than in those of the lower carbon contents, but as increased brittleness accompanies the greater hardness the treatment given must be modified to meet these conditions. For example, the final quenching must be at a lower temperature in order to produce the desired toughness and other properties. The strength of these steels depends upon the heat treatment and may be controlled closely over a wide range.

Nickel-chromium Steels

There are three types of nickel-chromium steels in common use, known as low, medium, and high nickel-chromium steels. In general, it may be said that the heat treatment and properties of these steels are much the same as those of the plain nickel steels, except that the effects of the heat treatment are somewhat augmented by the presence of chromium. The low nickel-chromium steels with carbon contents up to 0.20 per cent are intended primarily for casehardening, while those with carbon contents from 0.25 to 0.40 per cent are intended primarily for structural purposes. Those with carbon contents from 0.45 to 0.50 per cent may be used for gears and other structural parts where a high degree of strength and hardness is demanded and where toughness is not of first importance.

The medium nickel-chromium steels are of the same composition as the low nickel-chromium steels except that they contain more nickel and chromium. Their general usage is practically the same as already mentioned for the low nickel-chromium steels.

The high nickel-chromium steels require different heat treatments from the other two types mentioned on account of the amount of nickel and chromium that they contain. Annealing before machining will be found necessary for these steels. The higher percentages of nickel and chromium make machining in a natural condition difficult. The steels with low carbon contents are casehardened the same as in the case of low nickel-chromium steels, and those with higher carbon contents are used for structural parts. In general, these steels are used for parts of an important character, and where unusual strength is demanded. The 0.45 per cent high nickel-chromium steel, for example, is used for gears where extreme strength and hardness are necessary. The carbon content is sufficiently high to cause the material to become hard enough to make a good gear when quenched, without being casehardened. This steel, however, is difficult to forge. During the forging operation it should be kept at a high or plastic heat and should not be hammered or worked after dropping to ordinary forging temperatures, as cracking is liable to follow. On the other hand, too high a temperature is not advisable, as the steel then becomes red-short and breaks.

Chromium-vanadium Steels

Chromium-vanadium steels are used for many automobile parts, particularly springs, axles, driving-shafts, and gears. They are used interchangeably with carbon steels, nickel steels and nickel-chromium steels. Those qualities which contain from 0.15 to 0.20 per cent carbon are intended primarily for casehardened parts, while those of from 0.25 to 0.50 per cent carbon are used for structural parts. The 0.25 per cent carbon steel may be casehardened, but is not suitable for this purpose. The 0.40 per cent carbon steel is of a very good quality, to be selected where a high degree of strength is desired coupled with a moderate measure of toughness. It is a first-class material for high-duty shafts. The 0.45 per cent carbon steel may be used for gears and springs. When used for structural parts, if an exceedingly high strength is desirable, heat treatment "T" should be used instead of treatment "U." The 0.50 per cent carbon chromium-vanadium steel is suitable for springs and gears. The final drawing temperature must vary with the section of material being handled; it must be taken into account, for example, whether light spiral springs or heavy flat springs are being heat treated.

Valve Metals

Specifications for valve metals are not given in tabulated form in the Data Sheet Supplement. Nickel valve metals, however, may be made to two specifications: Valve metal No. 1, which should contain not less than 96 per cent of nickel, and valve metal No. 2, which should contain from 28 to 35 per cent of nickel. These metals also contain carbon, not over 0.50, manganese, not over 1.50, and phosphorus and sulphur, each not exceeding 0.04 per cent; the remainder to be iron. These metals do not respond to heat treatment. The best that can be done with them is to treat them for the purpose of securing uniformity of structure by annealing or quenching at 1500 degrees F. or thereabouts.

Steel Castings

The specifications for steel castings are not given in the Data Sheet Supplement, but the following composition is desired:

Carbon, from 0.30 to 0.40 per cent (0.35 per cent desired);
Manganese, from 0.50 to 0.80 per cent (0.65 per cent desired);
Phosphorus, not to exceed 0.05 per cent;
Sulphur, not to exceed 0.05 per cent;
Silicon from 0.10 to 0.30 per cent.

This composition refers to genuine steel castings and not to malleable iron or complex mixtures often found in the market masquerading under the name of steel. Genuine steel castings should be annealed and may be heat treated to great advantage. A steel casting of the composition given in the specifications should be tough enough to bend to a considerable angle without breaking. The elastic limit of such a casting in an annealed condition is in the neighborhood of 35,000 pounds per square inch. Like other castings, steel castings are subjected to blow-holes. They are, therefore, not to be used in vital parts of the mechanism. It is impossible to inspect against blowholes, and steel castings for axles, crankshafts and steering-spindles are used only at great risk. The specifications given furnish a fair commercial analysis. Freedom from blowholes and proper physical conditions are of more importance than the exact adherence to the analysis given.

* * *

THE TITANIC TRAGEDY

Immediately following the wreck of the White Star steamer *Titanic*, which sunk April 15, a few hours after colliding with an iceberg 800 miles off the coast of Newfoundland and carried down over 1600 of the passengers and crew, an investigation was started by a United States Senate committee appointed to determine the facts of the disaster. Appalling as is the tragedy the facts of the contributing causes brought out in the sworn testimony of survivors are no less so:

It was shown that the captain had received wireless warnings of the proximity of icebergs, that a speed of approximately twenty-one knots was maintained in the face of the known danger, that the vessel was undermanned, that the passengers were not promptly warned of the imminence of sinking after the collision, that the lifeboat equipment was sufficient for less than half the passengers and crew, that the crew had not handled the lifeboats and were unfamiliar with the vessel, that the boats were not systematically filled, and that the wireless equipment of this and other vessels is inadequate.

The theory of the unsinkableness of modern vessels fitted with bulkheads dividing them into compartments, is based upon the supposition that collision would, at most, cause the rupture of not more than two compartments, but the experience with the *Titanic* shows the fallacy of the idea. When the iceberg was sighted a quarter mile dead ahead, the helmsman immediately shifted the rudder hoping to avoid the obstruction but instead the vessel "sideswiped" it and tore her side open, making a great rent probably over two-hundred feet long. Foundering was inevitable.

Great as is the loss of life, it is but a small fraction of the total annual human destruction due to accidents of the industries in the United States alone, which goes on year after year, creating hardly a ripple of protest in the world at large. To the average engineer the fact that this great vessel could be lost so quickly and so hopelessly is probably a greater shock than the loss of life. His pride of achievement is humbled; he is brought face to face with the grim fact that all the practicable improvements in marine vessels so far devised will be of little avail if the commanding officers are required to break speed records when dangers of fog, derelicts and icebergs are imminent. The energy of a vessel displacing 66,000 tons and moving at twenty knots is so great that almost any structure that can float will be torn asunder if that force is suddenly expended on it. Airtight compartments, that is bulkheads and airtight decks between, with pipes connected to a compressed air supply, might have saved the *Titanic* had the crew been disciplined to act promptly in a great emergency, but under the conditions existing as brought out by the Senate committee, it is doubtful.

* * *

Idler gears should be made as large as possible, because the wear on the teeth of these gears is twice as great as on the driving or driven gear.

HEAT-TREATMENT OF STEEL BY THE ELECTRIC FURNACE*

By H. RALPH BADGER†

In properly managed shops, the heat-treatment of steel is today receiving thorough attention. To produce a tool of such high quality that it will give several times the service of a tool that has not been properly heat-treated, is an important factor in shop economy. To accomplish this result it is necessary to know the laws governing the hardening of steel. If we clearly understand the causes underlying the changes which take place when steel is subjected to various heat-treatments, we have the basis for a positive control of the quality of the finished product. "Electric heat" is a new and important means to this end.

Heat-treatment of Steel

We heat and quench a tool because we want it to be harder. In every case the object of this treatment is to change, in some degree, certain of the physical properties of the steel. The effect of heat upon a piece of steel depends on the nature of the steel—that is, upon its composition, its form or external shape,

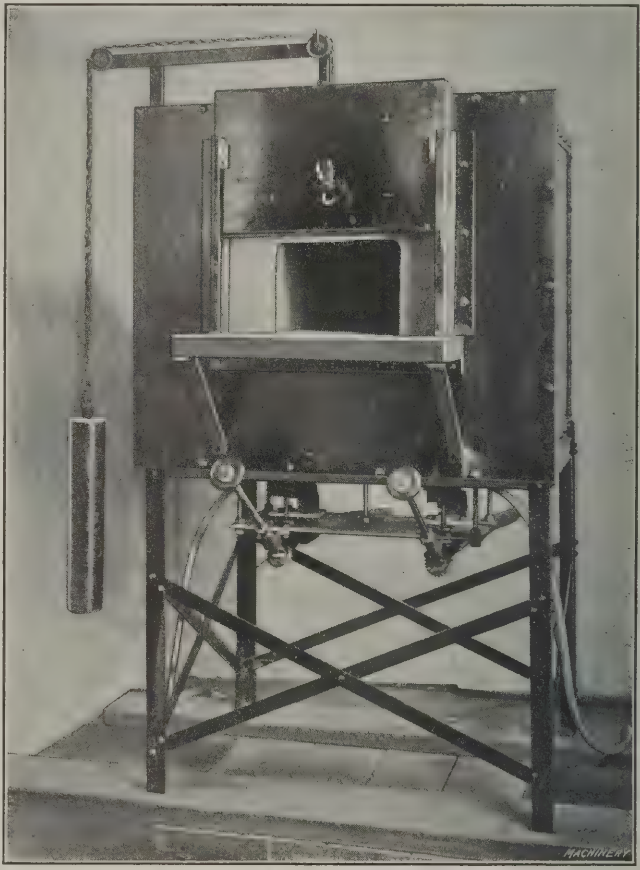


Fig. 1. Hoskins Electric Furnace for Use in Hardening and Tempering Carbon and High-speed Steel Tools

and its internal structure. The raising of the temperature of the piece sufficiently will produce a change in the form, so as to increase its volume by causing a lengthening in some directions. In the structure of the steel itself this may introduce mechanical strains in the fibers. Mostly, however, these are but temporary changes, and, with proper heat-treatment, they disappear when the piece is again cooled.

Changes in the chemical arrangement of the elements composing the steel are produced when the temperature of the

* For additional information on this and kindred subjects see the following articles previously published in MACHINERY: February, 1912, "Enamelite for Selective Hardening," and "Notes on Quenching Fluids"; January, 1912, "Hardening Solution for Tool Steel," "A Hardening Solution," and "Mixture for Hardening Tool Steel and Casehardening Machine Steel"; December, 1911, "Cramer Process for Hardening High-speed and Carbon Tool Steel"; November, 1911, "The Correct Use of Hardening-room Terms"; September, 1911, "Composition and Heat Treatment of Carbon and Alloy Steels"; April, 1911, "The Use of Barium Chloride for Heating Steel for Hardening"; August, 1910, "Hardening High-speed Steel"; June, 1910, "Heat Treatment of Carbon Steel," and "Apparatus for Hardening Milling Cutters"; June, 1910, engineering edition, "The Hardening of Carbon Steel," and "Hardening Carbon and Low Tungsten Steels"; March, 1910, "Hardening Small Blanking Dies"; January, 1910, "Hardening Carbon Steels." See also the previously published information referred to in connection with the last-mentioned articles, and MACHINERY's Reference Book No. 46, "Hardening and Tempering," and No. 63, "The Heat Treatment of Steel."

† Address: 26 Commonwealth Ave., Detroit, Mich.

piece is raised to a sufficient degree. These are the changes that are effective in hardening and tempering. If the piece, once heated to a sufficient temperature to produce hardening, is allowed to cool very slowly, these "changes" of chemical arrangements revert to their original condition; but if the piece is cooled quickly — quenched — immediately upon removing it from the source of heat, the changes are made permanent.

For steels of different composition, that is, made up of either different elements or of different proportions of the same elements (iron, carbon, etc.), there are different critical temperatures at which these changes take place. Corresponding differences in the heat-treatment are, therefore, necessary to produce the best results. Even two pieces of the same steel which vary greatly in their form must be treated differently. This is true also of two pieces of steel whose composition and form may be identical, but whose ultimate use may be different.

Examples of all three of these conditions occur constantly in shop practice. The intelligent hardener knows that a complicated die must be handled differently from a straight lathe tool, and a shaper tool for soft metal need not be as hard as one for hard metal, even though all of these pieces be made from the same steel. The next step ahead is to treat different kinds of steels according to their particular requirements. Various high-speed steels, high-carbon steels, and low-carbon steels are given individual treatment. Each is subjected to the conditions of heating and subsequent handling that will bring out the maximum of its useful characteristics. To meet the wide range of requirements and to avoid the losses of tools spoiled in hardening, there are three factors in the heating of steel which should be observed: First, the quality of the heat; second, its uniformity; and third, its degree.

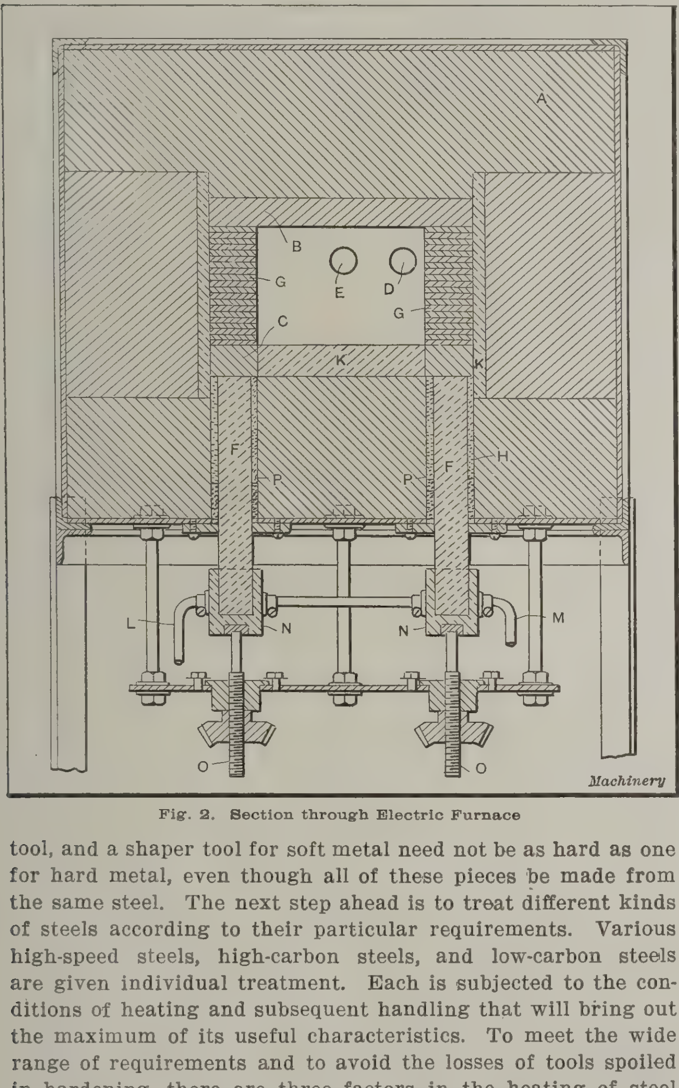

Fig. 2. Section through Electric Furnace

Under ideal conditions the steel would be subjected to a heat effect only, as this alone is necessary to produce the desired changes. In practice, however, it is difficult to produce heat of the necessary intensity without having the quality of it impaired by the presence of flames or oxidizing gases and sulphur and other injurious fumes. Freeing the heat from such attendant defects would obviously greatly improve the quality of the finished product; also the more uniformly heat can be applied to all parts of the piece, the more uniform will be the hardening or tempering. These two factors are positive and constant in their desirability for all ordinary work. The third factor—the degree of heat—is the variable quantity. It is this factor, the temperature, that is chiefly manipulated to meet the requirements of different steels and of the same steels for different purposes. While other conditions have a certain influence, the temperature is the controlling factor in all heat-treatment. The evil effects of too high a temperature—the common failing—are well understood.

The length of time during which the steel is actually heated is an important point closely connected to that of the temperature. With a heating chamber of sufficient size to supply the necessary heat to the piece, the internal change in the steel that results in hardening can be effected, in general, in one of two ways; either the piece may be heated for a short time at a relatively high temperature, or for a longer interval at a lower temperature. Both may produce hardness. The writer has seen fractures of small pieces of steel which after preheating were heated for but thirty seconds at a temperature 300 or 400 degrees higher than the hardening point, that compared very favorably with similar fractures of the same steel heated for four or five minutes at a temperature but little above the critical point. Thus the quantity of heat absorbed by the piece being treated is seen to be practically a product of the temperature of the heating chamber and the time the piece is left in it. In other words, the time of heating varies inversely as the temperature of the chamber in which the piece is heated. This still further emphasizes that "temperature should be the controlling factor," because, of the two extremes, the ordinary dangers of burning the steel on account of too high a temperature, and of causing it to crack due to too rapid, irregular heating, are far greater than those of "over-soaking" at lower temperature. To heat at the lower temperature is plainly the safe course, due both to its cutting down the grave danger of over-heating and to the greater uniformity with which heat is absorbed by the piece.

It is clear, then, that the heat-treatment of a particular steel can be greatly improved by definitely knowing beforehand the correct temperature at which it should be hardened. Also, when a large number of tools of approximately uniform sizes and shapes are being handled, the time necessary for proper heat absorption should first be determined, using an experimental tool that represents a fair sample. It will be found that the time element varies practically in proportion to the thickness of the steel. From the furnace standpoint, therefore the accurate and flexible control of the temperature is a most important consideration. A positive means, such as a pyrometer, for indicating at any time just what the temperature is, becomes, of course, an incidental requirement.

Until recently, the only known way of producing heat of the required intensity was by combustion—the burning of some fuel. The attendant disadvantages of this are well known. The crude open coal forge is capable of heating the steel, but leaves much to be desired as regards the quality of the heat, its uniformity, and the temperature control. In order to produce heat at all, the carbon in the coal must be combined with the oxygen of the air, and a strongly oxidizing flame is unavoidable. The steel exposed to this action, or to the inevitable results of it suffers accordingly. The coke-burning furnace offered some improvements, but only in detail. Now there are highly-perfected furnaces for burning oil and gas, and some of these offer still further advances, but the principle at the basis of all of these is the same—there must be a "burning" process to produce the heat; oxidization must be present with all fuel-combustion furnaces.

Through what means, then, may we obtain the proper quality of heat, uniformly applied, and of the right degree? The electric furnace for the heating of steel brings the answer. It overcomes all the objections to the "combustion process" by introducing a new principle.

Electric Heat

The heat of the electric furnace is produced in an entirely different way from that of the process of combustion. Electric heat can be produced by means of the electric arc, as in the arc lamp, and by the resistance of a conductor, as in the incandescent lamp. It is the latter principle—due to its greater flexibility and convenience—that was utilized by Albert L. Marsh in the electric furnace developed by the Hoskins Mfg. Co., Detroit, Mich., for the heat-treatment of steel. Fig. 1

shows a complete furnace of one of the larger sizes, the chamber in this being 18 inches deep (front to back), 12 inches wide and 8 inches high. The two hand-screws, directly under the operating shelf, are for the temperature regulation. In Fig. 2 the relation of the various constructional parts is clearly shown; *A* shows the fire clay insulation; *B*, the carbon connector plates; *C*, the graphite bottom plates; *D*, the draft hole; *E*, the pyrometer hole; *F*, the electrodes; *G*, the resistor plates; *H*, fire sand; *K*, cement filling; *L*, the inlet for the water used for cooling the electrode clamps; *M*, the outlet for this water; *N*, the electrode clamps, and *O*, the pressure regulating screws. The electrodes are surrounded by asbsetos at *P*.

The full length of the side walls and the entire roof of the chamber are formed by the heating elements; the walls are composed of a series of thin carbon plates resting on the top of a heavy block of the same material, and the roof, of a thick graphite plate connecting these two columns at the top. One graphite electrode projects up to the middle of each side-wall plate and connects electrically, through water-cooled clamps at the lower end, with the source of energy. The chamber floor is of cement. Outside of the carbon plates there is a lining of the same material. This lining, with a carefully designed backing of heat resisting material, retains the heat developed within the furnace. The counterweighted door fitted with a peep-hole serves as a quick access to the chamber, while in the rear wall are holes for the insertion of a pyrometer tube and for draft regulation. A rigid enclosing case of steel holds all parts securely.

The principle of operation is simple. A heavy low-voltage electric current is supplied through the electrodes to the resistor plates forming the side walls of the working chamber. Heat is generated here, due to the resistance offered by these plates to the passage of the current. The electrical "resistivity" of the carbon causes each plate to heat exactly as the carbon filament in the incandescent lamp "lights" when the current is turned on. In addition to this action, advantage is taken, in the furnace, of a second form of electrical resistance —that of the contact of one plate with another. This may be readily varied by altering the mechanical pressure on the plate columns by means of the hand-screws. The turning of these, changes the resistance of the circuit and hence the resulting temperature produced.

While the furnace is "electric" in its nature, it is not at all necessary that the hardening man handling it be an electrician. The simple electrical features of the furnace are quickly grasped. It is also safe, both because it practically eliminates the fire hazard and because it brings a corresponding protection to the operator. Normal working temperatures are acquired in a little over an hour's time after the switch has been closed. An average of 12½-kilowatt energy consumption will maintain the chamber at approximately 2250 degrees F.; higher temperatures, up to 2500 degrees F., which is even above the requirements of high-speed steels, or lower, as desired, may be obtained by increasing or decreasing the energy supply.

The life of the various parts of the heating unit is shown to be from 150 to 200 operating hours (for the side-wall resistor plates) to 500 hours (for the electrodes). Based on ten hour day operation, it is found that the upkeep cost of these items, even on this larger-sized furnace, is less than 40 cents a running day. The rest of the furnace does not depreciate rapidly.

The Advantages of Electric Heating

The atmosphere in the heating chamber of the electric furnace is inherently "reducing" in its nature, due to the fact that the hot carbon plates absorb all of the atmospheric oxygen. By raising the door slightly, and opening the draft-hole at the rear, a slight current of air may be admitted which will counteract this tendency. Leaving the door open slightly more would allow an excess of air to enter, so that an oxidizing atmosphere could be produced. Between the extreme points fine shades of atmospheric conditions can be obtained. Thus the quality of the heat can be absolutely and easily regulated.

Because of the arrangement possible with the electrical resistor, the heat may be generated within the working chamber itself. In the furnace described, the very walls of this chamber constitute the heat-generating device. The "resistivity" of the carbon plates is uniform—the same electric current runs through them all—with the result that an equal radiation of heat into the chamber takes place from practically every point in the walls.

In any type of furnace the temperature is varied, within limits, by varying the amount of energy transformed into heat. The regulation of the energy supply thus becomes the means of the temperature control. The electric energy control lends itself with exceeding exactness to meeting this principle. In the furnace described both a very fine and a wide regulation of temperature may be obtained by slight variations in the mechanical pressure between the carbon plates.

Commercial Importance

Mr. Samuel S. Roberts, testing engineer of the Carnegie Steel Co., is among the men who are carefully investigating the subject of steel heating furnaces. In an interesting report of a series of tests which he, together with a number of steel experts, recently made on the heat-treatment of carbon and high-speed steel tools in the electric furnace, he says in part:

"A realization of the inadequacy of the prevailing furnace designs usually employed for the specific purpose of hardening and tempering specially formed tools of high-speed steel, such as formed milling and gear cutters, twist drills, taps, threading dies, reamers and other tools that do not permit of being ground to shape after being hardened, and where any melting or fusing of cutting edges must be prevented, has created a demand rather than prompted the large tool steel consumers to welcome the advent of refined heating appliances, whereby the destructive influences hitherto encountered, are eliminated.

"The modern electric resistance furnace, with its perfect heat control, evenly distributed heat maintenance at any desired point, reducing atmosphere, absence of all products of combustion, and thermo-electric pyrometer for measuring the temperature, offers not only the most attractive method whereby the consumers of tool steel are insured maximum efficiency, but has caused the science of treating the rapid cutting tools, to take a long step forward."

The commercial importance of increasing the endurance and efficiency of the some 2400 cutting tools that Mr. Roberts points out require special heat-treatment monthly at the Homestead Steel Works, is self-evident.

Practical Application

As to the cost of operation, it is a demonstrated fact that the higher the temperature it is desired to produce, the lower the cost of electric heat in comparison with fuel heat. At the lower ranges, considering only the production of the necessary heat alone and with electric power at the usual commercial rates, heat from this source costs considerably more than heat from fuels, especially the cheaper ones. Where water-power supplies of electric current are available, this ratio decreases in favor of electric heat; but the cost of producing the energy for the heat-treatment is only a part of that of the whole operation involved. When we consider that this broad factor includes the resulting service of the finished tool, as well as the labor, material and overhead charges to produce it, we see how comparatively small this part is. It is from such a view of the entire cost of production that the improved hardening of steel in electric heat is seen to be a real economy. The electric furnace, due to its advantages, makes possible a higher quality of product than is possible with fuel heating.

* * *

The immense inertia overcome and the speed developed in electrically-driven machinery of recent years is almost inconceivable. One example is that of the reversing motor drive for a large plate mill installed by the Crocker-Wheeler Co. last year in the works of the American Sheet & Tin Plate Co., at Gary, Ind. The weight of the revolving parts of the reversing motor is about 100,000 pounds, and it is ten feet in diameter. The reversing of this motor and of the rolls from fourteen revolutions per minute in one direction to fourteen revolutions per minute in the other is accomplished in the amazingly short time of nine-tenths of a second. This means that this electrically-driven mill reverses more quickly than any other of its class. Thus a point on the face travels in one minute a distance of 15,708 feet or practically at a rate of 180 miles an hour. Power for operating this reversing motor is supplied by a motor generator set having a 60,000-pound steel flywheel ten feet in diameter running at 500 revolutions per minute.

HOW CAN THE MECHANICAL JOURNALS BE MADE OF THE MOST VALUE TO THEIR PATRONS?*

By FRED E. ROGERS†

The answer to the question can be put in one word, and that is cooperation. This paper will then be for the most part an explanation of my views on what cooperation between the reader, advertiser, publisher and editor means and how it can be promoted. I am, of course, addressing men who are chiefly interested in the machine business, but much that is said applies to technical journalism generally.

Trade and Technical Journals.—The term "trade journal" is indiscriminately and improperly applied to many specialized publications. A trade journal is one that is exclusively devoted to the news of a trade, giving prices, sales, accounts of new projects, changes in personnel of concerns, combinations and other matters of a purely commercial nature. This term cannot be properly applied to the leading mechanical journals, as they are really technical publications containing little of a purely news character, as news is regarded by the daily papers. They are chiefly given over to the science and practice of a specialized business and are recognized mediums for the exchange of the best ideas on theory and performance. They are, in short, the invaluable records of progress which have materially assisted in the upbuilding of the industries they represent.

Specialization in Journalism.—Not many years ago the leading journals in the mechanical field published matter on railway operation, locomotive running and repairs, car building, machine shop practice, general manufacturing, steam engine and boiler design and construction, foundry work, bridge building and many other topics with which the old-time engineer was supposed to be generally conversant. In America there is now a well-defined specialization among engineers, and the technical journals are sharply differentiated by the subjects to which their pages are chiefly devoted.

Printing and Publishing.—Contrary to a not uncommon belief, the business of publishing periodicals is quite distinct from printing them. Not all publishers are printers any more than all printers are publishers. I mention this to show that the business of publishing a technical journal is somewhat intangible, consisting essentially of an organization having three definite objects—first, to produce a journal which readers will subscribe for; second, to obtain a circulation which makes the advertising space valuable to manufacturers in its field; and third, to secure advertising patronage from the manufacturers in the field which the journal represents. This is the logical order in which these different departments of the business should be placed, but frequently inexperienced publishers endeavor to reverse the order, putting the advertising first and the circulation last. Advertising is necessary for any periodical under present conditions, and the advertising income is more than three-quarters of the total. The subscription income is barely sufficient to pay for the white paper and postage.

But though I have placed the editorial function, that is, the collection and presentation of suitable reading matter in the first place it is really one leg of the tripod on which a publishing business is supported. The reading matter is that which gains and holds a paid circulation among the men to whom the products displayed in the advertising pages appeal; without circulation the advertising will not bring returns; and without advertising patronage the modern trade journal cannot be maintained.

Value of the Reading Pages.—For the sake of emphasis we will expand a little in following around the circle of relative values. It is the circulation of a paper which gives the advertising pages their value, and it is the reading pages which maintain that circulation, although we are not unmindful of the fact that a paper may be of little value, or it may contain no matter at all, and still have a circulation. There is a vast difference, however, between a paper containing high-grade technical matter and one having little or no material that would interest an engineer, superintendent or foreman. One is creative, the other a drone in the hive; one educates and contributes much toward mechanical development by the interchange of ideas between superintendents, designers, foremen and machinists, whereas the other is a non-producer and contributes nothing. The real value of a mechanical journal, then, can be gaged to a large extent by the educational value of its reading pages, because the demand for modern equipment is directly proportional to the knowledge possessed by those who are to use the equipment. A journal without interesting reading pages has no backbone. What that means is clearly stated in the little girl's definition: "The backbone is something that holds up the head and ribs and keeps one from having legs clear up to the neck."

Technical Advice.—Every technical journal acts in an advisory capacity to many readers who look to it as being an authority on machine design, mechanics, kinematics, patent law, mechanical history, etc. We have no fault to find with this attitude, but encourage it, as we believe that while it is not the province of a technical journal to run a free consulting bureau on every topic, we do feel that there are many subjects on which the readers naturally turn to us for information, and which is practically their inherent right. To make our work of greater usefulness we have recently retained a well-known engineer in a consulting capacity to advise upon those technical matters in which he is especially proficient. I mention this to show you what our conception is of the relation of a trade or technical journal to its readers.

While it may be that the problems that stump you will also stump the editor unaided, remember that he is in close touch with an army of men—machinists, toolmakers, draftsmen, engineers, superintendents and others—who are up against almost every conceivable problem in the world of mechanics. Your mechanical perplexities turned into the editorial sanctum will act as suggestions, if nothing more, for articles and editorials on subjects of timely and vital interest. You probably know that the mechanical journals receive many more contributions than they can publish. The ratio of articles rejected to those accepted in the case of the journal I represent is about as one to one. More than fifty per cent of the number offered cannot be used. Many of these articles are well written and sound in argument. Their rejection is mainly due to lack of available space. No doubt in some cases we return articles that would be very helpful to some and which we would have used in preference to others had we received an intimation from any reader that he was interested in the subjects treated.

Make Advertising Interesting and Instructive.—The advertising pages of a mechanical journal should be and can be made as interesting and as instructive to the progressive and ambitious mechanic, whatever his position may be, as the so-called reading pages. Years ago mechanical journal advertising was stereotyped and lifeless; it was hardly changed from one year to the next. Electros were run until worn out and changed only when the advertising solicitor came around to secure a renewal of the contract. We believe no advertisement should be repeated consecutively, and that the copy should be changed every issue; also that those who devote as much attention to the furnishing of live copy as to any other branch of their selling organizations will realize as definite results.

The advertisers should cooperate with one another as well as with those who publish the journal. It may seem strange to speak of cooperating in an arena where you are seeking to gain advantage over competitors, but it can be done. To show what I mean let us think of a plant that is to be equipped with machine tools for building, say, gas engines. The engineer who selects the equipment will first decide on a certain number and size of so-called standard machine tools to be installed. In other words, he plans an ideal shop according to his understanding of the needs of the case and then specifies in general terms the equipment that should be purchased. He has planned for that which certain ones of you will furnish. Now why can there not be established an understanding between groups of machine tool builders to the end that they will advertise in harmony, having in mind certain combinations of equipment which are most often specified? Take, for ex-

* Paper read before the semi-annual convention of the National Machine Tool Builders' Association, Atlantic City, N. J., May 16-17.
† Editor of MACHINERY.

ample, ten machine tool builders. They could use ten pages of advertising space in conjunction to much greater advantage than when working independently. In this space plans and specifications of much value could be set forth and the references to the various makes of tools would be read with an entirely different understanding by a large part of those whom you seek to interest. This, of course, is a very rough idea, but I leave it with you as a suggestion for cooperative work in plant engineering that may be worthy of your consideration.

Photographing Work of Interest.—You should know that a camera and a dark room properly fitted up is one of the best investments for publicity that you can make. It is not necessary to hire a regular photographer, if the amount of work is comparatively small; the equipment can be turned over to one of your men who has a taste for photography, with instructions to photograph every interesting job of work having features out of the ordinary; also to photograph the erecting floor regularly, say once a week. These photos should be dated, and a sure way to prevent confusion is to display the date in the foreground, using a suitable changeable sign for the purpose. These photographs will serve you in more ways than one. They will give you a record of the shop conditions from week to week and in the case of special work often secure valuable publicity. Editors traveling in the interest of their publications are hungry for such photographs and will often gladly publish them with descriptions. To make these photographic records of the greatest value they should be accompanied with memoranda giving the main features of special work, such as weight of castings, time of operations, nature of operations, tools employed, etc. These photographs are, of course, valuable also for your catalogues and advertising.

Editors and Advertising Men.—One of the things that distresses the editor is to be mistaken for an advertising man and to be treated as such. In the first place he feels that his salary is not commensurate with the responsibilities of that exalted job, and in the second place his training has not given him that confidence of approach which is one of the best assets of your successful "ad" man. But although the editor does not come to you as an "ad" man, he nevertheless believes in advertising and will gladly advise you about advertising copy and the best way to obtain the widest publicity for your new machinery and tools.

This subject of publicity for new products is, by the way, one of the greatest importance to you. Every manufacturer should know how to introduce his new products to possible customers to the best advantage. He should know that a description of a machine embodying new principles or combinations is news matter to the field covered by the journals and is so regarded by their editors. But news is no longer news to an editor when it has been published by his contemporaries weeks or months before being offered to him. It may be argued that the competing journals do not go to the same general readers, which is in the main true, but they do go to the same advertisers; and the moral effect of stale news is detrimental in the long run to the journals that publish it.

"Write-ups" and Descriptions.—All of you, of course, are aware of the great change that has come about in the ethics of technical journalism during the past few years. Twenty years ago an advertising contract in a mechanical journal virtually carried with it the right to publication of "write-ups" of any old tool or machine at the discretion of the advertiser, without regard to the value of the matter or the truth of the claims made for the machines. The technical journals were worked to take as much of this free advertising as the editors would stand for. One firm of machine tool builders actually used to send electros requiring a full page space. Today none of the leading technical journals will insert anything of this character; the use of reading matter is strictly based on its merit, and if this policy is consistently adhered to no manufacturer has just cause for complaint. No journal that is filled with write-ups can obtain or hold any considerable number of readers, and without the readers of course the advertising space has no value.

You can help the editors and that means benefiting yourselves when writing descriptions of new things to include all matters that a customer is likely to inquire about. No doubt many points obvious to you may seem trivial, but on the plan of leaving nothing in doubt, put it down in black and white. A specification list is the most useful data you can furnish if disinclined to write letters fully describing the features, but never omit to call attention to those points in which the machine differs from its predecessors. Standard engine lathes are about the most difficult things to describe enthusiastically, but even these can be made interesting to possible buyers by giving spindle bearing dimensions, weights, back-gear ratios, power of motors required, etc.

Eligibility of Descriptions of New Products.—The specialization of technical journals and consequent narrowing of the fields to which the editorial pages are principally devoted, of course restricts descriptions of new machinery and tools generally to those classes displayed in its advertising pages. This may at first appear to be a narrow policy, but it is founded on very good reasons. First the demands for space in the reading pages for descriptions of new products often tax the available space to the limit, and second the appearance of those things that are distinctly foreign to the general character of the reading matter lowers the tone, being, of course, uninteresting to the average reader. For example, a description of a new road roller in a journal devoted principally to machine shop practice, machine design and closely related topics could not be justified on the ground that the subject is of general interest to the readers of that publication. The only justification for publication of a description would be that the mechanism is inherently interesting and that novel principles are employed that might be applied in other machines, and for that reason would be of interest to designers.

The test that you can readily apply to determine for yourselves whether a description of a new product would be welcomed by the editor of a technical journal is to decide whether or not you would advertise it in that journal. If you believe that advertising would pay, that means the general character of the journal should appeal to the class likely to be interested in your new machine.

Syndicate Matter.—If you have a piece of general news matter for distribution among technical journals it should be sent to the selected publications with a letter stating frankly that it is being sent to several and setting a release date, that is, a date some days or weeks ahead when it is to be published. This practice of syndicating, borrowed from the daily and weekly newspapers, is not favorably regarded by the editors of technical publications. Newspapers circulate in a limited territory, having a radius of say three or four hundred miles. The technical publications go all over the world and though not two per cent of the ordinary subscribers regularly read more than one, manufacturers often subscribe to several and their engineers see them all. The cheapening effect of the same articles in all makes the distinction obvious. However, the distribution of syndicated matter will often result in publicity in many journals in the way of extracts, abstracts and editorials, and some will publish in full. The editors under such conditions feel free to make such use of the matter as their judgment dictates and if you play fair with them they will generally be good to you.

Illustrations.—Remember that the day of the electrotype for editorial purposes, in the mechanical field at least, has practically passed away. Don't waste postage by sending electrotypes of your new products to illustrate descriptions that are to be published in the reading pages. They rarely will be used. In the first place they are hardly ever of the right width to suit the columns, and in the second place the style is hardly ever in harmony with the style of illustrations used. Instead of sending electros, send good photographs, either gelatine prints or glossy velox for halftones and regular blueprints for line illustrations. If the photographs have required much retouching to bring out details clearly you can keep them in your possession and send photographs of the retouched photographs. For line illustration copy it is not necessary to go to the trouble of making special drawings without dimensions. Simply blue pencil the dimensions and parts you do not want used. All that the editor is generally concerned with are the principles of construction and operation, and dimensions are preferably omitted.

Changes in Personnel.—We welcome all news regarding changes of personnel in your organizations. These should be sent to the journals in all cases whether they are to be published or not. Of course important changes should always be published for the information of those who have dealings with you in any way. So much for the business side. Recognition of the personality of employes is a policy that almost invariably pays and often you can please a man immensely without unduly swelling his head by sending in a personal item on his promotion to a position of some importance.

Catalogues and Other Literature.—All new catalogues and other advertising literature should be sent to the journals in your field as soon as published. We strongly advise that a letter be sent at the same time advising that the matter has been sent and calling particular attention to the new machines and tools listed. You will be pleasantly surprised sometimes no doubt to have your own words used in the notice if you have taken pains to express accurately and concisely what the contents are. Now don't think that we want you to fix up everything nice and easy so that we will have nothing to do, but on the principle that tne knowledge anyone has on a given subject because of his intimate connection with it is better than that of one who can only devote a few moments to it, we ask for an expression of your ideas of what should be of general interest in your line to our readers.

Criticism.—Criticism is of two kinds—constructive and destructive. We call the latter "knocking" and no one relishes it, but all enlightened men, which, of course, includes all editors, welcome honest criticism of their publications, by which we mean the pointing out of mistakes and errors of statement. I suggest that you can do no greater service to the technical press than by systematically writing to the editors and telling them which articles you like best and which ones do not meet with your approval; by this I mean, the collective opinions of your men as well as of the management. These criticisms should be made with the knowledge that the editors endeavor to publish matter that will be helpful to men in every mechanical pursuit besides the building of machine tools.

Playing Favorites.—Don't believe that editors favor one concern at the expense of another. If your competitor gets considerable free publicity in the reading pages, you may be sure that "he has the goods" and has afforded the editors the opportunity to see his practice and describe it fully. They will be glad to do the same for anyone else and will be your willing slaves if you have stuff for good copy.

Discussions and Disputes.—Sometimes an article will be published, perhaps unconsciously, in the interest of a competitor which puts forth certain claims that you take exception to. You are entitled to a hearing and should take advantage of the columns of the same paper for a rebuttal if you have a good case, but that rebuttal should never descend to abuse or personalities, for it is not likely to be published if it does. Do not put the editor in the "undesirable citizen" class because of such outcome without carefully weighing the case and looking at it from all possible points of view.

Filing Articles for Future Reference.—Hardly any engineer commits to memory a large number of rules and formulas for deducing the strength and proportions of machine parts. The volume of specialized mechanical lore is so great that the human mind cannot retain in an orderly and workable shape the mass of data available. The engineer's education is chiefly on means and methods of applying a science, the record of which is mostly in books and periodicals. To apply the known laws accurately we must employ the methods of mathematical analysis. Hence the engineer is more or less of a mathematician in his manner of thought and the way he attacks a given problem. But in order to profit most from what others have done as recorded on the printed page, systematic records are necessary; hence the importance of keeping card indexes of the articles in the technical journals in your field. The present speaker is not in favor of clipping files where space is available to keep the bound volumes of the journals themselves. A clipping file is generally of value to the compiler only, and to even him its value is problematical. A change in his position, or a change in the activities of his concern may make necessary an entirely new line of research and if his bound volumes are available the articles that he previously cared nothing for may have become of great value.

Manufacturers should keep files of the leading journals in their industry properly arranged and indexed for the benefit of the engineers or draftsmen. The latter can hardly afford to do it for themselves. Many a man is working over a drafting-board for a draftsman's salary who is truly an engineer within the limited range of his activities and should be credited with all the ability he displays and be encouraged to keep records of engineering data at your expense.

Trade Secrets.—One of the troublesome things that gall editors is the attitude of many manufacturers toward "trade secrets" and alleged trade secrets. We realize that commercial prestige and success in some cases depend upon keeping certain processes and methods closely guarded, but in the manufacture of metal products there is very little indeed that is not known to a large number of men who are well-versed in their trades. The plant that excludes visitors in order to keep its specialized knowledge *in*, by that policy generally keeps *out* the knowledge of what is going on elsewhere. A close corporation—close in the sense of keeping its methods secret—will eventually die of dry rot. A policy of secrecy puts the management at the mercy of its superintendent and foremen and workmen. The writer has found in a few cases that superintendents foster the idea that many of the methods introduced by them are original and should be carefully guarded, when as a matter of fact they originated elsewhere. These employes build themselves up by deceit and lull the management into a state of fancied security when their supposed monopoly of special processes has existence only in their imaginations.

Now as to the best policy to accord to editors in regard to real secret methods. It is our belief that the best way to guard them so far as general publicity is concerned is to take the editors of reputable journals into your confidence and show and explain to them the general principles employed. You will thus preserve the methods from publication in the first place if they are actually known only in your plant, or in the second place you may learn that you have been deceived and that your supposed secret is no secret at all.

To illustrate how effectively the confidence of a manufacturer may safeguard his interests, the following example is taken from personal experience:

A manufacturer of small tools notable for his courtesy to visitors some years ago personally conducted the speaker through his plant and in the course of the inspection showed him the principal features of the toolmaking practice followed in making certain tools. This work was of extraordinary interest, and permission was asked to publish a description, which was courteously denied for good and sufficient reasons. In the course of a few weeks the editor received a contribution describing minutely a system of making tools that seemed strangely familiar and which upon reading closely was recognized as a literal description of the practice of the concern mentioned, although no name was given. Of course we could not publish that article, much as we wanted to. If our friend had not taken us through his plant and shown us his practice, we would have known nothing about it and would naturally have published the contribution. The fact that the article has never been published elsewhere leads us to suspect that other editors also have been muzzled in this very effective manner.

The Advantages and Disadvantages of Publicity.—A manufacturing enterprise that produces dividends for its stockholders has to solve two main problems which are: the making of a product and the marketing of it. That the manufacturing of most goods is easier than selling them is generally conceded. It is a curious anomaly of our present commercial system that to induce a customer to purchase a thing he wants and intends to buy often costs more than to produce it. Whether this condition is due to the machinations of the middlemen, the stupidity of customers, or economic relations too subtle to define, is not our province to determine. The fact is that publicity is the breath of life of modern business.

The cautious man objects that his competitors will find out all about his methods, and says that would never do. The cautious man is right in saying that his competitors will learn about his methods—but most of them they already know. They will know, however, what the methods of the cautious

manufacturer are and that may be of some disadvantage, even if they are common to the industry. In fact, general advertising sometimes works to one disadvantage in that it usually stimulates competition; but that is unavoidable. The thing that must be kept clearly before the manufacturer's eyes is his public. What matter if he does give away some information to a few competitors, when at the same time he gains the appreciation of thousands of possible customers? Let the manufacturer educate his public and take them into his confidence and never mind about the competition. When he has the public tagging after him the competitor will have to do some shouting for himself to keep the wolf from his door.

Technical Journals Educational Forces.—The technical journals should be recognized as one of the most valuable aids in selling machinery and accessories. The reason is, they are educational. To sell anything you must first create a demand. There are several ways of creating a want for that which you produce. Your salesmen can go to manufacturing plants and tell their managers all about the economy and accuracy of your machines; you can tell the same story by advertising, but lastly and most effectively your representative journals by editorials, descriptive articles and discussions of the principles of design create in the minds of your possible customers ideals which you will be required to fulfill. In other words the educational force of the technical journals rightly directed influences users of machinery unconsciously to want the best that is produced. Thus the more you help to make the mechanical journals more valuable to their readers, the more you contribute to your own success.

Help us to help you.

AN EXPERIMENT IN EXTRUSION*

By CHESTER L. LUCAS†

The success with which aluminum, copper, and brass tubes and shells have been made by the extrusion process led the writer to experiment with the extrusion of wing-nuts and similar articles. While the results of these experiments were not wholly satisfactory, an outline of the work done may be of interest, and should be of value to others working along the same lines.

Most of this experimenting was done in trying to produce a brass wing-nut similar to that shown at *A*, in Fig. 1. The wing-nut, with its principal dimensions, is also shown in the line engraving, Fig. 2. The desire to produce such a piece arose from the fact that on the outside of each of certain instruments that were being manufactured at the rate of two thousand per week, two of these wing-nuts were required. Cast brass wing-nuts were being used at the time, and as the rest

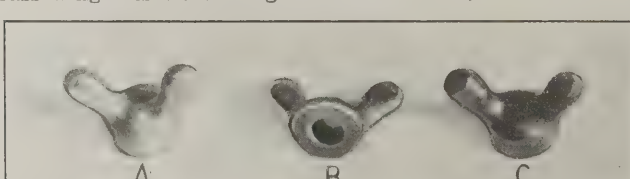

Fig. 1. Extruded Wing-nuts—A, Aluminum; B, Zinc; C, Brass

of the instrument was finely finished, the contrast between the rough cast wing-nuts and the rest of the instrument was marked, especially as the wing-nuts were not polished. A small wing-nut is a difficult piece to polish cheaply.

An experimental pair of dies was first made on the principle shown in Fig. 4. This first set of dies, however, was not as large in proportion to the size of the wing-nut as that shown in the illustration. First, a ring was turned from carbon steel, hardened and tempered to a very dark straw color, after which the interior was ground out true with the bottom face. Within this cylindrical opening were fitted the two die sections, which, together, fitted the interior of the ring closely. In the face of each of these sections one-half of the shape of the wing-nut was cut, so that together the two halves comprised a steel mold. It was very necessary to have the outline in one half match perfectly with the outline in the other half. Referring to Fig. 3, it will be noticed that the impression for the cylindrical part of the wing-nut was made considerably longer than that part of the nut itself. This was done to provide a guide for the extruding punch as it acted upon the metal.

The extruding punch was made of one piece of carbon steel, with its largest diameter ground a sliding fit for the ring; the smaller diameter was a sliding fit in the circular impression in the two die-sections, and the purpose of the pilot on the end of the punch was to form the central hole in the wing-nut. This pilot was made slightly tapering, so that it could be easily withdrawn from the finished work. Both sections of the

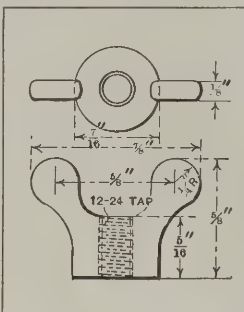

Fig. 2. Dimensions of Wing-nut to be extruded

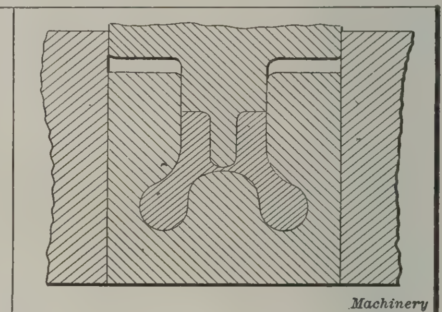

Fig. 3. Section of Die and Wing-nut after Extrusion

die, as well as the punch, were hardened, and the temper was drawn to a light straw color, except for the tip end of the punch, which was drawn to a purple color.

While the object of this die was to ascertain whether or not it would be possible to extrude a brass wing-nut, the softer metals were tried first, to see how the dies would work. Accordingly, a piece of lead was turned to 7/16 inch diameter, and several pieces, each about ½ inch long, were cut off. One of these pieces was placed in the die cavity as shown in Fig. 4, the punch placed on top and pressed in under a hand screw press. The dies were then pushed out of the ring, separated, and a perfect lead wing-nut was picked out of the dies. Aluminum was then tried in the same manner, with equal

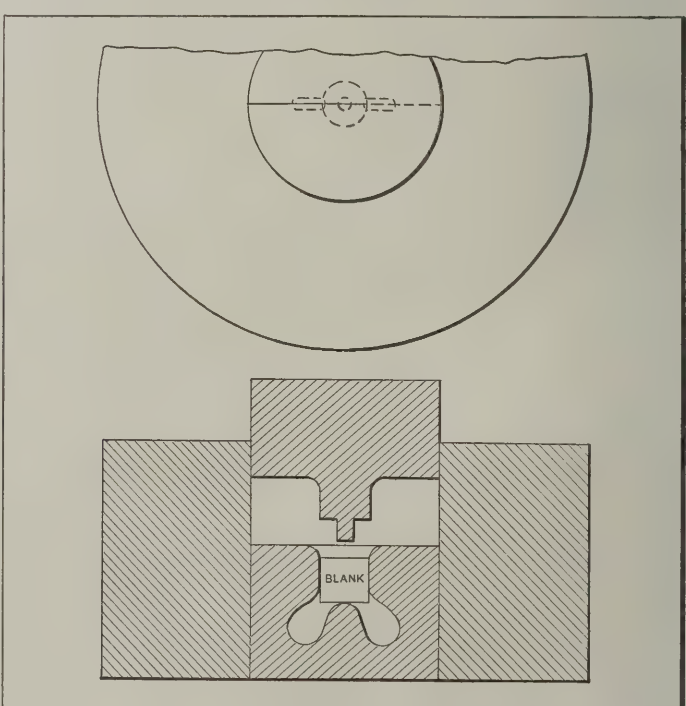

Fig. 4. An Extrusion Die, Punch and Ring, with Blank in Position

success, being extruded in the hand screw press very easily. Zinc, which is looked upon as a "dead" metal, extruded without trouble. Aluminum and zinc extruded wing-nuts are shown at *A* and *B*, Fig. 1. It was also found that several small scrap pieces of any of these metals could be used in place of a solid blank, and the resulting wing-nut was apparently as homogeneous and strong as one made from a solid blank. The pressure required for extruding seemed to unite the particles

* See MACHINERY, October, 1911, engineering edition, "The Extrusion Process"; November, 1911, "The Extrusion of Shells and Tubes"; December, 1911, engineering edition, "Making Collapsible Tubes by the Extrusion Process."

† Associate Editor of MACHINERY.

of metal in a permanent manner. By varying the amount of metal in the blank, the body of the wing-nut could be made longer or shorter as desired. It was not considered practical to put the hole entirely through the wing-nut when extruding, on account of possible injury to the die or punch; the idea was to put the hole nearly through and rely upon the tap in tapping to push through the remaining 1/64 inch of metal.

The extrusion process gave the nuts made of these soft metals considerably more strength than the cast brass wing-nuts possessed; in fact, the zinc and aluminum wing-nuts were very much stronger than the cast brass wing-nuts, but "their color was against them." As the studs upon which the wing-nuts were used were made of brass, and as the other instrument trimmings were also of brass, it was thought desirable to have these parts of brass also.

When experimenting in brass, however, the troubles began. Although the softest brass possible was obtained, and although all methods of annealing were tried, the pilot on the punch would invariably break before the extrusion had fairly begun. After making several new punches of different degrees of temper, it was decided to omit the pilot, drilling the hole in a subsequent operation. Next, trouble in the extrusion itself arose; the brass would extrude about half way into the wings, at which point the limit was apparently reached. In order to make the brass flow at all, a power screw press was necessary, and upon forcing the metal beyond the point mentioned, the dies cracked.

A pair of dies was then made from Ajax high-speed steel, and in the meantime the leading brass manufacturers were applied to for samples of their softest brass rod. The new dies proved to be all that could be desired, but the brass would not go beyond the apparent limit—half way into the wings of the nut. Upon striking harder blows with the press, a wing-nut, shown at *C*, Fig. 1, was produced. This wing-nut, except for the tip of one point, was "full," and several others, all more or less defective, were extruded. The few brass wing-nuts that were made were found to be extremely hard and close-grained; in fact, they were a great deal harder than necessary and would have been very difficult to drill and tap. After making two or three of these brass wing-nuts, however, the dies broke, owing to the excessive stress.

About this time it was decided that the extrusion of a brass wing-nut was impracticable, and the experimenting stopped. It would, however, seem as if it should be possible to obtain a grade of brass or composition having a faint yellow color that possesses some of the extruding qualities common to zinc and aluminum, or that at least would be softer than commercial brass. With such a metal, wing-nuts and similar articles could be easily extruded, and dies could be made that would work automatically, receiving the blanks from a hopper feed, and permitting the press to be continuous in its operation. If anyone else has had experience along this line, the results would undoubtedly be of interest and value if published.

[The question may be raised as to the propriety of including the foregoing experiment as an example of extrusion. The extrusion process ordinarily produces shapes conforming to the opening of a die, the product taking its ultimate form as it is ejected by pressure, exerted through a punch or ram. In this case the ears of the wing-nuts are not extruded beyond the die but are forced, by the pressure exerted through the punch, into cavities in the die which have the shape required to be reproduced. This process seems to be a combination of extrusion, and cold swaging or die-forging.—EDITOR.]

* * *

The U. S. S. *Florida*, which has just won the title of the world's fastest battleship, broke all speed records off the Atlantic Coast with propellers of monel metal. The *Florida* attained a greater speed than its sister ship, the *Utah*, which was not equipped with that material. Monel metal is very suitable for propellers. It has the strength of steel, shines like silver, and is less corrodible than bronze. The non-corrodibility is a strong asset, as it assures the propeller's cutting the water cleaner. Propellers of this material have been furnished battleships of the United States and foreign navies.

WUEST HERRINGBONE GEARS

Having read the article in the January, 1912, number of MACHINERY, engineering edition, entitled "Herringbone Gears," the writer is prompted to make a few remarks. Let

P = normal diametral pitch,
P_n = normal circular pitch measured on the normal helix (pitch measured on the pitch cylinder perpendicular to the face of the teeth),
P_c = circular or circumferential pitch measured on the circumference of the pitch circles,
N = number of teeth,
d = pitch diameter,
D = blank diameter,
α = angle of teeth with axis of gear. (In this case $\alpha = 23$ degrees.)

Then, for spur gears, with teeth cut straight, we would have:

$$d = \frac{N}{P} \qquad (1)$$

and for spiral gears:

$$d = \frac{N}{P \cos \alpha} = \frac{N P_n}{\pi \cos \alpha} = \frac{N P_c}{\pi} \qquad (2)$$

As herringbone gears are spiral gears, Formula (2) will hold true. In the article mentioned, however, Formula (1) is applied. Apparently, the author of that article assumes the pitch to equal a certain quantity p, as follows:

$$p = \frac{\pi}{P_c} = P \cos \alpha = \frac{\pi \cos \alpha}{P_n}, \text{ and } d = \frac{N}{p}$$

This, however, is not standard practice, as it is not p but P which is the quantity commonly called the diametral pitch in spiral gears.

Furthermore, in order to keep the center distance to some even dimension, the author simply reduces the pitch diameter of the gear to suit the center distance. By doing this, and keeping all the other quantities the same as before, the pitch of a gear is changed without changing the pitch of the pinion; hence, the gears will not mesh perfectly. The difference may be small, but interchangeability cannot be claimed on this basis.

Rheydt, Düsseldorf, Germany. G. R. HULSBERG

Reply by Percy C. Day, Milwaukee, Wis.

Your correspondent, Mr. G. R. Hülsberg, evidently finds it difficult to regard herringbone gears as spur gears. He has applied the same methods as are used for calculating ordinary spiral gears, and has complicated the problem to an unnecessary extent. Spiral gears are usually employed for connecting shafts which are not parallel to each other. Under these conditions the circumferential pitch of gear and pinion may be quite different, but the *normal* pitch of both must be the same.

In herringbone gears, if the spiral angle is made constant, there is a definite and fixed relationship between the normal and the circumferential pitch. This is the case with Wuest herringbone gears. It is a great convenience to discard all reference to the normal pitch and treat the gears just like spur gears on the basis of the circumferential pitch. When this is once done, it makes no difference whether the circular or diametral pitch system is used. It is, of course, necessary for the gear cutter to set his calipers to the normal tooth thickness, and if circular cutters or inclined hobs are used they must be designed for the normal pitch; but the designer of machinery involving the use of these gears need not be troubled with any such complications.

Wuest herringbone gears are cut by specially constructed hobs which are used with the hob axis perpendicular to the gear axis. The pitch of each hob, measured along the axis in the same way as the pitch of a screw is measured, is the same as the circumferential pitch of the gears which it cuts. The normal pitch line thickness of the hob is a matter for the toolmaker alone.

The point raised in regard to the use of enlarged pinions is not so easily understood and requires a clear definition of what constitutes the "pitch diameter" and the "pitch" of a gear.

Let us suppose that we wish to connect two shafts a and b by means of a pinion and gear. Let

L = distance between shaft centers,

$$V = \text{velocity ratio} = \frac{\text{R.P.M. of } a}{\text{R.P.M. of } b}$$

N_a = number of teeth in pinion,

N_b = number of teeth in gear,

R_a = pitch line radius of pinion,

R_b = pitch line radius of gear,

P_c = circular pitch of gear and pinion.

Then

$$V = \frac{R_b}{R_a} = \frac{N_b}{N_a};\ L = R_a + R_b;\ R_a = \frac{L}{V+1}$$

$$R_b = L\left(\frac{V}{V+1}\right);\ P_c = \frac{2\pi R_a}{N_a} = \frac{2\pi R_b}{N_b}$$

If the center distance and velocity ratio are given, then the true pitch diameters of the gear and pinion are fixed. Now it is well known that involute gears will run satisfactorily when set farther apart than the designed center distance. In other words, L may be varied to a limited extent. This variation of L does not affect either the number of teeth or the velocity ratio, but it alters the pitch. The foregoing arguments lead to the curious conclusion that the pitch of a pair of involute gears has no definite value, but depends on the center distance and velocity ratio. Conversely, if we maintain a fixed center distance and ratio for a given pair of gears, we can cut involute teeth in various ways without altering the pitch.

For instance, if we require a small pinion to mesh with a large gear, we may generate the teeth to standard thickness on their true pitch diameters or we may enlarge the blank diameter of the pinion and reduce that of the gear by a corresponding amount. The teeth will be generated from the same base circles in each case, and the true pitch diameters and pitch will be the same, but the shape of the teeth will be quite different in the two cases. The pinion which is cut on standard lines will probably have badly undercut teeth with consequent weakness and loss of wearing surface. The enlarged pinion, on the contrary, will have teeth with broad bases and unimpaired shape. Since the center distance and velocity ratio have not been altered, the true pitch circles and the pitch remain unchanged; but the change in outside diameters has increased the addendum of the pinion and decreased the addendum of the gear.

There is nothing new in this method,* as it has been in use on bevel and worm gears for many years; the most curious thing about it is that it continues to be so little understood by the majority of gear users. It is the writer's practice to give progressive enlargement to all pinions with less than twenty teeth and to reduce the corresponding gears in proportion, so as to maintain standard center distances.

An enlarged pinion will mesh correctly with any gear in its series, whether reduced or not, but if the gear is of standard proportions the center distance will be greater than standard by half the enlargement of the pinion. This applies to all involute gears with generated teeth, no matter whether they are hobbed, shaped or planed. When this method is applied to herringbone gears, the enlargement or reduction of the blank is left entirely out of consideration, and the machine is set to cut the correct spiral angle on the true pitch circle. Given a proper degree of accuracy in the cutting and reasonable care in setting up, such gears are perfectly interchangeable, bear evenly from end to end, and do not jam. There is no question of approximation. These methods have been in use for several years, and there are thousands of gears in service which bear eloquent testimony that your correspondent's misgivings have no foundation in fact.

* * *

It is stated in *Power* that hydro-electric installations in Switzerland have been developed and utilized to such an extent that there are some towns in that country where no coal is being used. Power, light, and heat are furnished by electricity throughout the towns.

MOTOR-DRIVE IN THE MACHINE SHOP*

By GEORGE H. HALL†

For the shop where electric power is already installed, all kinds of machine tools may be purchased completely equipped with individual motors. When, however, it is desired to institute a change in a shop that has been employing belts and shafting, and to substitute electric power, it becomes necessary to consider each of the belt-driven tools separately, so as to secure as nearly as possible the same results that are obtained with the tools built for motor drive. At the same time excessive expenditures in the alterations must be avoided. It is the purpose of this article to outline the principles of motor application, and to suggest methods by which the belt-driven tools may be accommodated to motor drive.

The first problem to consider is that of the transmission of the power. In large plants, covering acres of ground, alternating current is employed in order to permit the use of high voltages with the corresponding saving in the copper used for wiring. In plants consisting of but a few buildings, grouped fairly close together, the use of direct current possesses advantages in variable speed possibilities that far outweigh the gain to be secured by the use of the high-voltage alternating current. It is, therefore, the general practice at the present time to use 230-volt direct current for the operation of plants of the nature of machine shops, in which a large part of the load will consist of motors driving tools requiring variable speed. Where long transmissions make the distribution of power by alternating current a necessity, a motor-generator may be installed at the point of distribution for the purpose of supplying direct current to the variable-speed motors. This is often the system employed in the case of railway shops which are spread out over a considerable territory and contain a large proportion of constant-speed tools. Here the transmission current is 440 volts, alternating, and the constant-speed motors are operated on this current, while the motor-generator supplies 230-volt direct current for the operation of the variable-speed motors.

Types of Motors

In the first place the three types of direct-current motors should be thoroughly defined, so that the proper type may be selected for the particular tool to which the motor is to be applied. These three types are series-wound, shunt-wound, and compound-wound motors.

The series-wound motor is one in which the field winding is in series with, or forms a direct continuation of, the armature circuit, so that all of the current that passes through the armature passes also through the fields. The amount of current drawn from the line by a motor depends upon the work, or horsepower, which the motor is developing. It therefore follows that in the series motor the strength of the fields will depend upon the load which is placed on the motor, and as the speed of the motor depends inversely upon the field strength, the speed of the series motor will be inversely proportional to the load. Since the speed of a motor also depends upon the voltage that is impressed upon the armature, the speed of a series motor may be controlled by introducing resistance in series with the armature, and this is accomplished by means of a controller which is used also for starting the motor. The use of the controller enables the operator to start the motor slowly under light loads, and also prevents too great a flow of current when starting under heavy loads. The characteristics of the series motor are heavy starting torque and a speed dependent upon the load.

The shunt-wound motor is one in which the field winding is connected across the main lines, or is said to be in shunt with the armature circuit. The amount of current passing through the fields is inversely proportional to their resistance,

* The following articles on this and kindred subjects have previously been published in MACHINERY: December, 1911, engineering edition, "The Selection of Direct-Current Motors for Factory Use"; April, 1911, engineering edition, "Electric Motor Supports"; November, 1910, engineering edition, "Wiring on Motor-Driven Machinery"; May, 1910, engineering edition, "Methods of Applying Motors to Machine Tools"; April, 1909, engineering edition, "Improvements made by Motor-driven Tools in a Repair Shop"; February, 1909, engineering edition, "The Application of Motors to Machine Tools"; June, 1908, engineering edition, "Reliability of Motor Drives for Machine Tools"; January, 1906, "The Simplicity of the Electric Drive."

† Address: 508 W. 140th St., New York.

and, except in the case of the variable-speed motor which will be treated later, remains practically constant under all conditions of load. This results in a constant-speed motor whose output, in horsepower, is dependent upon the current, in amperes, which passes through the armature. The characteristic of the shunt-wound motor is approximately constant speed under all conditions of load.

The compound-wound motor is one having both a shunt and a series field winding. The shunt field is connected to the main line as in a shunt motor, while the series field is in series with the armature and carries all of the current passing through it as in the series motor. The field of an average compound motor is composed of about eighty per cent of shunt winding and twenty per cent of series winding, although this proportion may be varied to suit the class of work for which the motor is to be used. The speed of a compound motor is more nearly constant than that of a series motor, but the drop in speed from no load to full load is considerably more than in a shunt motor, owing to the action of the series part of the winding. The characteristics of the compound motor partake of those of both the series and the shunt motors in about the same degree as the relative proportion of the two windings composing the field.

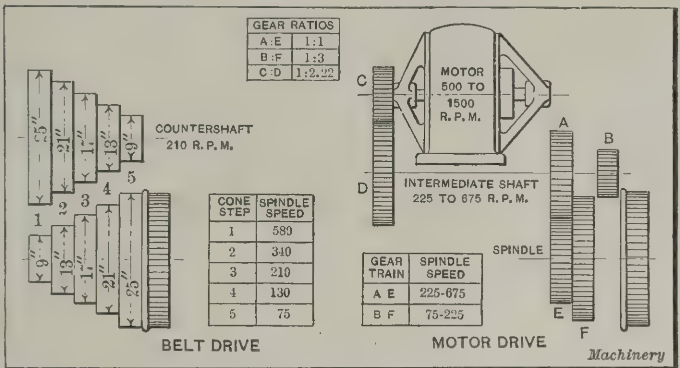

Fig. 1. Comparison of Belt and Motor Drive of Engine Lathe

Selection of Motors

To determine the type of motor to be employed for the different classes of tools in the machine shop, the character of the power requirements of the tools should be carefully analyzed. In the case of lathes, boring mills, milling machines, etc., in which the work of cutting is continuous, it will be seen that the tool is required to run at a speed which can be adjusted to the character of the work being machined, and when so adjusted, will remain practically constant. Also, the tool is usually started before the work of actual cutting begins, so that no excess of power is needed to start. The foregoing requirements correspond to the characteristics of the shunt motor, and for this class of work this motor should invariably be used.

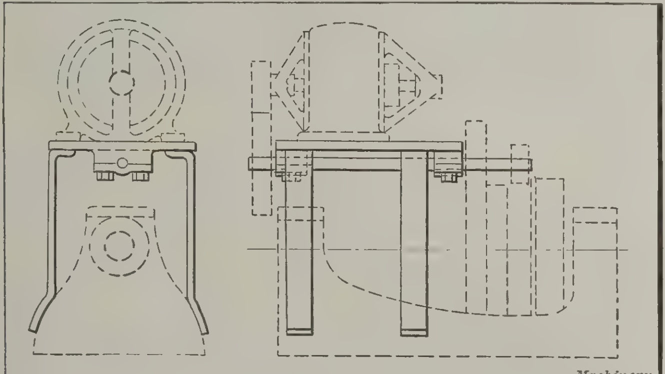

Fig. 2. Plate and Brackets for Supporting Motor

In the case of planers, shapers, slotters, etc., the work is intermittent, being far greater at some portions of the stroke than at others, and for this class of work the compound motor is best suited. The same type of motor is also used for the operation of punches, shears and other tools having heavy flywheels, as the motor will slow down at the period of greatest load, which is just after the completion of the stroke. The actual cut is effected through the inertia of the flywheel, and the maximum load on the motor is that of accelerating the flywheel and bringing it back to normal speed after it has carried the tool through the work.

When operating hoists and cranes, the motor must be started under the full weight of the load to be handled and at the same time slowly enough to prevent the shock of too sudden acceleration. These requirements are best met by the series motor with a controller having a heavy starting resistance, as it provides high torque at low speeds. This type of motor is also used for auxiliary purposes such as raising the cross-rails of planers and boring mills, traversing the carriages of large lathes, and elevating the tables of horizontal boring mills.

Constant-speed shunt motors are, of course, used for the operation of groups of machines that are driven by a common countershaft, but for individual drive the constant-speed motor is little used, as one of the greatest advantages of individual drive is the ability to vary the speed of the tool to suit the requirements of each piece being machined. This naturally brings up the question as to where the line should be drawn between tools that should be arranged for group drive and those which may advantageously be equipped with individual motors. No fixed rules can be laid down in answer to this question, but, in general, it is customary to group the smaller tools, as the initial expense of separate equipments for such tools as bench drills, tool grinders, emery wheels, and sensitive drills, often equals or exceeds the cost of the tools themselves. In the tool-room, also, the value of individual equipment is questionable, as the work on each tool is intermittent and there is not the demand for high efficiency from the tools that obtains in the case of tools used in the manufacturing departments. If the product of a given tool is especially valuable, or forms a very important part of the shop's output, the first cost of the drive is of minor consideration, and an individual equipment which will secure the greatest output is warranted.

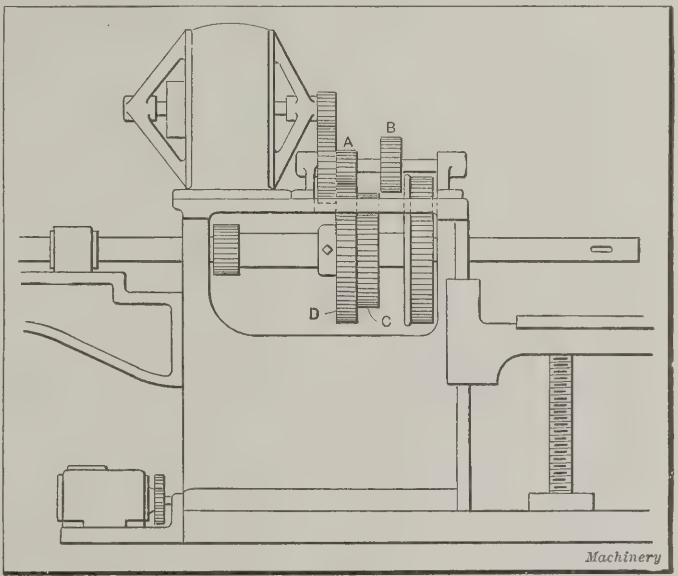

Fig. 3. Motor Equipment of Horizontal Boring Machine

Variable-speed Motors

Variable-speed motors, in the generally accepted use of the term, are, strictly speaking, adjustable-speed motors, in that the speed may be adjusted by means of a controller. There are two methods in common practice by which this adjustment of speed may be accomplished. These are known, respectively, as armature regulation and field control.

The first method consists of introducing resistance in series with the armature circuit, thereby reducing the voltage that is impressed on the armature. With constant field strength, as in a shunt motor, the speed of the motor will be directly in proportion to the impressed voltage. If the load on a motor remains constant, the speed will be inversely proportional to the resistance inserted in the circuit, as the torque is in proportion to the current in amperes, and the voltage equals the amperes divided by the resistance. From the

foregoing it will be seen that if the motor load varies, the voltage and, therefore, the motor speed will, with a fixed resistance, vary with the load.

Now, consider the output of the motor when armature control is employed; the torque, or turning effort, is proportional to the amperes drawn by the motor, while the horsepower is a function of the product of the volts and the amperes. Thus a motor developing a given horsepower draws from the line a definite amount of current and produces a torque corresponding to that horsepower. If, now, we cut the speed in half, by halving the impressed voltage, while the torque remains the same, the product of the volts by the amperes will be but one-half, and the motor will be delivering but one-half its former horsepower, although it will be drawing just as much current as when delivering the full horsepower. Thus it will be seen that this method of control is uneconomical and gives a speed varying with the load, while the demand of most machine tools is for a drive that will give a desired speed regardless of the load. In employing the method described it is almost impossible to secure slow motor speeds with very light loads. For this reason this method of control is but little used in connection with machine tools.

The second method, that of field control, is most generally used for motors employed in the operation of machine tools. With the voltage impressed on the armature constant, the speed of a motor will be inversely proportional to the strength of the fields. This field strength is directly proportional to the ampere-turns in the field, and as the actual turns of wire must remain constant, the ampere-turns may be easily regulated by inserting resistance in series with the field winding and thus decreasing the current in amperes passing through the field. The torque of the motor is, in this case, proportional to the field strength, and, as the field strength varies inversely as the speed increases, the horsepower of the motor will remain practically constant.

Considering the average class of tools, such as lathes, boring mills, etc., we can readily see that the foregoing motor characteristics correspond to the requirements. When the cutting tool is run at a high speed, the cut taken by the tool is light, and when taking heavy cuts, the speed is slow, thus calling for a practically constant horsepower throughout the working range of the tool.

As the field current is but a small proportion of the total current used by the motor, the total current consumption of motors using this type of control is practically in proportion to the work being done, so that this is an economical method. The speed, also, being regulated by the field strength, is independent of the load, so that for a given controller position it will be practically constant regardless of the power developed. As a matter of fact, the shunt motor with constant field strength will vary about 5 per cent from no load speed to full load speed.

Application of Motors to Machine Tools

Considering the application of motors to specific tools, we can best divide the problems presented into two classes. The first class comprises those tools in which the removal of metal is continuous, such as lathes and drilling machines. The second class contains those tools in which the removal of metal is intermittent, as with planers, shapers and slotters.

For use with machine tools of the first class, variable-speed shunt motors will be employed, and the next point to be considered is the speed range for which they must be adapted. For a given horsepower the size of the motor will be inversely proportional to the minimum speed, and as the use of gearing or chain drives places a practical limit on the maximum speed, the minimum speed, and consequently the size of the motor, will depend upon the speed range. The best idea of the actual results that can be obtained with field controlled motors may be secured from a table showing the outputs and speed ranges of a standard line of such motors. Although different makes vary somewhat in their ratings from those given in Table I, this gives a correct average of the various lines upon the market.

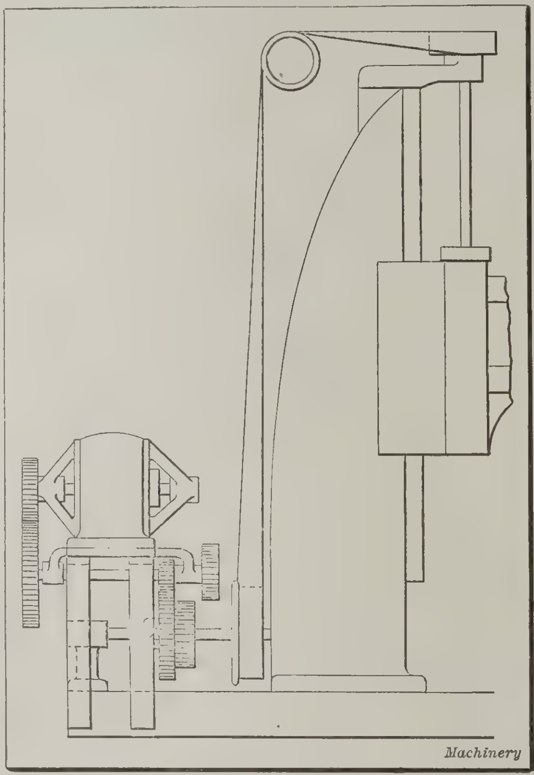

Fig. 4. Motor applied to a Radial Drill

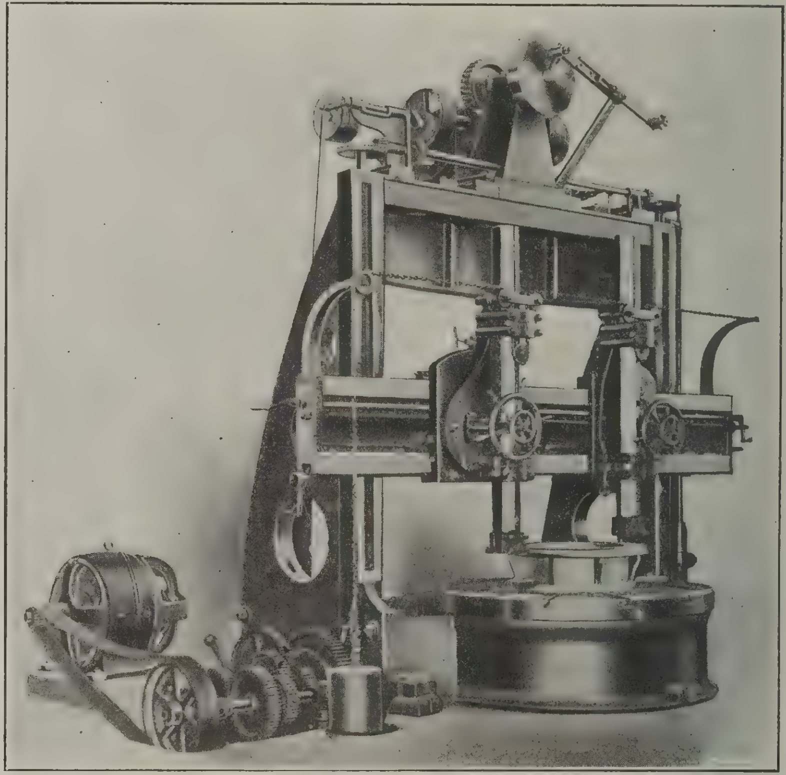

Fig. 5. Motor Equipment of Large Boring Mill

With a wide motor speed range, a larger part of the working range of the tool is, of course, covered than with a more limited range, but as it is impracticable to cover the entire working range of such a tool as a lathe or boring mill by a corresponding motor range, it is customary to use one or more mechanical speed changes to augment the electrical range. The problem is, therefore, to select a motor speed range that will give satisfactory results without involving too elaborate mechanical changes. Actual experience has shown that, under average conditions, a motor speed range of 2½ to 1 or 3 to 1, together with two mechanical speed changes, will cover practically any range of speed that is obtainable with a cone-pulley drive on any of the ordinary types of machine tools.

To show just how this works out, we will take an actual case of an engine lathe provided with a five-step cone pulley. In making applications to old lathes it is desirable to retain the back-gearing, while the cone is removed from the spindle sleeve and two gears mounted thereon as shown in Fig. 1.

The motor is placed above the headstock, on a bracket, and is geared to an intermediate shaft running directly below. This shaft carries two gears, *A* and *B*, either of which may be meshed with its corresponding spindle gear *E* or *F*. The en-

graving shows a comparison of the spindle speeds obtained with the original belt-drive and those that may be secured by the application of a 3 to 1 motor. Not only is the range of spindle speeds increased, but whereas in the belt range of

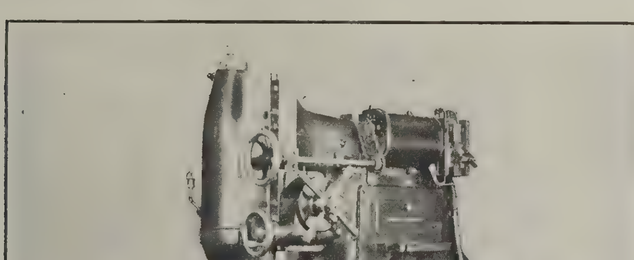

Fig. 6. Motor applied to a Vertical Milling Machine

75 to 580 revolutions we obtained but five distinct speeds, with the motor and a twenty-step controller we obtain a range of 75 to 675 revolutions with forty different running speeds, varying by about 6 per cent. This calculation considers only the range of speeds obtained without the back-gearing of the lathe and the range is, of course, repeated at correspondingly lower speeds by the introduction of the single or double back-gearing with which the lathe is provided.

Just here it may be well to point out one of the greatest advantages of the motor drive. It will be noticed that the belt drive, which gave a range of 75 to 580 revolutions, did so in five steps varying by at least 60 per cent per step. If the lathe is running on, let us say, the fourth step it may be found that the cutting speed, owing to the size of the work or the condition of the tool, is not as high as could be used to best advantage. To jump to the next speed, however, increases the cutting speed over 60 per cent, which will be too much, and the work will consequently be done on the fourth step, although this may be 30 or 40 per cent below that at which the best economy would obtain. With a motor drive giving speed increments of 6 per cent or less, the work can at all times be done at practically the best speed, and the increase of output that will be thus secured will be readily appreciated.

Another typical case where the advantage of the motor drive is clearly shown is in the facing of a large surface such as a flange. The ordinary practice is to adjust the speed properly for the cut at the largest diameter and then cover the

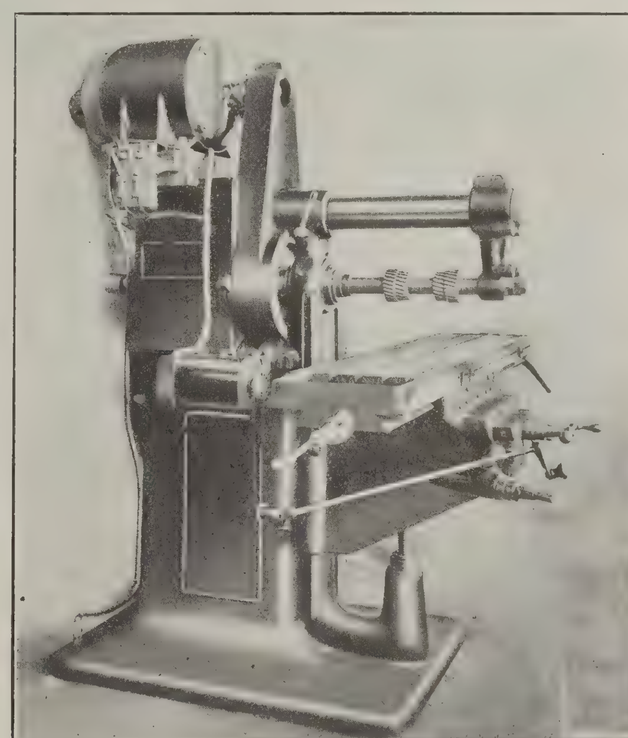

Fig. 7. Motor Equipment of Universal Milling Machine

entire surface at this speed, although, as the tool approaches the center, and the cutting diameter becomes smaller, the cutting speed will be too low. To be sure, an energetic lathe hand can shift his belt from time to time as the work progresses, but this is practical only after a reduction in speed of the 60 per cent made necessary by the large intervals between the cone steps. With the motor drive, requiring only the slight movement of the controller handle to adjust the speed, the operator will continually "notch-up" his controller, so that the entire surface will be covered at practically maximum speed.

In making this application to belt-driven lathes, if a considerable number are alike, it will be found economical to make a pattern and cast a bracket that can be attached neatly to the headstock. This bracket will be provided with bearings for carrying the intermediate shaft below the motor. As this entails expensive pattern work, it will be cheaper, if the number of similar lathes is small, to use wrought-iron brackets to support a plate on which the motor can be placed. This plate will require a very simple pattern which can be readily changed to suit different sizes of motors for various tools with which it can be employed. Fig. 2 gives a general idea of such a bracket, and indicates the method of supporting it over the headstock of a lathe.

The same scheme works out very satisfactorily for applying motors to other types of tools, although certain modifications may be needed in order to obtain the best results. Fig. 3 shows a horizontal boring machine which has been equipped in a manner similar to that of the lathe. The cone is replaced by the two gears *C* and *D*, but in this case the pinions *A* and *B* are fast on the intermediate shaft, while the gears *C* and *D*

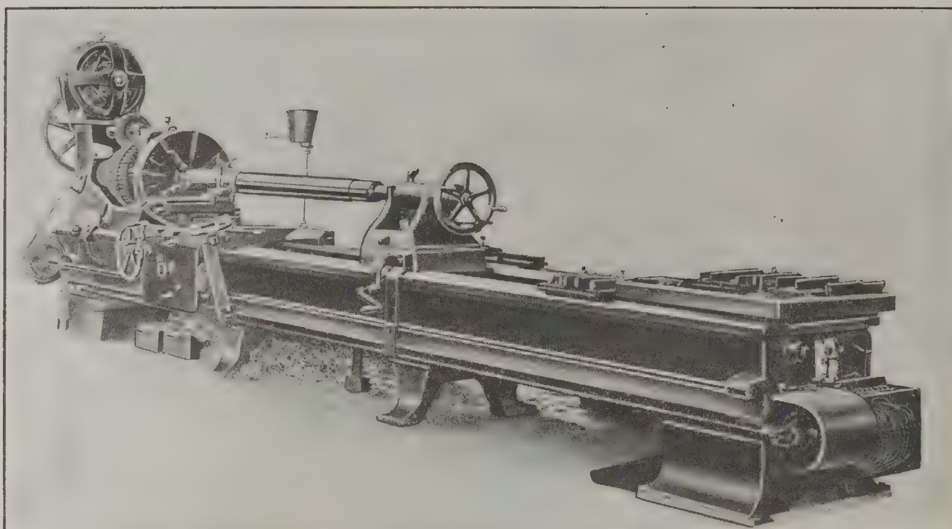

Fig. 8. Motor Equipment of Engine Lathe

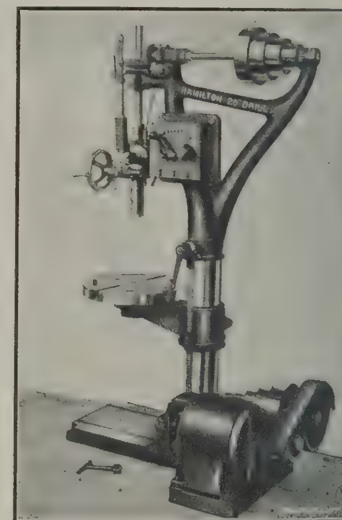

Fig. 9. Motor applied to an Upright Drill

are free to slide on a feather in the spindle quill, so as to be engaged at will with their corresponding pinions. The intermediate shaft, in this case, is carried in brackets in front of the motor rather than beneath it. Fig. 4 shows how this type of drive, with underneath intermediate shaft, may be applied to a radial drill, and the same arrangement will be found readily applicable to upright drills.

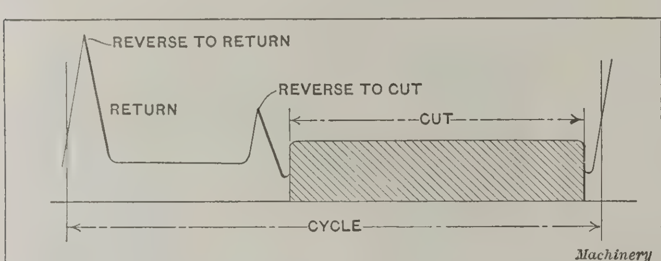

Fig. 10. Cycle of Operations of Planer

The halftone Fig. 5 shows the application of a motor drive to a large boring mill. The arrangement is extremely simple, consisting of replacing the driving pulley with a chain sprocket, and driving from the motor which is set at any convenient nearby point. The two pinions for the gear changes are seen in front of the original driving gears of the mill.

For operating milling machines the most successful appli-

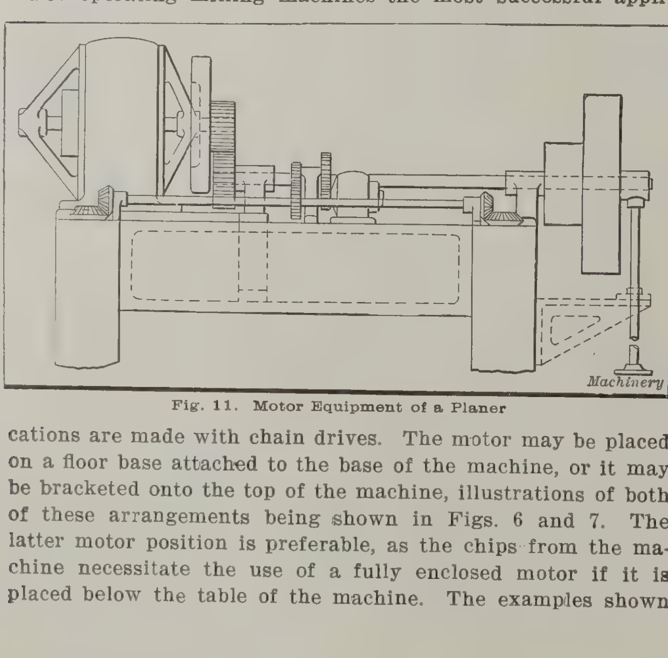

Fig. 11. Motor Equipment of a Planer

cations are made with chain drives. The motor may be placed on a floor base attached to the base of the machine, or it may be bracketed onto the top of the machine, illustrations of both of these arrangements being shown in Figs. 6 and 7. The latter motor position is preferable, as the chips from the machine necessitate the use of a fully enclosed motor if it is placed below the table of the machine. The examples shown are offered mainly as suggestions, as the construction and speeds of each particular tool will call for separate consideration.

Horsepower Required

Having decided upon the desirable speed range and the mechanical details of the application, the next problem is the selection of a motor of suitable power. Upon this point no positive rules can be followed, as so many factors enter into the consideration. For the operation of a lathe for general work a 5 horsepower motor might be fully adequate, while for driving the same size of lathe for manufacturing purposes, and using only high-speed steel at maximum cutting speeds, a 10 or even a 15 horsepower motor might be needed. For running a milling machine, for example, it is obvious that a much smaller motor could be employed if the machine were to be used only for finishing work, with light cuts, than would be needed on the same machine if it were to be used for heavy

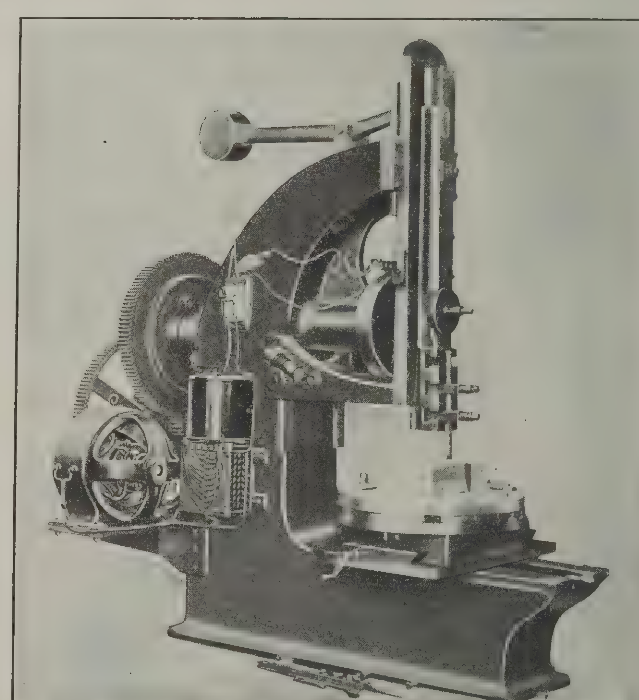

Fig. 12. Motor applied to a Slotter

roughing work. Any tabulated data, therefore, based on the size of the tool, must necessarily give averages only, and should be modified by one's best judgment, based on the actual conditions obtaining.

A most excellent plan is to determine the power requirements, by actual test, before purchasing the motors. This can be done, at a comparatively small expense, by belting a test motor to each tool successively, and taking readings with a recording ammeter for a day or two while the tool is running under actual operating conditions. Remember that all

good motors have a 25 per cent overload capacity for periods of at least two hours, so that if the day's run on a certain tool shows about 7½ horsepower as the average load, with occasional peaks for short runs, of 8 or 9 horsepower, a 7½ horsepower motor will be sufficient. The following tables which have been compiled from the recommendations of the tool builders and from actual tests, will, with the modifications mentioned, serve as fairly accurate guides in the selection of proper motors.

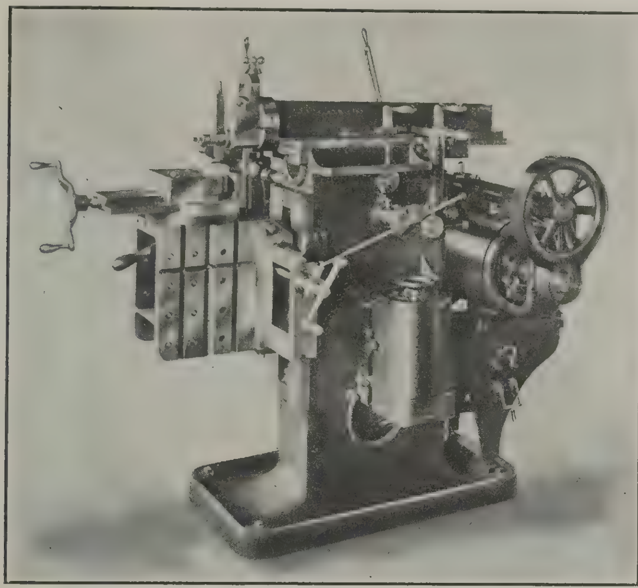

Fig. 13. Motor Equipment of Gear-driven Shaper

TABLE II. AVERAGE POWER REQUIREMENTS OF ENGINE LATHES

Swing, Inches	Character of Work: Light, H. P.	Heavy, H. P.
12	½	1
16	1½	2
18	2	2½
20	2½	3
24	3	5
30	3	5
36	5	7½
42	7½	10
50	7½	15
60	10	20

TABLE III. AVERAGE POWER REQUIREMENTS OF BORING MILLS

Swing, Inches	Horsepower	Swing, Inches	Horsepower
20	1 to 2	72	10 to 12½
30	3 to 4	84	12½ to 15
40	5 to 6	96	15 to 20
50	5 to 7½	120	20 to 25
60	7½ to 10		

TABLE IV. AVERAGE POWER REQUIREMENTS OF DRILLING MACHINES

Swing, Inches	Upright, H. P.	Radial, H. P.
18	1 to 1½	
24	1 to 1½	
36	1½ to 2	2 to 3
42	2 to 2½	2 to 3
48	2 to 3	3 to 4
54		3 to 5
60		4 to 6
72		5 to 6

As universal milling machines are usually rated by numbers, rather than by any dimension, a tabulation of their requirements is somewhat difficult, but for comparison the figures are given for the Brown & Sharpe machines, and these will serve as a guide for the equipment of machines of other makes.

TABLE V. AVERAGE POWER REQUIREMENTS OF BROWN & SHARPE UNIVERSAL MILLING MACHINES

Machine No.	Horsepower	Machine No.	Horsepower
1	1½ to 2	3	7½ to 10
1½	2 to 3	4	10 to 15
2	5 to 7½	5	

For horizontal milling machines the power requirements may be based upon the machine capacity as expressed by the width between the housings.

TABLE VI. AVERAGE POWER REQUIREMENTS OF HORIZONTAL MILLING MACHINES

Width between Housings, Inches	Horsepower	Width between Housings, Inches	Horsepower
12	3 to 3½	36	9 to 10
18	4 to 5	42	12½ to 15
24	7 to 7½	54	15 to 20
30	8 to 9		

Application of Motors to Planers, Shapers, etc.

The second class of tools comprises those in which the cutting stroke alternates with a non-cutting return stroke, as in the case of planers, shapers and slotters. Here the successive operations of the tool occur in cycles, as shown in Fig. 10. The highest points in the cycle are those which occur when reversing takes place. As the return stroke is taken at two or three times the speed of the cutting stroke, the power required to accelerate the bed of the planer or the head of the slotter to its return speed usually constitutes the greatest power-demand, while a somewhat lower point is reached on the reverse to cut. It is not, however, necessary to power the tool to meet the extreme peak, as the overload capacity of the motor will take care of this demand. Instead, the average cutting load represents the desirable nominal rating of the motor.

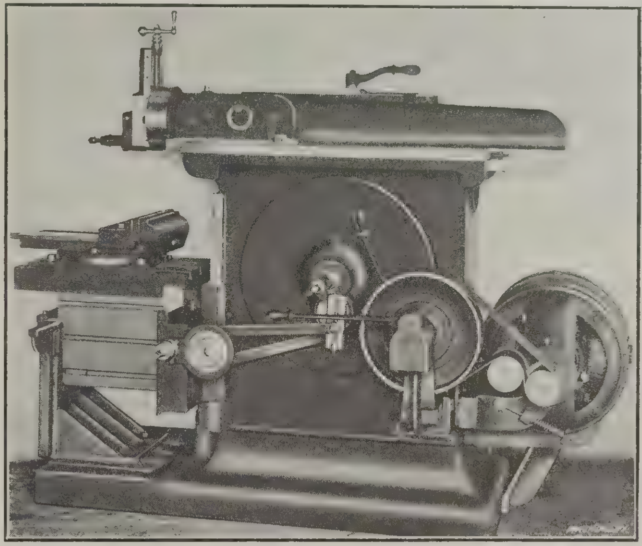

Fig. 14. Motor Equipment of Belt-driven Shaper

In this class of work, a constant speed of the motor is not of as great importance as with constant cutting tools, but it is, rather, desirable that the motor shall be designed to take care of the overloads that occur at the reversals, and for this reason motors for use with tools of this class should be compound-wound. The result is that, as greater demand is made on the motor, the increase of current that passes through the fields strengthens them, and thereby increases the torque of the motor. This also causes the motor to slow down, so that the speed for which the motor should be adjusted is that desired when operating under cutting load. On the return, when the load is light, the motor will consequently run faster than during the cutting stroke.

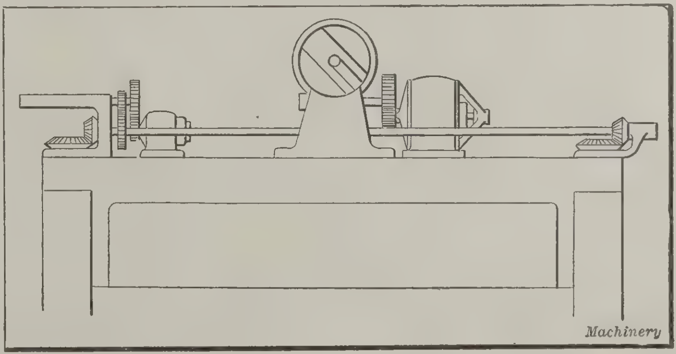

Fig. 15. Auxiliary Motors on Large Boring Mill

The average cutting speed of any of this class of tools will be between 25 and 50 feet per minute, so that a 2 to 1 range

motor is sufficient for nearly all cases and often a range of 1½ to 1 will be found satisfactory. Compound-wound motors are not used for such wide speed ranges as the shunt-wound motors, since any considerable weakening of the shunt field so changes the relation of the shunt to the series winding as to cause the motor to attain the nature of a series motor, which is undesirable.

In some new planers on the market, pneumatic or magnetic clutches are used for reversing, but in equipping old tools it will be found more practical to retain the cross-belt drive with belt shipper. A diagram of such an application is shown in Fig. 11. The motor is mounted on the top of the planer housings, and geared to a countershaft which carries the driving pulleys. The use of the flywheel on the motor shaft is most desirable, as it greatly relieves the motor on the peak loads. By mounting it on the motor shaft, instead of on the slower running countershaft, the flywheel effect is much increased. It is also well to provide the driving pulleys with extra heavy rims for the additional flywheel effect that they will produce. On slotters it will usually be found convenient to place the motor on a bracket on the side of the frame, and employ a gear drive, while shapers may be either geared or chain-driven, or belt-driven by using an idler as shown in Fig. 14.

The remarks regarding the power requirements for constant-cutting tools apply with equal force to this class of machines.

TABLE VII. AVERAGE POWER REQUIREMENTS OF PLANERS

Width between Housings, Inches,	Length of Bed, Feet	Horsepower
20	6	4 to 5
30	8	6 to 7½
42	10	8 to 10
60	12	10 to 15
72	16	15 to 20
84	18	20 to 25

The figures in Table VII are based on the use of two toolheads and a return speed having a ratio to the cutting speed of about 3 to 1. If more than two heads are used, or if the planer has a longer bed than that given, the horsepower should be somewhat increased.

TABLE VIII. AVERAGE POWER REQUIREMENTS OF SHAPERS (SINGLE HEAD)

Stroke, Inches	Horsepower	Stroke, Inches	Horsepower
16	2 to 3	24	3 to 5
18	3 to 4	30	5 to 7½

TABLE IX. AVERAGE POWER REQUIREMENTS OF SLOTTERS

Stroke, Inches	Horsepower	Stroke, Inches	Horsepower
10	4 to 5	24	10
12	5 to 6	30	10 to 15
18	7½		

In addition to the motors employed for operating the tools of the above classes, there are a number of uses for auxiliary motors as will be noticed in some of the illustrations. In Fig. 3 is shown an auxiliary motor used for raising and lowering the table of a horizontal boring machine, while Figs. 11 and 15 show similar motors employed for elevating and lowering the cross-rails of a large planer and boring mill, respectively. On large lathes auxiliary motors are often used for moving the tailstock along the bed, and they may also be arranged for turning the turret heads on heavy turret lathes.

Series motors only are used for these purposes, as they are always started under full load, and have their speed regulated by armature control. No rules can be laid down for the power of these auxiliary motors, but the requirements are comparatively small, from 2 to 5 horsepower covering all of the above cases except for the very largest tools. The time of duty is very short. The drives are invariably by means of gearing to the operating shaft, one set of reducing gears frequently being needed to reduce the speed of the motor sufficiently. These motors should never be belted, for if the load should be thrown off, by breaking the belt, they will run up to a dangerously high speed, and may be badly damaged. Another type of auxiliary motor is shown in Fig. 15, where it is used to operate the slotting attachment of a large boring mill. Such a motor should be compound wound and the data relative to slotters are applicable for such motors.

Controllers

For use with motors on machine tools the drum-type controller is most satisfactory, as it has sufficient mechanical strength to withstand the rough usage to which it is liable to be subjected, at the same time being completely enclosed so that all current-carrying parts are fully protected from dirt and chips and from external injury. Drum controllers are built for both armature and field controlled motors as well as for combined control. They may be either reversing or non-reversing, as desired. When used with motors having a 3 to 1 speed range, obtained by field control, they will ordinarily contain about twenty speed steps. In some sizes the necessary resistance is mounted on the back of the drum, while in others it is supplied as a separate unit which is connected to the drum by wiring.

The controller should be mounted on the tool at any point to best suit the convenience of the operator. The various applications illustrated by the halftones will serve as suggestions for suitable locations. In the case of long lathes a good arrangement is to mount a handle on the lathe apron, and this, by means of gears and shafts can readily be arranged to operate the controller when mounted on the end of the lathe bed. (See Fig. 8.)

The resistance, if separate, should be mounted near the controller in order to economize in wiring, but it should be so placed as to be exposed to the air and at the same time protected from dirt and cuttings from the tool. Do not cover up the resistance or place it inside of the tool frame, but select some place above the table of the tool, away from the path of the chips. In Figs. 8 and 12 the resistances, which are in the form of iron boxes with slate tops, are shown in excellent positions.

A SPIRAL GEAR CALCULATION

By GUY H. GARDNER*

A man in the shop was given a pair of new spiral gears with orders to ascertain all dimensions necessary to enable the shop to duplicate them in the future. He was about to find the angle of spiral in the time-honored way of rolling the gear on a piece of carbon transfer paper with white paper under it, so as to be able to measure the angle of the tooth marks with an ordinary protractor and figure what fraction of the circumference a tooth advanced in the width of the gear face. A neighbor then suggested that an easier method would be applicable, as the gear was new and of standard pitch. The gear was 8 diametral pitch, 52 teeth, 8.237 inches outside diameter; hence the pitch diameter was 7.987 inches. The pitch diameter of a spur gear of 52 teeth, 8 diametral pitch, is 6.5 inches. This divided by the pitch diameter of the spiral gear ($6.5 \div 7.987 = 0.8138$) gives the cosine of the tooth angle, which is thus found to be 35 degrees, 32 minutes. The mating gear had 106 teeth, and if the previous calculations are correct, its tooth angle must be 54 degrees, 28 minutes, as the shafts are at right angles. The pitch diameter of the large gear then is $106 \div (8 \times \cos 54 \text{ deg. } 28 \text{ min.}) = 22.799$ inches, and the outside diameter 0.250 inch more, or 23.049 inches. By actual measurement, it was found that this outside diameter was 23.044 inches, so that the calculations could be assumed to be correct. To make absolutely certain, however, the calculations could be checked in accordance with the rules on page 5 of MACHINERY'S Reference Book No. 20, second edition.

* * *

The Krupp firm in Essen, Germany, has built two new guns which are larger than anything hitherto used in marine or fortification service. The largest of these is a 15-inch gun. The total length of the bore is about 66 feet and the weight of the gun proper is about 226,000 pounds. The weight of the projectile is 1650 pounds, and the gun requires a charge of 690 pounds of powder. The muzzle velocity is slightly over 3100 feet per second, and the energy at the muzzle about 122,000 foot-tons. Close to the muzzle the projectile is capable of penetrating steel plate to a thickness of 4 feet 5 inches.

* Address: 101 Eustis St., Revere, Mass.

NEW PLANT OF THE GISHOLT MACHINE CO., MADISON, WIS.

The new plant of the Gisholt Machine Co., Madison, Wis., manufacturers of Gisholt turret lathes, boring mills and tool grinders, the construction of which was started last August, has just been completed. The layout of the plant is shown in Fig. 3, where the various departments are numbered, the key to this numbering being given in the illustration. As will be seen, the new building is of the regular sawtooth roof construction—tile supported on steel T-iron purlins—with trusses provided with extension gusset plates, to which hangers or other fastenings for holding shaftings, etc., can be readily attached. The area of the wire skylight glass is equal to about one-third of the floor space, which insures a good distribution of a flood of light. The building is constructed of fireproof material and every provision is made to secure the best sanitary and hygienic conditions.

Fig. 1. General View of Gisholt Machine Co.'s New Plant in Madison, Wis.

Fig. 2. View of Small Bay taken at Night, Ten Minutes Exposure, 16 Stop

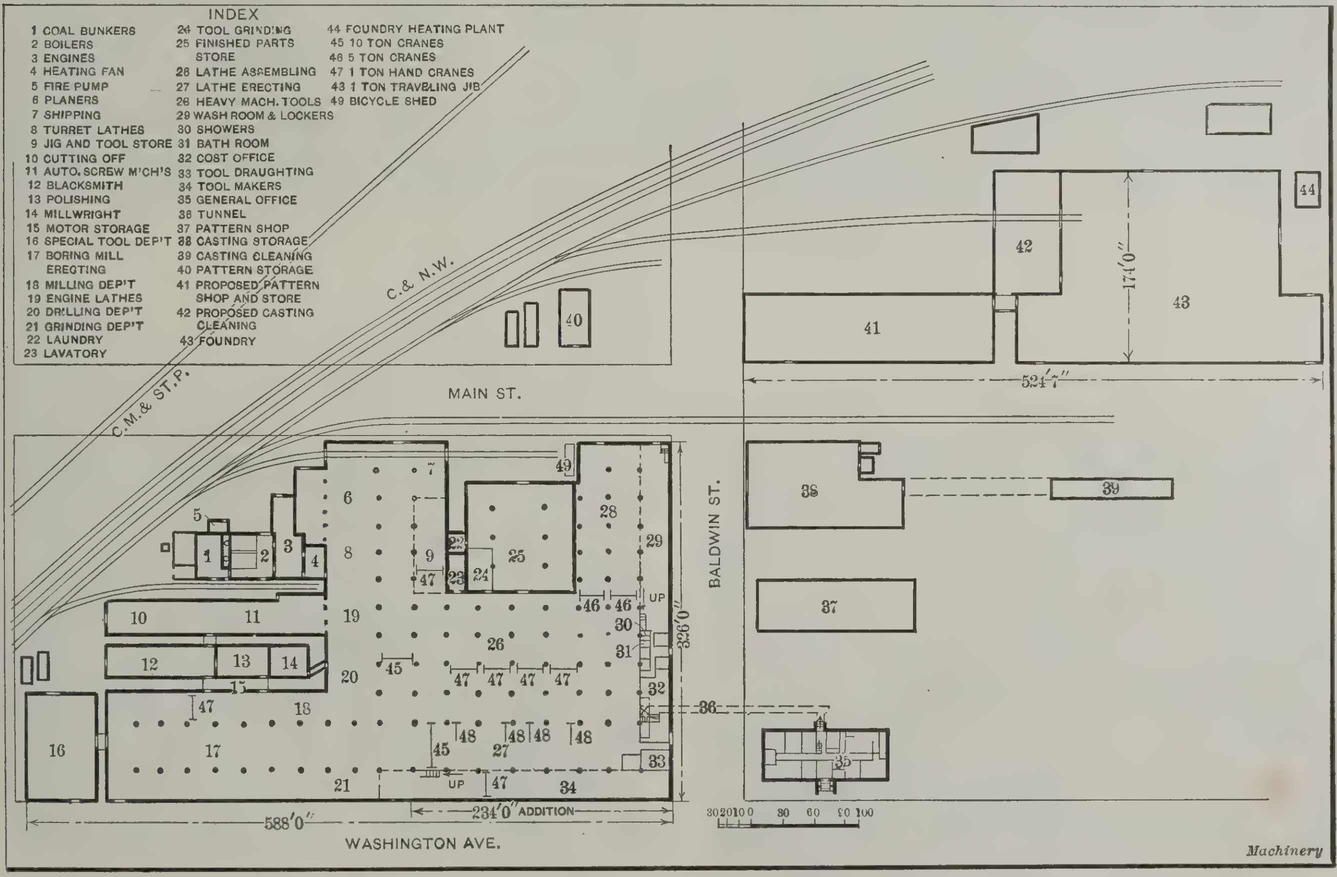

Fig. 3. Plan showing Location of the Various Departments and Buildings, Gisholt Machine Co., Madison, Wis.

Storerooms and Crane Service

The storerooms in which the finished material is held until wanted, are shown in the background in Fig. 4. The parts are brought on small trucks out to the assembling benches, shown in the foreground, where the carriages, headstocks, turrets, and feed-boxes for the turret lathes are assembled. A notable feature of the arrangement shown here, is that the trucking does not interfere with the man at the assembling bench. A good wide alley-way provides ample room for the trucks to pass through. There is also considerable space left in which to place the parts to be assembled. All the various parts of the turret lathes and boring mills made by this company are assembled on the unit plan, and are finished and tested before being attached to the machine proper.

The manner in which the traveling cranes are arranged, is commendable for a plant producing heavy machinery. The beds of the turret lathes are machined in Department 28, where the large planers are located. When a lathe bed has been machined, the small five-ton traveling crane which may be seen to the left in Fig. 5, operating in the small bay, is used to convey the finished bed to the erecting floor. As can be seen by referring to this illustration, the tracks on which this crane is mounted extend out past the posts, and are located low enough so that the crane carriage will

pass under the ten-ton crane, which travels the entire length of the large bay or erecting floor. It is evident that it is a simple matter with this arrangement to transfer a bed from the small crane to the large one, and in this way avoid a second handling or resorting to trucking. The work can be carried directly from the planer or the machine used in performing the required operations to the erecting floor with comparatively little effort. The gallery, a portion of which is shown in the background in Fig. 5, extends around two sides of the building. It is 25 feet wide by about 500 feet long, and is used for erecting light machinery, such as tool grinders, countershafts, etc. In the gallery are also located the lunch room, lecture hall, and emergency hospital, which will be referred to again later. The factory is illuminated at night by overhead tungsten "Mazda" lamps, 250-watt lamps being located over all crane-ways and 100-watt lamps over the assembling benches. The heating is of the direct vacuum system, and it has been found to give very satisfactory results.

Fig. 4. Assembly Floor for Carriages, Headstocks, Turrets and Feed-boxes. Storeroom in the Background

Fig. 5. Main Bay showing the Five- and Ten-ton Cranes

The Tool-room

The tool-room, a view of which is shown in Fig. 6, is located beneath the gallery shown to the right in Fig. 5, and is equipped with milling machines, boring machines, lathes, grinders, etc. In the tool-room all the jigs and fixtures used in the manufacture of both the boring machines and turret lathes are produced. This department is about 25 feet wide by 150 feet long, and is screened off from the main portion of the erecting floor.

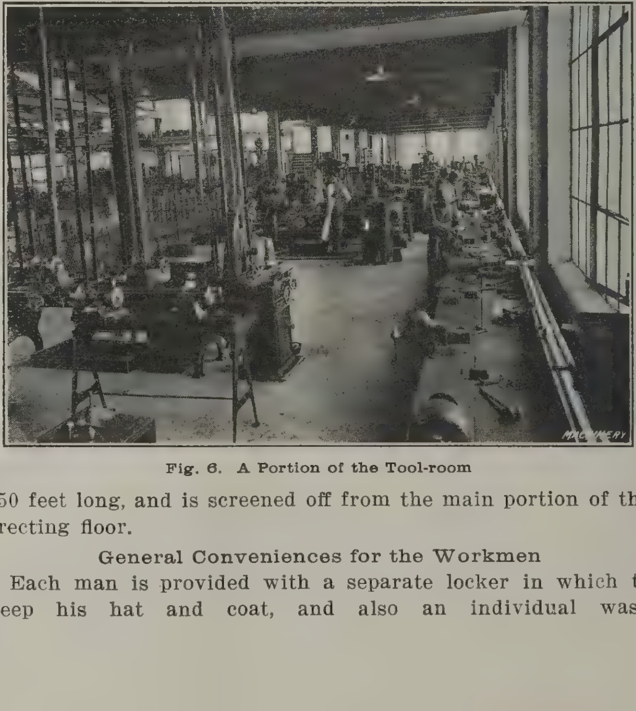

Fig. 6. A Portion of the Tool-room

General Conveniences for the Workmen

Each man is provided with a separate locker in which to keep his hat and coat, and also an individual wash

bowl. Two shower baths and a bathtub are installed to be used by the workmen, and every sanitary condition possible is provided for. Above the gallery is a lecture hall where meetings and entertainments can be held when desired. This hall has a seating capacity of about 300, and can be made still larger by throwing back the folding doors, some of which are shown thrown back in Fig. 7. The seats are in sections of three and are of the folding type. The rear portion of this hall is used as a lunch room for the workmen. Provision is made for a motion-picture machine and tne stage is equipped with scenery.

Fig. 7. Lecture Hall looking from the Stage

In this illustration the extended gusset plates of the roof construction are clearly shown.

The First Aid Room

The first aid room or emergency hospital shown in Fig. 8, is 12 feet square, and is equipped with the following: One examining table and stool, one cabinet, one instrument stand, one sterilizer, one waste receptacle, one irrigator and one hospital sink, the latter being equipped with foot pedals for opening the cold and hot water faucets. The cabinet contains a set of surgical instruments and all first aid supplies. A desk, not shown, is provided for the convenience of the surgeon in making up records of injuries. The room is painted in white throughout and is provided with a tile floor. All of the furniture is of steel construction painted white.

Offices and Engineering Departments

As shown in Fig. 3, the office building is located on the corner of Washington Ave. and Baldwin St., opposite the new

Fig. 8. The First Aid Emergency Hospital

main building, and is connected to the latter by an underground tunnel. The steam pipes and wiring for the electric lights in the office building are conveyed from the power house through this tunnel. The office building is of fireproof construction, with tile flooring, and is trimmed in quartered oak. It is 48 by 116 feet, and consists of two stories and a basement. In the basement is located a ventilating fan, which supplies the various offices with fresh air and forces the foul air out. The building is heated by direct and indirect radiation, the direct radiation being controlled by air-operated valves of the Johnson system. The fresh air being drawn from the outside, and the foul air being forced out through a ventilator in the roof mechanically, heating and ventilation are independent and separately controlled. On the ventilating fan is an automatic humidifier to keep the humidity in the offices constantly at a certain point, a very necessary provision for comfortable working conditions in offices.

All lighting in the office building is of the indirect type. Fig. 9, which shows a part of the engineering department, looking towards the vault and blueprint room, illustrates the effectiveness of this system of artificial lighting. This photograph was taken at night with the room illuminated only by the lamps. The negative was given eight minutes exposure, using a 32 stop. This system of lighting, as can be seen, eliminates all shadows and provides uniform distribution of light. Each unit is composed of four 150-watt lamps spaced at fourteen-foot centers. It requires seventeen kilowatts to illuminate the entire office building.

The system used by this company for keeping track of the workmen's time is a little out of the ordinary and worthy of note. A register called a "periodograph," is used throughout the factory to record the time. The system is worked out on the quarter hour basis, that is, the minimum time recorded is fifteen minutes. The time when the job is started is recorded by the instrument, as is also the time when it is finished. The difference between the two numerals stamped on the card shows the number of quarter hours the man has been on the job. The clocks in these periodographs are regulated by a master clock, located in the engineer's office. The data can be taken directly from the cards and added on an ordinary adding machine. As this system will be explained more

Fig. 9. A View of the Engineering Department taken at Night, Eight Minutes Exposure with a 32 Stop

fully in another article it will not be necessary to make further mention of it here.

The plant, the new part of which is briefly described in the foregoing, is one of the best in the United States, especially designed for manufacturing machine tools. It is an expression of the development of a business that has steadily grown in strength and prestige since it was founded about twenty-five years ago in Madison by Mr. John A. Johnson. Originality in design and efficiency in operation have been the characteristics of machine tools, known as "Gisholt"—the name of the boyhood home in Norway of the founder.

* * *

FIRST TELEGRAPHIC TRAIN ORDER

A bronze tablet was set in a monument May 21 at Harriman (formerly Turners), N. Y., as a memorial presented by the Erie Railroad Co., to commemorate the spot where, in 1851, the first telegraphic order was given directing a railroad train to move. The order was sent by Mr. Charles Minot, general superintendent of the Erie Railroad, a vignette of whose face appears at the top of the tablet, enclosed in a wreath. Prior to directing train movements by telegraph, the engineers and conductors ran their trains by the time-table and "judgment." The telegraph is now being displaced by the telephone and the probability is that in the not distant future the train despatcher will be in direct communication with all the trains on his division all the time, either by a wireless or sliding contact system.

WATCH MOVEMENT MANUFACTURE—2

METHOD, MACHINES AND SPECIAL TOOLS USED BY THE SOUTH BEND WATCH CO.

By DOUGLAS T. HAMILTON*

The special tools, gages, etc., used in watch movement manufacture compare favorably, from the standpoint of accuracy, with the tools used in any other line of manufacture. Accuracy is an absolute necessity in this class of work, if interchangeable manufacture is to be carried on successfully, and on a paying basis. In the following article a few of the representative gages and tools used by the South Bend Watch Co., South Bend, Ind., will be illustrated and described before the making of the various members of the watch movement is taken up.

The Transfer Chuck

The transfer chuck which is illustrated in Figs. 12 and 14 has been developed for making watch models and master plates, a group of the latter being shown in Fig. 13. The transfer chuck consists mainly of two dovetailed circular plates *A* and

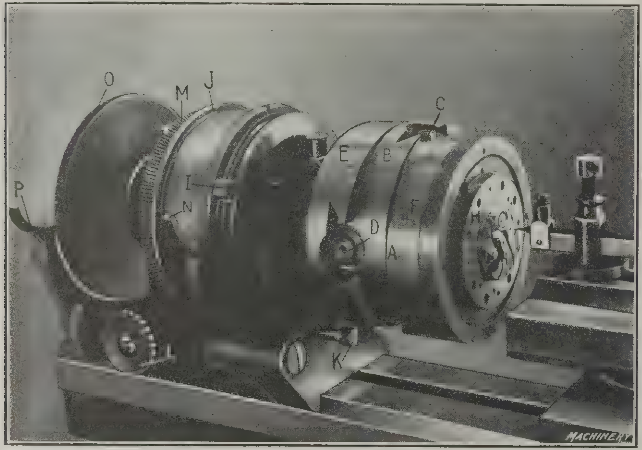

Fig. 12. Transfer Chuck used in making Master Plates and Model Watch

B, which can be adjusted at right angles to each other by screws *C* and *D*, the latter being provided with micrometer collars reading to 0.001 inch. Readings to 0.0001 inch can be easily obtained by means of the auxiliary vernier scale on the end of the slide, Fig. 14. These two adjusting circular plates *A* and *B* move in north, south, east and west directions to correspond with the geographical lines used in laying out the various holes in the watch plates, thus making it possible to drill any hole in its exact position.

The circular plate *F* is provided with a circular tongue which fits in a corresponding groove in plate *A*. The cir-

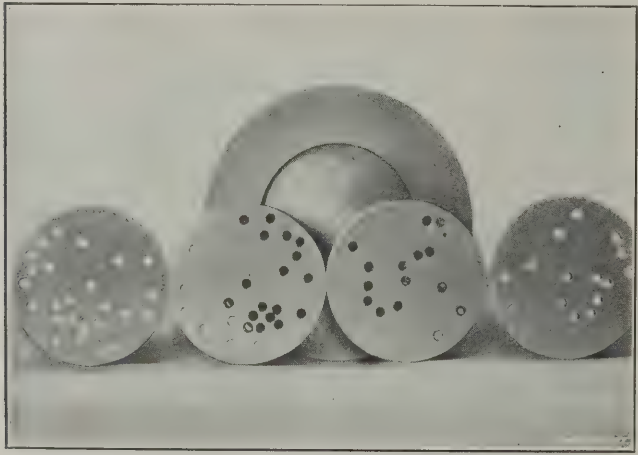

Fig. 13. A Representative Group of Master Plates

cumference of plate *F* is marked off in degrees, and the vernier scale on plate *A* makes it possible to set plate *F* to an angular position reading in minutes and fractions thereof. Plate *F*, as shown in Fig. 14, is held to plate *A* by fillister-head screws and elongated washers, which fit in a tee-slot cut in plate *A*. Fastened to the swiveling plate *F* is a brass disk *H* to which the master plate, or the various parts of the model watch to be made, are clamped. The boring of the holes and the other machining operations are completed before the master plate or model watch is removed from the brass disk. In Fig. 12, a bridged-type model watch is being worked upon.

It will be evident now, upon referring to Figs. 12 and 14, and also to the preceding description, that all dimensions north or south, east or west of the center lines can be laid out very accurately by means of these adjustable calibrated circu-

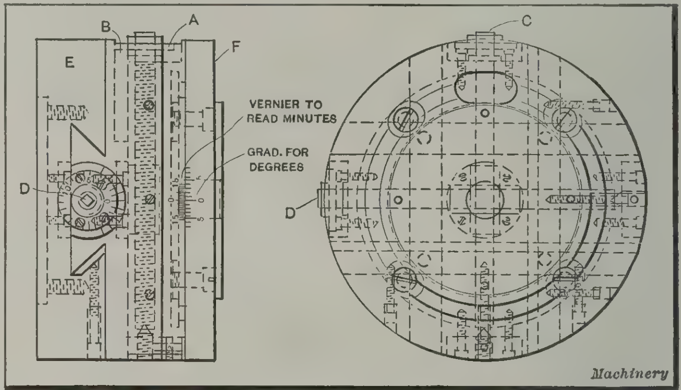

Fig. 14. Construction of the Transfer Chuck shown in Fig. 12

lar plates or slides. Also, in addition, any angular dimensions, or parts to be machined, can be accomplished by rotating the swiveling plate *F* to any desired angle.

Arcs of any length can be milled by simply setting adjustable dogs *I* in a slot in the front face of the driving pulley *J*, Fig. 12. These dogs come in contact with a pin *K*, which when pushed in acts as a stop. When small end mills are being used, and when it would be dangerous to pull the pulley *J* around by hand, a worm attached to handwheel *L* is engaged with the

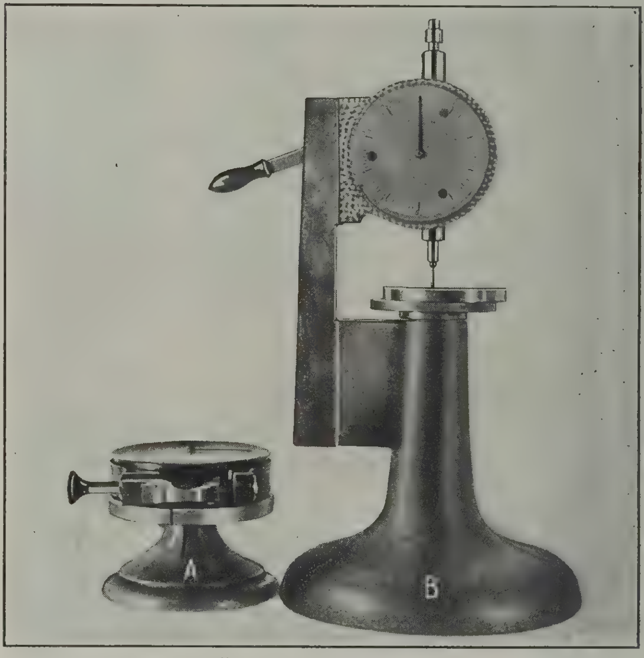

Fig. 15. Upright and "Fine" Multiplying Gages used for measuring the Various Parts of a Watch during Process of Manufacture

worm-wheel *M*. Of course the belt must be thrown off the pulley before the head can be rotated by handwheel *L*.

The head of this transfer chuck can be indexed by hand to the four positions—north, south, east and west—where it is held by a latch *N* fitting in notches cut in the front flange of the driving pulley. Other indexing disks giving a greater number of divisions are placed on the rear end of the spindle. A disk *O*, which is graduated in degrees, is located by finger *P*, as shown in Fig. 12. This transfer chuck is never taken from the model department, so that it cannot be mutilated in any way or its accuracy impaired.

Master Plates

All hole distances for the various tools are located by means of master plates, a group of which is shown in Fig. 13. These plates are all made of the same size—1.6 inches in diameter, 0.22 inch thick, while the holes are all made 0.100 inch diam-

* Associate Editor of MACHINERY.

eter, regardless of the size of the hole required to be produced in the plate of the watch. The holes in these master plates are accurately spaced in the transfer chuck and are lapped to size. All of the holes are numbered to correspond with the chart, Fig. 6 (see the May number of MACHINERY), each hole having its own particular number regardless of how many plates it may be located in.

Measuring Gages

Two types of multiplying gages are shown at *A* and *B* in Fig. 15. These are used for measuring the various parts of a watch during the process of manufacture. The gage shown at *A* is called a "fine" gage, and that shown at *B* is called an "upright" gage. The fine gage is used for measuring such parts

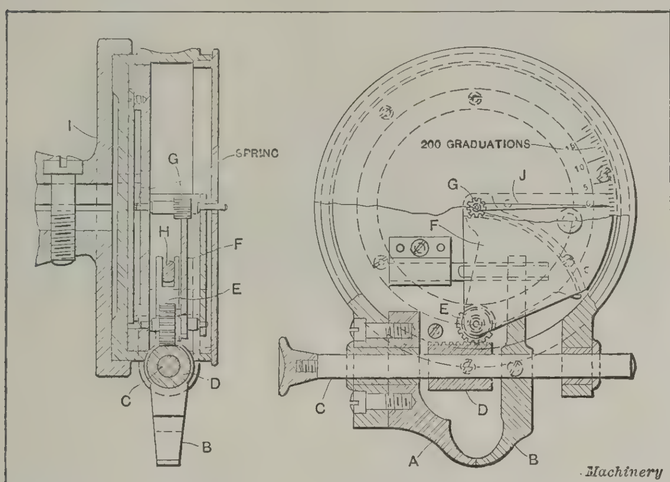

Fig. 16. Construction of "Fine" Gage shown at A in Fig. 15

as balance staffs, pinion staffs, and most of the circular work; the upright gage is used largely for measuring flat work.

The construction of the fine gage is shown in Fig. 16, to which reference should now be made. This gage is provided with a dial having 200 graduations laid off on its face. The work to be measured is placed between the jaws *A* and *B*, these jaws being separated by forcing in the rod *C*, to which jaw *B* is attached. Held on this rod by a screw, is a rack *D* which meshes with a pinion *E* having 40 teeth. Pinion *E* is connected to fan gear *F*, (the whole number of teeth in which should be 225) which meshes with pinion *G* attached to needle *J*. Jaw *B* which is held by a screw to rod *C* has a slot cut in its rear end, which fits a flattened stud *H*, thus preventing the jaw from tilting. One complete revolution of needle *J* around the dial gives a corresponding opening between the jaws *A* and *B* of 0.080 inch, so that the space between each graduation on the dial represents a movement of the jaw of 0.0004 inch. The working mechanism of the gage is enclosed in a case, which is supported on the stand *I* as shown.

The working mechanism of the upright gage is illustrated in Fig. 17. This gage is furnished with a dial having 100 graduations. The measuring spindle *A* is moved up and down by a handle *B*, which is connected to the spindle by a link *C* and a collar *D*. As spindle *A* is raised, the rack teeth cut in it mesh with a pinion *E*, which transmits motion to gear *F*, pinion *G* and needle *H*. Gear *I* is interposed to eliminate back lash in the gearing. The dial, as already mentioned, is divided into 100 equal spaces and each graduation corresponds to a movement of the measuring spindle of 0.001 inch. The capacity of this gage is ½ inch.

The table *J* is adjustable, and a plate *K* for holding the work to be measured is attached to it by screws. The stud on which table *J* is held, is screwed into a babbitt bushing *L*, the latter being clamped on the stud by the screw *M*. The babbitt was poured in through the screw hole, after the stud was put in place. The spindle *A* works in hardened and lapped bushings inserted in the case holding the measuring mechanism.

Master Thickness Gages

All measuring gages throughout the factory are kept in repair and tested from time to time by means of standard thickness gages. A remarkable illustration showing twenty-seven of these thickness gages wrung together is presented in Fig. 18. These gages are made from ½ inch diameter Sanderson drill rod, and vary in thickness from 0.025 up to and including ½ inch. The gages presented in the illustration were made twelve years ago by Mr. William R. Zessinger, foreman of the tool-room. For the benefit of those who would be interested to know how these gages are made and lapped, the following description is given.

Making and Lapping Master Gages

A piece of ½-inch diameter Sanderson drill rod is held in a chuck and is cut off, leaving sufficient material for facing, grinding and lapping. After hardening, the temper is drawn slightly—just enough to remove the strains set up in hardening. Then the block is ground, leaving 0.0002 inch on a side to be removed by lapping. The next thing to do is to prepare the cast-iron lapping block. This is planed as true as possible, using a flat tool for finishing. After the cast-iron block is planed, a hardened and ground steel block is used to rub No. 6 diamond dust into it.

Before describing the lapping of these gages it might be well to describe briefly how the No. 6 diamond dust is obtained. Splint and broken pieces of pure water diamonds are put in a mortar, and the plunger which is made of hardened steel is struck repeated blows until the broken diamond chips are crushed to powder. The powder is now removed and placed in a receptacle partly filled with watch oil. The receptacle holding the diamond dust and oil is allowed to stand for ten minutes; then the oil is poured off and the sediment which is left, is removed and labeled No. 1. The oil with the finer dust in it is then allowed to remain in the receptacle thirty minutes, after which the sediment is removed and called No. 2. The diamond dust still remaining in the oil is now allowed to settle from 4 to 6 hours, then the dregs are removed and labeled No. 3. This process is again repeated and the oil is allowed to stand for 24 hours, the sediment removed being called No. 4. The diamond dust that has not sifted through the oil is very fine, but it is still there, so that the receptacle is put away and left for two weeks. The sediment is then removed and labeled No. 5. This is the diamond dust which is used for lapping these fine thickness gages.

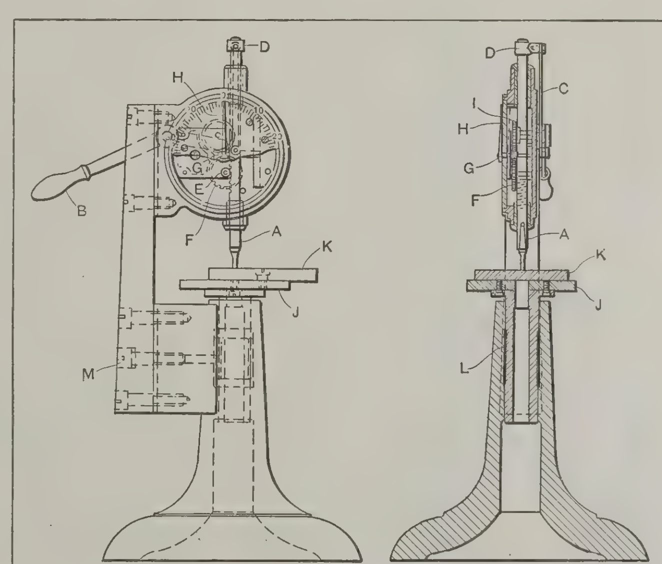

Fig. 17. Construction of Upright Gage shown at B in Fig. 15

To proceed with the lapping operation; the gages in this case have a hole in them and are held in contact with the lapping block by means of a piece of steel pointed like a lathe center, and fitting in the hole, but not passing completely through the piece. The gage to be lapped is held down firmly on the diamond charged block, and is given a rotary motion. The pressure on the gage should not be released before the lapping is stopped. After rotating the gage a few times on the block, remove all foreign matter with benzine, and repeat the lapping process until the gage is reduced to the desired thickness. Here is a point about lapping with diamond dust to be observed—never apply any more dust after the lap has once been charged, but remove the material ground from the work with

benzine when the block commences to glaze. When a lapping block commences to glaze some toolmakers apply more dust; this is wrong. The reason for the glazing, is that the material removed fills the pores of the iron and prevents the diamond dust getting at the work.

These gages, if properly lapped, can be wrung together and can be held without dropping apart as shown in Fig. 18. To wring the gages together, they should be slid back and forth on each other, and not brought together with their faces in a parallel plane, as the dust particles in the air adhere to their surfaces and prevent them coming together. It has been demonstrated that the reason that these gages adhere is because there is an extremely thin oil film on them which acts as a binding medium. Of course the more closely the surfaces approach true planes, the greater will be the power required to separate them. This work is not as difficult as it appears, but there is a slight "knack" in lapping which can only be acquired by experience. However, even a novice by following the foregoing method will be surprised at the results he will achieve.

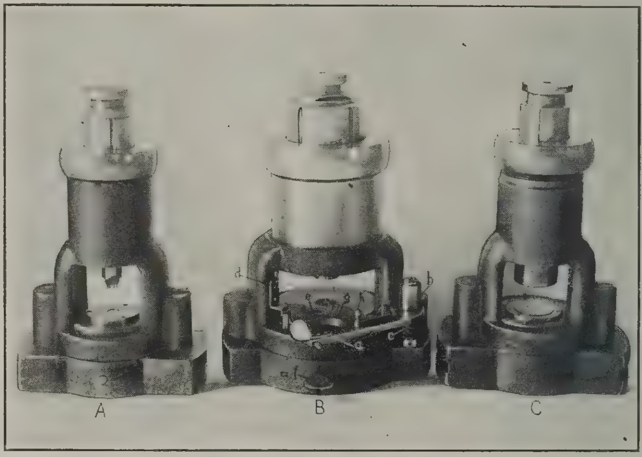

Fig. 19. Standard Sub-press Dies of the Blanking, Shaving and Burnishing Types

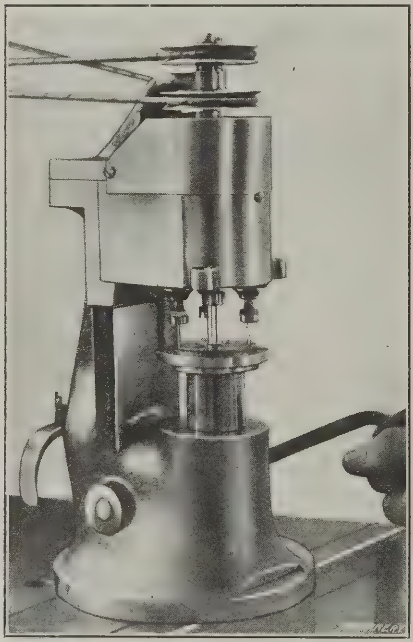

Fig. 20. Three-spindle Drill Press for Drilling Dial Foot Holes in Watch Plates

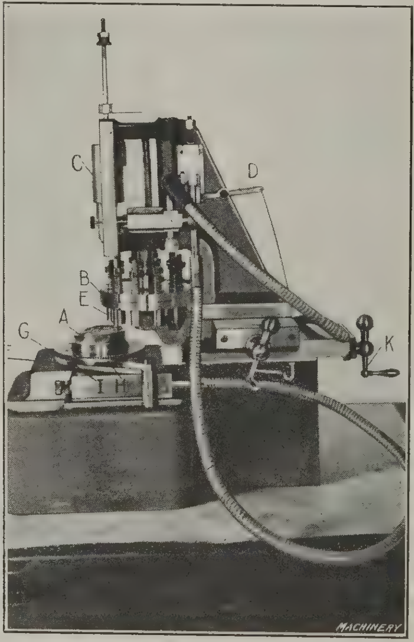

Fig. 21. Numbering Machine for Watch Plates, etc.

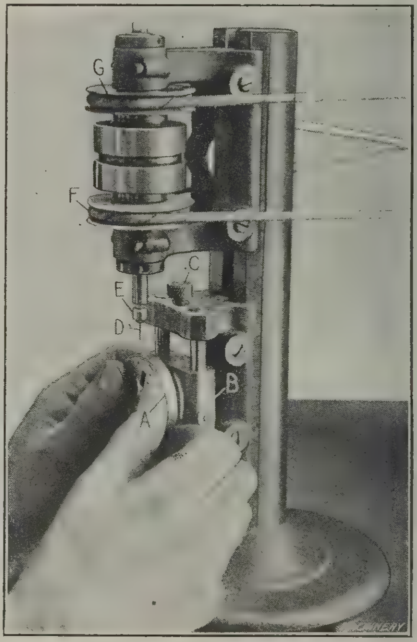

Fig. 22. Friction Tapping Machine for Dial Foot Screw Holes

Sub-press Dies

The sub-press type of punch and die is used almost exclusively in watch movement manufacture, because of the accuracy which can be obtained by its use. Three types of sub-press dies are shown in Fig. 19 where *A* is a blanking die, *B* a shaving die, and *C* a burnishing die. The general construction of these sub-press dies has previously been described in MACHINERY. The device shown attached to the shaving die at *B* in the illustration, however, is novel and worthy of description.

The particular sub-press die shown at *B*, Fig. 19, is used for shaving wheels, after they have been blanked, and is provided with a shaving locator. This consists of a nest *a*, hinged at *b*, and kept out by a coil spring *c*. The blank is placed in the nest, and the latter forced in by the thumb piece until the setscrew touches stop *d*. In this position, the blank is located over the ejector *e*.

Now supposing a wheel has just been shaved, the nest is pulled back until the front hole is in line with the ejector; then the lever *f* is depressed, which operates the ejector and places the blank in the nest. A blank is now placed in the hole *g*, in the nest, the latter being pushed in to the stop and latch *h* operated. This series of actions puts a blank in position to be shaved, and at the same time locates a blank in the "chuck" of the ejector ready for the next operation. This eliminates the necessity of the operator putting his fingers near the punch, and also allows the press to run continuously.

The burnishing die shown at *C* is a type of die which is used to a large extent in the manufacture of the steel parts of a watch movement. The use of this die obviates the necessity of polishing, as a nicely finished and accurate surface can be obtained with very little trouble. Of course it requires good work on the part of the toolmaker who must produce the die without scratches or other imperfections. The work is forced by the punch entirely through the die, which is made with straight and polished sides.

Making Watch Plates

The mechanism of a watch is retained between plates and bridges, holes being drilled and jewels inserted to act as bearings for the shafts on which the various pinions and wheels are mounted. In the South Bend watches, all plates and

bridges are made from nickel alloy and are blanked out in the punch press. The lower plate is then drilled, reamed, faced, tapped, and recessed for the various wheels, barrels, etc. The bridges are punched, shaved, faced, stoned, drilled, counterbored, recessed and pinned. After all the machine work is completed, these parts are nickel-plated.

Drilling Dial Foot Holes

The three holes in the lower plate of a watch are used for holding the dial by the pins riveted into the latter, and they

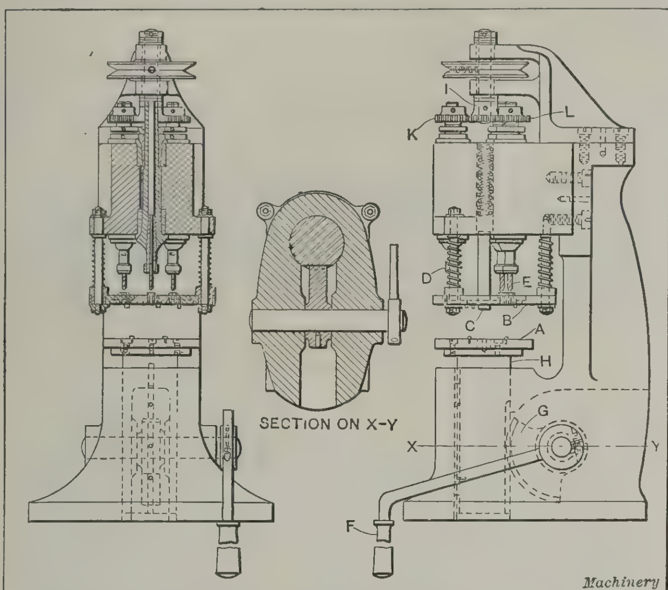

Fig. 23. Construction of Three-spindle Drilling Machine shown in Fig. 20

also serve as locating points in all the subsequent turning and counterboring operations. It is evident, therefore, that these holes must be accurately located, drilled and reamed.

The three-spindle drilling machine used for this purpose, is shown in Figs. 20 and 23. The watch plate, when being drilled, is held between two circular plates *A* and *B*; the work, however, does not come in contact with the plates, but rests on small contact points in them, thus making it impossible for dirt to get between the plates and prevent the holes in the plates from being dead in line. The work is also held down tightly by a spring plunger *C*. The upper plate *B*, which is held down by coil springs *D*, carries the drill bushings. The lower plate with the work on it is raised to the drills *E* by means of a handle *F* fastened to a shaft on which a fan gear *G*

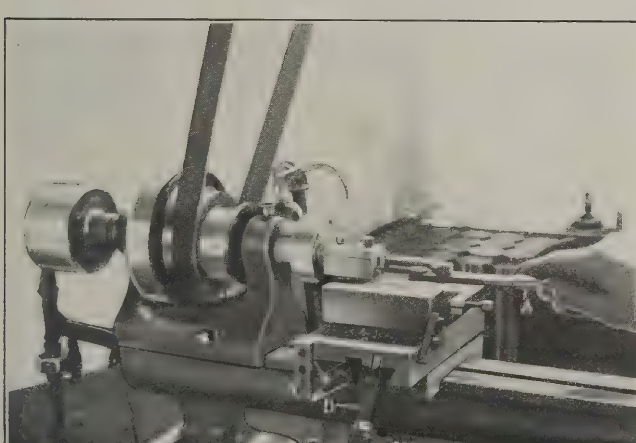

Fig. 24. Lathe equipped with Air-chuck for facing Plates

is retained. This fan gear meshes with a rack in stud *H*, on which the table is held. The top plate acts as a shedder for the drills, and at the same time by means of bushings guides the drills. The three drilling spindles are driven from the overhead works by grooved pulleys and spur gears. Intermediate gear *I* is held on the same shaft as the grooved pulley, and meshes with spur gears *K* and *L* which are fastened to the other two drilling spindles. The drills are 0.052 inch in diameter.

It is of vital importance that the dial foot holes are accurately located as to relative position and absolutely uniform as to size. This is secured by a subsequent operation performed in the same machine which does the drilling. This operation is done by means of accurately sized reamers.

Lathe for Facing Watch Plates

The lower plate after the dial foot holes and some of the other smaller holes have been drilled and reamed is faced off in the lathe shown in Fig. 24, which is provided with an automatic air chuck for holding the work. This air chuck is operated by a foot treadle which, when pressed, opens a valve, admitting air behind the piston connected to the outer sleeve of the chuck; this action holds the plate tightly against the hardened and ground stationary points in the chuck. The chuck is split and is provided with six bearing points so that the plate is always made the same thickness. The facing is accomplished by a turning tool held on the slide-rest. This tool is brought into contact with the work and fed to the desired depth by handle *A*, while handle *B*, having a gear that meshes in a rack under the slide, traverses the tool across the work.

Numbering Machine for Watch Plates

The bridges of a watch are numbered and lettering is stamped on the various parts of the watch, such as the number of jewels and other information of similar character. The

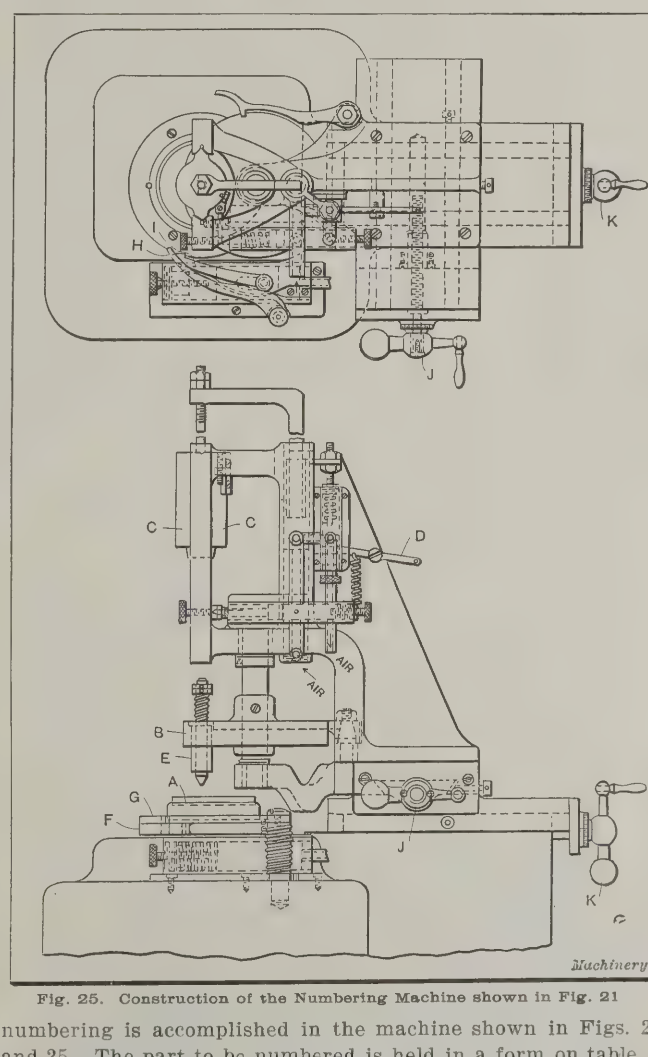

Fig. 25. Construction of the Numbering Machine shown in Fig. 21

numbering is accomplished in the machine shown in Figs. 21 and 25. The part to be numbered is held in a form on table *A* by a spring finger, and the head *B* carrying the letters or stamps, is indexed by hand, indexing slots and a latch being provided for this purpose. The hammer *C*, which gives a blow to the stamp to sink it into the work, is released by a compressed air device which is operated by tripping lever *D*, connected by a string to a foot-treadle. By a system of valves and air pipe connections, the hammer is returned to its "up" position after the blow has been delivered. The spindles *E* carrying the stamps, are forced down by the hammer against the tension of open wound springs. These springs are made of various tensions, so that the stamps will receive just sufficient pressure to force them in to the required depth. It is

evident that figure "8" will require a considerably greater blow than figure "1".

The table A is indexed by means of two ratchet dials F and G, operated by compressed air, one of which is used for indexing, and the order for locking, or holding the table when the stamping is being done. Finger H does the indexing, while finger I retains the table in position. Stops on top of the indexing dial are used as locating points, so that the stamp can be started in any desired position. The number of teeth that the dial is indexed can be changed to compensate for the diameter of the circle on which the letters are to be stamped. Of course a small circle will require a larger spacing than a large circle. The head carrying the letters is provided with adjustable slides which are operated by handles J and K, so that the stamping can be done in any desired position on the work.

Friction Tapping Machine

The pins which hold the dial to the lower plate, and which pass through the dial foot holes, are held in place by screws. Clearance holes are drilled in the pins that are fastened to the dial, so that the screws instead of being tapped into the pins, are threaded into the plate. The tapping size holes are drilled in an index drilling fixture. The tapping is accomplished in the machine shown in Fig. 22. The plate A to be tapped is held in a small fixture B, recessed to fit it, which is pushed up and down by the operator. The depth to which the tap extends into the work is governed by stop-screw C, which retards the fixture at any desired point in its travel. The tap D is not fluted, but is filed three cornered with flat sides and is held in a split chuck E. The spindle carrying the tap is provided with two cone clutches tapered to an angle of 8 degrees. These cones fit in corresponding cones which form integral parts of the two pulleys F and G, driven in opposite directions.

In operation, when the fixture holding the work is pushed up, the tap travels in to the correct depth. Stop-screw C then comes in contact with the fixture holding the work, and in so doing withdraws the cone from pulley G. Now as the fixture is pulled down, the cone comes in contact with pulley F, running in the opposite direction, and backs the tap out of the work. The tap is 0.047 inch in diameter and 110 pitch, and the fixture works so successfully that no taps are broken, or threads stripped in the work.

* * *

BORING LATHE PARTS IN RADIAL DRILLING MACHINE

The jigs and tool equipment used in the shops of the American Tool Works Co., for machining quick-change gear boxes and aprons of lathes, are shown in Figs. 1 and 2. These two

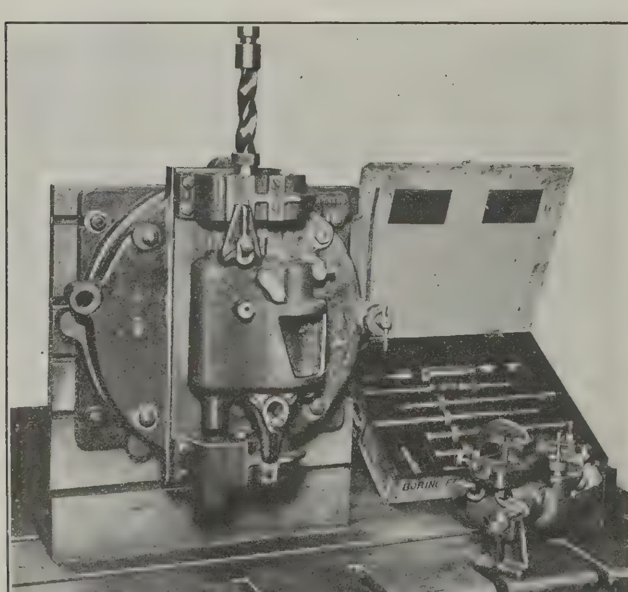

Fig. 1. Jig and Tools for Machining Change-gear Boxes with Radial Drill

views also illustrate how a radial drill is now used for machining these parts, instead of a horizontal boring machine, which was the type of tool formerly employed.

Fig. 1 shows the jig used for the quick-change gear-boxes and also the tool equipment required for this particular job. All of the necessary tools are kept in the box seen to the right, so that no time is lost while hunting for boring tools or drills. The convenience of a radial machine and the rigidity and power of a modern design, makes it possible to perform operations of this class very efficiently. When a horizontal machine was used for this work, 216 hours was required for machining thirty-six castings. The same number of parts are now done in a 6-foot radial drill (by means of a suitable jig) in 45 hours, thus effecting a saving of 171 hours for every thirty-six parts machined.

Fig. 2 shows the jig and tool equipment for machining a 24-inch lathe apron on the radial drill. These aprons were formerly bored on a horizontal machine in lots of twelve, each lot requiring 72 hours. A similar number of aprons of the

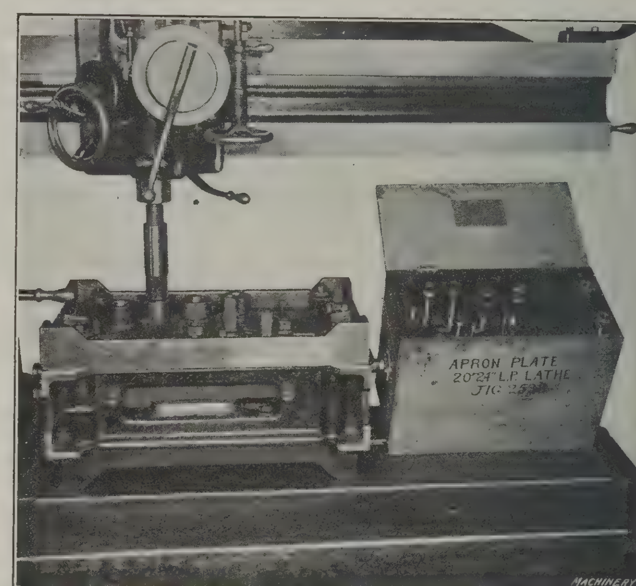

Fig. 2. Tool Equipment for Drilling and Boring Lathe Aprons

same design are now being done on the radial machine (by means of a jig), in 24 hours, thus effecting a saving in time of 48 hours. All of the tools required for the aprons are also kept in a wooden box which is marked with the name of the part, the size of the lathe, and the number of the jig, as the illustration shows.

SPECIFIC GRAVITY OF SOLIDS SUBMERGED TO GREAT DEPTHS IN WATER

Some "scientific" contributors to the daily papers have worried about the fact that "scientists have failed to agree" as to whether the *Titanic* actually sank to the bottom of the sea, the estimated depth at the part of the ocean where she foundered being some 10,000 feet. They have argued as a reason for this uncertainty that the great pressure of the water at these immense depths would prevent the vessel from sinking. The fallacy of this reasoning is, of course, obvious to anyone who has the least idea of the meaning of specific gravity; in fact, the deeper the vessel sank the more certain did it become that it would sink to the bottom; for while the specific gravity of water is practically the same at all depths, increasing only one per cent under a pressure of 3000 pounds per square inch, that of solid substances immersed in water may be greater the deeper they are immersed, on account of the fact that these substances can be compressed. In many cases the specific gravity is apparently raised because the water, on account of its pressure, fills minute cavities between the fibers of various substances. Wood offers a familiar example of this. Some woods can absorb water until their specific gravity becomes almost as great or even greater than water. Cork offers another interesting example. Cork is one of the most buoyant of substances, but if it is sunk to a depth of 200 feet in water it will not rise to the surface, being compressed to such an extent by the pressure of the water at this depth that it sinks instead of rising.

THE BALOPTICON—AN INSTRUMENT FOR PROJECTING LARGE OPAQUE OBJECTS

A new field for optical projection has been opened up by the "balopticon," an instrument by means of which pictures and objects can be reflected in their natural colors on a large screen. The accompanying illustrations show a large instrument of this type recently constructed by the Bausch & Lomb Optical Co., Rochester, N. Y., the special feature of which is that it projects an image of objects much larger than has ever before been attempted, and, hence, presents new possibilities for this method of showing, before a large audience, illustrations of objects which otherwise could not be properly exhibited.

The original model of the device shown was designed as an experiment in response to a request from the National Cash Register Co. for an instrument of sufficient size to project an entire section of a cash register on the screen. The instrument made proved entirely satisfactory. The general features of its design are indicated in Figs. 1 and 2. The device has an opening for objects measuring 20 inches square, having any thickness up to 9 inches. In order to cover this wide area with sufficient illumination to the very edges, it was necessary to use two large 90-degree arc lamps in the light-tight houses at *A*, as shown in Fig. 2. These lamps are placed at a suitable angle so that the object on the table is covered with the light. The lamps are also placed near enough to the object being projected to avoid the use of condensers, thus avoiding the loss due to absorption of light. Two adjustable rheostats regulating the electric current are mounted one on each side of the base. Good results are obtained with a current of 25 amperes to each lamp.

The next problem to be met after having obtained the maximum amount of illumination for the area to be covered was

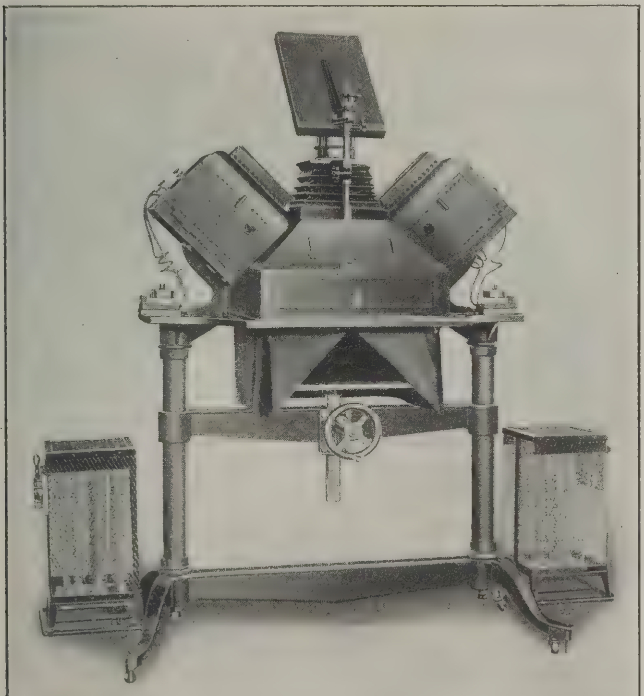

Fig. 1. The Balopticon for the Projection of Large Opaque Objects, made by Bausch & Lomb Optical Co., Rochester, N. Y.

to utilize this light so as to obtain an effective image. For this purpose a high-grade photographic anastigmat lens—a Bausch & Lomb-Zeiss Tessar Ic of 19 3/4-inch focus, 4 7/16 inches in diameter—was employed. A mirror *B* is used above the projection lens to direct the image toward the screen, this being necessary because the objects to be projected are held in a horizontal position on account of their size and weight. This mirror also serves the important purpose of reversing the view so that objects and printed matter are shown on the screen in their true positions. The mirror is silvered on the front surface, thus reducing the amount of light absorption practically to a negligible quantity.

The focusing is accomplished by bringing the object into the range of the lens by adjusting the large object table *C* vertically by means of handwheel *D*. A dark velvet curtain surrounds the table and prevents the light from escaping when the carrier is lowered. The corners of the curtain are draped up in Fig. 1 to show the table.

The instrument is of unusually large proportions for a projection lantern, the base being 54 by 24 inches, and the height of the stand to the top of the mirror being approximately 80 inches. The dark chamber is 23 inches square and is provided with a large door and an observation window of smoked glass, covered by light-tight doors, so that the object can be placed in position without lowering the carrying table.

An instrument of this kind, in addition to its commercial uses, can be used to advantage in projecting large illustrations and photographs of any size up to 20 inches square. This

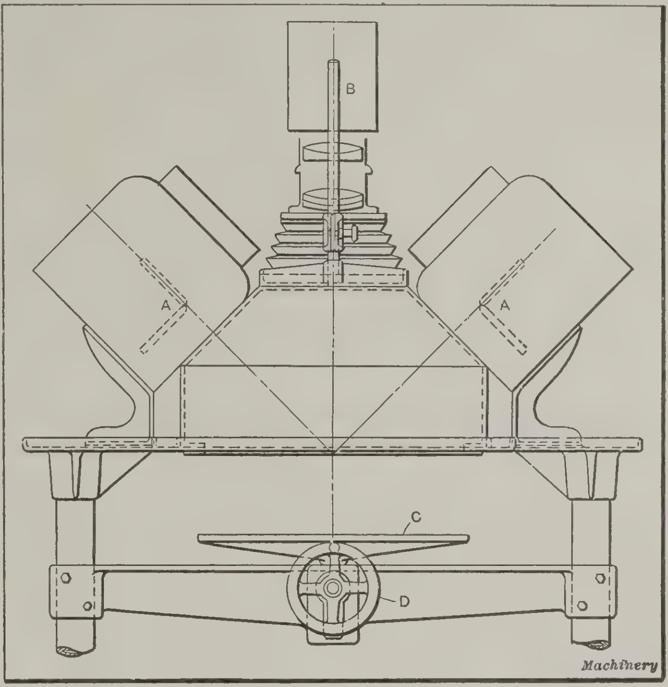

Fig. 2. General Design of the Balopticon

instrument, like a moving picture machine, undoubtedly would have considerable value in educational work, as small specimens and pictures could be shown to a large class simultaneously, and on such an enlarged scale as to make explanation of details easy and interesting.

* * *

Thomas A. Edison is an enthusiast on the value of moving pictures as an educational means. He proposes to revolutionize the present school system by teaching children through their eyes in the natural manner rather than by making them learn to read, and from reading gain knowledge of the world and its ways. He proposes to make 4000 films, costing $3,000,000, and requiring years to prepare, which will cover the subjects of the greatest importance in a general educational scheme. These films will be supplied to public and other schools to be used by the teachers as an easy and agreeable means of inculcating knowledge at an early age of sciences many of which are ordinarily taught only when pupils are approaching maturity. Take, for example, a course in physics. This can be presented by moving pictures so clearly and simply that children five or six years old will comprehend principles clearly. The pumping of water, for example, is shown, glass pumps having been constructed in which the action of water, lifting and closing of the valves, movement of the plunger, etc., can be clearly seen. Geography, botany, history, discovery, agriculture, industrial pursuits, the army, the navy and hundreds of other sciences and activities can be graphically, rapidly and effectively presented to all classes at low cost.

* * *

The designs of the two new White Star liners, now being built at Belfast, are being changed with regard to the arrangement of the bulkheads. The change provides for lateral bulkheads in addition to the transverse watertight compartments, so as to minimize the risk of disaster in case several compartments are torn open, as in the case of the *Titanic*.

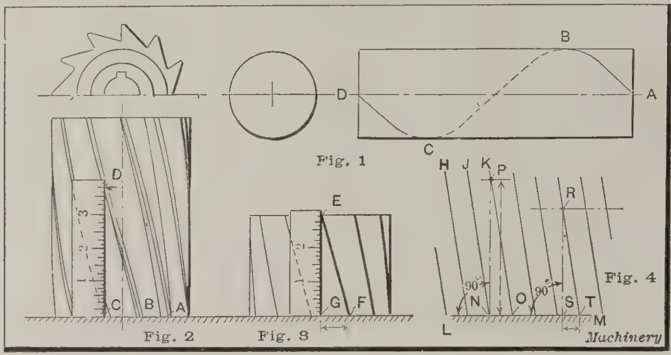
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

DETERMINATION OF MILLING-CUTTER SPIRALS FOR RECUTTING

Frequently a toolmaker is called upon to recut a spiral-toothed milling cutter. One of the first things he has to determine is the pitch of the spiral. If it is not stamped on the cutter this pitch must be calculated by methods such as those given in the following, or else guessed at; and guessing is very apt to involve several settings of the change-gears.

In order to understand the methods of calculation given herein it is necessary first to have a clear conception of what is meant by the *pitch* of a spiral. Referring to Fig. 1, the



Figs. 1 to 4. Different Methods of Obtaining Spirals of Milling Cutter Teeth for Recutting

spiral *ABCD* has a pitch equal in length to the axial distance *AD*, because this is the distance measured along an element of the cylinder from the point where a spiral crosses it, to the point where the same spiral crosses it again. Hence when cutting the spiral-tooth, the table will be fed forward a distance equal to the pitch, while the cutter-blank makes exactly one turn about its axis.

Cutters are seldom or never so long that one tooth makes a complete spiral. If such were the case, however, the spiral could be measured directly. Usually the cutter will conform to either Fig. 2 or 3.

First Method.—Set the cutter on end on a flat plate as shown in Fig. 2. The points *A*, *B*, and *C* represent the corners of the cutting edges. Now, set a square ended scale, as shown, so that its corner coincides with the cutting corner *C*. Measure the distance *CD* along the scale to where the next cutting edge crosses the edge of the scale. The pitch will be as many times this distance *CD*, as there are teeth in the cutter.

Second Method.—When the cutter is so short that the first method cannot be employed, set the cutter up on a flat plate as shown in Fig. 3. Lay the scale up against it so that its edge touches the cutting corner *E*. Now, measure the distances *EG* and *FG*, the latter being the distance from the lower cutting corner *F* of the same cutting edge to the base of the scale. Find the circumference of the cutter-blank by multiplying its diameter by 3.1416. Divide this by the distance *FG*, and then multiply this result by the distance *EG*. This final result will be the pitch of the spiral.

Third Method.—Roll the cutter on a piece of paper or wrap a piece of paper about it and rub the paper so as to get an impression of the teeth including the same ends of several teeth, as shown in Fig. 4. Here the inclined lines *H*, *J* and *K* represent the cutting edges. Draw the line *LM* through the ends of the inclined lines. From the end *N* of the line *JN* erect *NP* perpendicular to *LM*. If it cuts the next inclined line *OK* at some point *P*, the distance *NP* multiplied by the number of teeth in the cutter, gives the required pitch. If, however, the point *P* lies outside of the line *OK* it may be found by producing *OK* until it crosses *NP*.

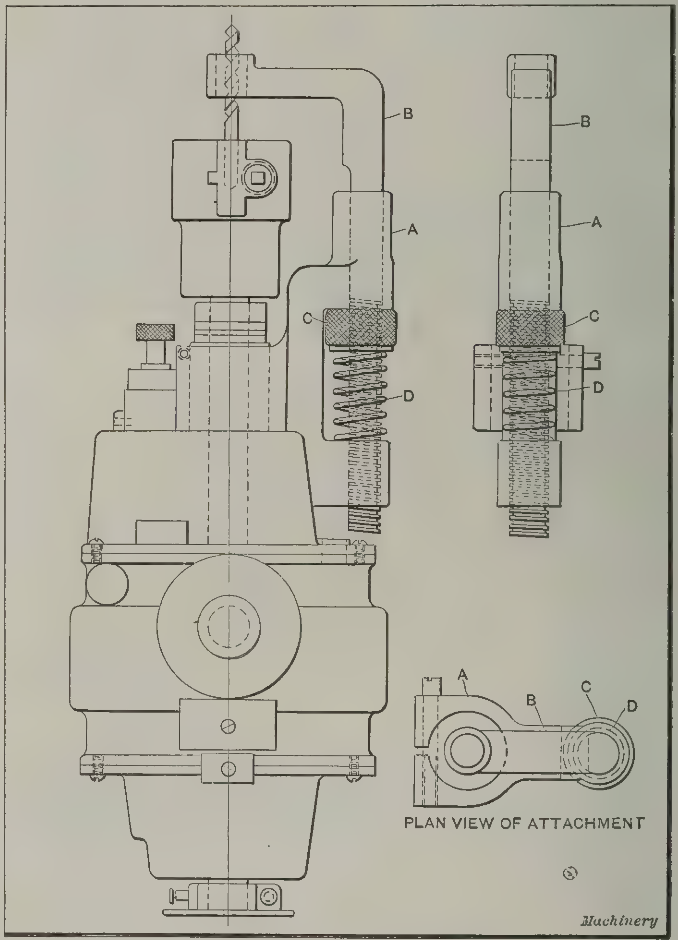
An alternative, when the cutter is narrow as shown by *SR*, is to draw from the upper edge and corner *R* a line *RS* perpendicular to *LM*. Measure the distance *ST* from the base of this perpendicular to the lower corner *T* of the cutting edge *RT*. Then the pitch will be found by multiplying the distance *RS* by the number of times that *ST* goes into the circumference of the cutter. Precaution should be taken when rolling a narrow cutter to be sure that it tracks straight, so that the points *N*, *O*, *T*, etc., will lie on a straight line.

South Bethlehem, Pa. H. A. S. HOWARTH

SAFETY STOP FOR ELECTRIC OR PNEUMATIC DRILLS

The accompanying illustration shows a safety stop for an electric or pneumatic drill. The breakage of drills used in these devices, especially in the electric drills, is very high. There are two main causes for this. In the first place, the device cannot be held very steadily, thus causing cramping of the drill in the hole. The second cause, and the more important of the two, is due to the drill's "breaking through" too suddenly after having passed through the work. This causes by far the greatest damage to drills. If the drill is large the driving device will come to a dead stop, causing damage to the mechanism itself.

Having the above difficulties in mind, the writer designed a stop which is shown applied to an electric drill in the accompanying engraving. At *A* is shown a stop bracket fastened to the frame of the drill; *B* is the stop proper fitted into *A* and bent so as to come in front of the drill chuck at the end. The hole in the end of *B* is made large enough so that the largest drill used can pass through it. The shank of the stop is threaded to receive knurled nut *C*, and spring *D* is inserted between nut *C* and the lower part of bracket *A*. The shank of stop *B* is milled flat on one side and the hole in *A* made to suit it, so that the shank of *B* cannot revolve. When using this stop the end or eye through which the drill passes is so adjusted by means of knurled nut *C* that the length of drill projecting outside of stop *B* is equal to the thickness of the work to be drilled. Then when the drill begins to break through, the stop will come against the work and a slight extra pressure



Safety Stop Device for Portable Drills

on the drill will be required to force it through the work, this extra pressure compressing the spring *D*. In this way, all danger of breaking through too suddenly and causing injury to the drill or tool is avoided. The writer has used this stop for over a year and it has given good results. T. C.

A GRINDING OR LATHE DOG WITH A CAM GRIP

The accompanying illustrations show a grinding or lathe dog made by the apprentice department of the West Lynn works of the General Electric Co. Fig. 1 shows the way in

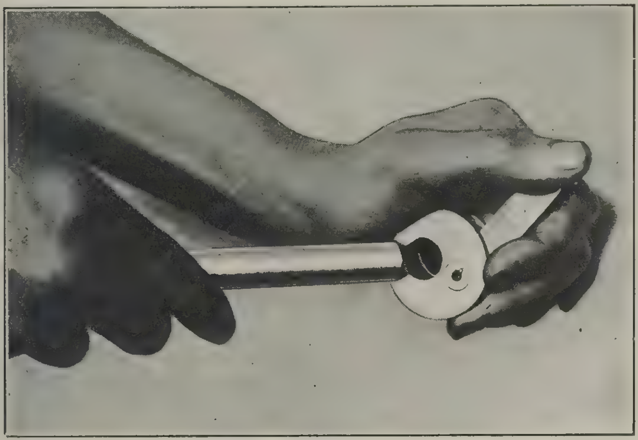


Fig. 1. Inserting the Work in the Dog

which the work is inserted. The lever is pushed back, putting under tension a spring which returns the lever as soon as it is released. The lever is provided with a cam face which

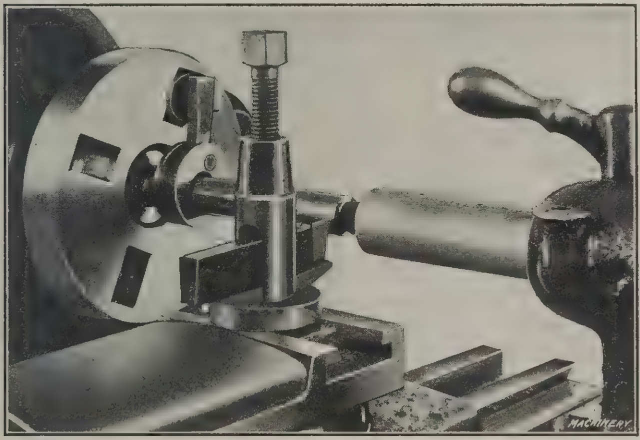

Fig. 2. Dog in use driv'ng Work in the Lathe

comes in contact with the work holding it securely. Fig. 3 shows more clearly the construction of this dog.

In Fig. 2 the dog is shown in use holding a piece in the

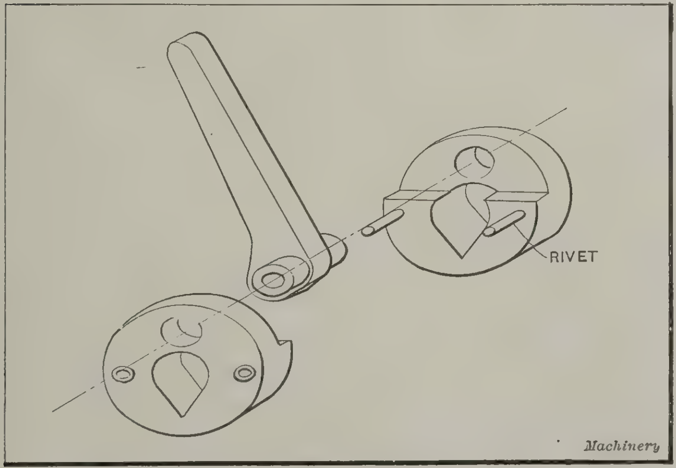

Fig. 3. Construction of Lathe Dog with Cam Grip

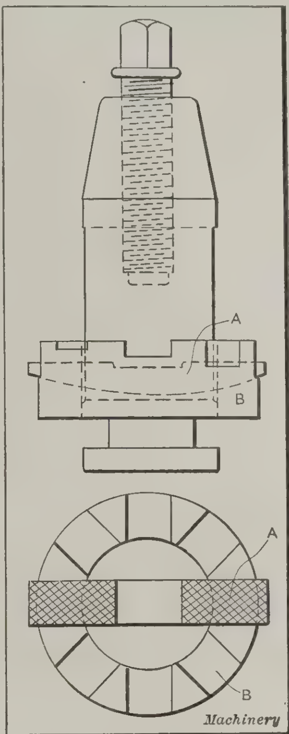
lathe. It has been found that in the lathe, the lever will break before the work will slip in the dog. The ¼-inch dog will take a variation in stock of 1/16 inch, and the 1-inch dog, a variation of 1/8 inch—this is the capacity of the cam. One advantage of this dog is that there are no set-screws or clamps to tighten, and it does not mark the shaft as a set-screw or clamp does, which is usually tightened more than is necessary.

West Lynn, Mass. CHARLES K. TRIPP

IMPROVED LATHE TOOLPOST

The accompanying illustration shows a lathe toolpost which the writer believes will prove of interest to the readers of MACHINERY. This design of toolpost was made long ago, but to the writer's knowledge it has never been published in the technical press.

It will be seen in the illustration that this toolpost has decided advantages over the ordinary types, in that a greater variation in adjustment is possible. This will be appreciated by lathe operators who know what a difficult thing it is to pack properly under a boring tool, for instance, in order to bring the tool to the center so that there may be plenty of clearance when boring small holes.



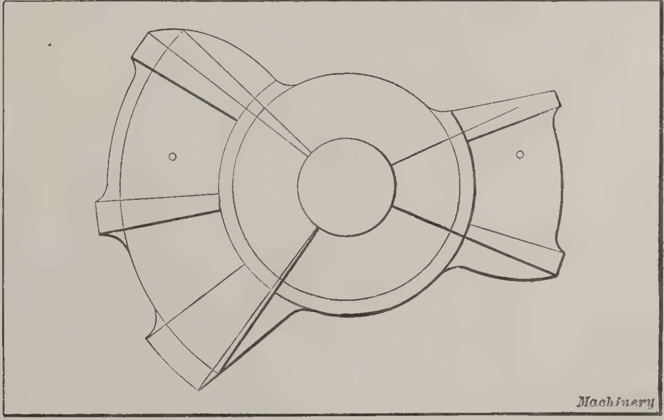
Type of Toolpost permitting of Great Range of Adjustment

One of the great advantages of this design is that it is comparatively easy to convert the toolposts now in use to this new type. In this way, toolposts with small adjustments can be changed into devices permitting a great range of adjustment and providing a simple method of setting the tool to the proper height. The only thing necessary is to cut four slots or grooves through the collar *B*. These grooves should fit the wedge *A*, as indicated.

Wickatunk, N. J. O. G. SIMMONS

TEMPLET FOR DRAWING RISES AND DROPS ON B. & S. SCREW MACHINE CAMS

The accompanying illustration shows a templet made by the writer, both in steel and celluloid, for drawing the rises and drops on No. 00 Brown & Sharpe automatic screw machine



Templet for Drawing Rises and Drops on Screw Machine Cams

cams. This device has been found more convenient than the templet regularly supplied by the Brown & Sharpe Mfg. Co. As will be noted, there is room enough around the two outer portions for three forms suitable for laying out the cut-away places between the lobes on the lead cam where the turret is revolved. The forms on this templet were so designed that one side of the templet can be used for the 4½-inch cam blanks and the other for the 5-inch cam blanks.

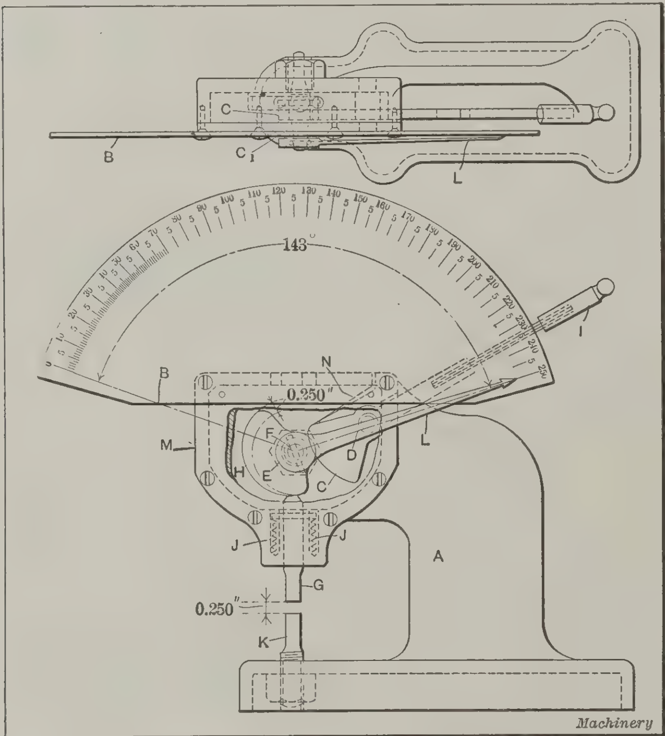
The writer finds it convenient to have the radial lines where the rises and drops meet the outside circumference of the cam, scratched on the templet. For the celluloid templet, the 1-inch center circle is simply scratched on it, but for the steel templet, the hole is machined and made to fit a 1-inch plug; this plug serves to locate the templet in the proper position on the cam blank. J. T. George

Providence, R. I.

[Templets can be used for laying out the rises and drops on the cross-slide and lead cams for the No. 00 Brown & Sharpe automatic screw machine with satisfaction, as the rise from the lowest to the highest point on the circumference of the cam is slight. However, the use of templets, constructed on this principle—drawing a line tangent to a circle for the drop or laying a line off from a circle for the rise—is not advisable on cams for the Nos. 0 and 2 machines. The reason for this is, especially on the lead cam, that the lobes are not all of the same height; consequently, when a rise for example, is laid out from a circle, it requires the same amount of cam circumference to rise a short distance as it does to rise to the full height of the cam. This adds to the time required for idle movements aand consequently reduces the production. The correct method of laying out the rises and drops for Brown & Sharpe automatic screw machine cams was described in the August, 1910, number of Machinery, engineering edition, in an article entitled, "Designing Screw Machine Tools and Cams."—Editor.]

A MEASURING DEVICE

The accompanying illustration shows a measuring device which has been used satisfactorily for measuring the thickness of mica for a number of years in our factory. For this class of work the regular micrometer is too slow, and would also show wear in a very short time. Of course, this device can be used for measuring paper, cardboard, sheet brass, sheet steel, etc. It consists of a cast-iron stand *A* to which a dial



A Measuring Device for Mica, Sheet Steel, etc.

B is attached by screws as shown. The graduations on this dial are laid off to read to 0.001 of an inch in a space of 143 degrees.

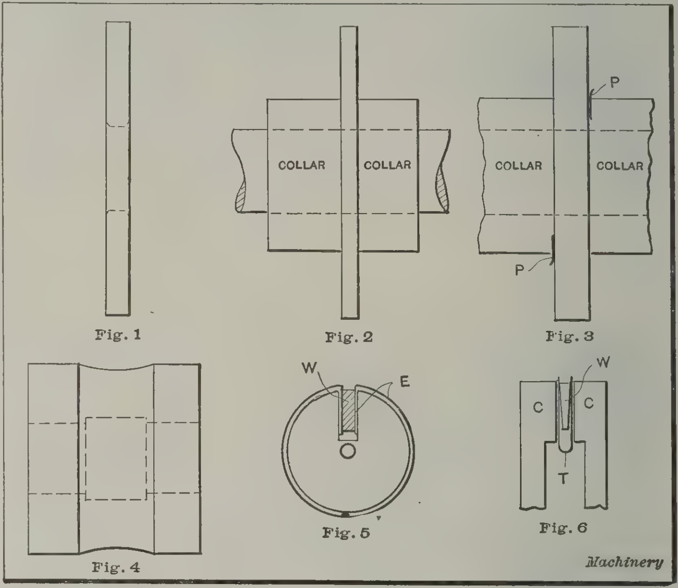
The working mechanism of this device consists of a segment gear *C*, 20 pitch (50 teeth) which is held on a shaft *D*, and is in mesh with a pinion *E* having 15 teeth, and keyed on shaft *F*. The measuring spindle *G* is operated by a cam *H* having a uniform rise of 0.250 inch in 143 degrees. This cam is fastened to the shaft *F*, and is rotated by means of the handle *I* through the segment gear *C* and pinion *E*.

The measuring spindle *G* is kept in contact with the cam *H* by two springs *J* which bear against a pin driven into the spindle. The anvil *K* is adjustable, and is held when set in the desired position by means of a nut as shown. The needle or pointer *L*, which indicates the movement of the spindle *G* is also pinned to the shaft *F*. The steel plate *M*, which is fastened to the casting *A* by screws acts as a cover for the mechanism, and also as a bearing for shafts *D* and *F*. The shaft *F* has hardened tapered journals and bearings, the rear bearing being adjustable in this case to provide for lost motion, this being accomplished by means of a lock-nut. The flat steel spring *N* keeps the spindle *G* as well as the handle *I* in the upward position. J. E. U.

SOME MILLING CUTTER SUGGESTIONS

Though improved management has greatly perfected manufacturing methods, set rules for odd jobs can hardly be formulated. This is true of jobbing and experimental work, some tool- and die-making, and of work in the smaller shops.

Milling cutters play an important part in shop practice. Saws and most other thin cutters frequently fit too tight on



Figs. 1 to 6. Various Suggestions relating to the Use of Milling Cutters

the arbors. By rounding the edges of the hole as in Fig. 1, much of this trouble will disappear. Another way of making a thin cutter work smoothly on the arbor is to use a collar of some width on each side of it when sliding the cutter on or off, as in Fig. 2, where the collars keep the cutter square with the arbor. In slotting, a cutter of the right width is not always to be found, nor is it always profitable to reduce the width of a wider one for the purpose. Lack of truth in arbor and collars will make a cutter leave a slot wider than itself, and it can be made to do likewise by inserting slips of paper between collars and cutter, on opposite sides, as shown at *P*, Fig. 3. It is not to be understood that this will produce an absolutely perfect job, but nine times out of ten it will do well enough.

A cutter used on a special milling machine for a certain manufacturing operation is shown in Fig. 4. A dozen were purchased for the machine, and in due time were ground to the limit. The shop undertook to re-cut them and put them back in service. The job was done, and, in hardening, the cutters contracted most decidedly. As no internal grinder was at hand, nor any lap of that particular size one had to be made. A piece of a shaft, 1/16 inch smaller in diameter than the hole, was procured, and a slot 2 inches long was milled in one end, as shown in Fig. 5, after which a strip of No. 0 emery cloth was wound about the shaft and the lap brought into the slot and held by a wedge; *E* is the cloth and *W* the wedge. Placed on the centers of the speed lathe, it made a cheap lap for the purpose, and was easily and quickly renewed.

To lap out the cutters, they were slipped on the shaft and the lathe started. Then by grasping a stick of soft wood in the hands and using it in the same manner as a file, the cutters were revolved two or three times for every stroke, and

with the pressure exerted, the revolving lap within soon corrected them to size. Kerosene was used as a lubricant.

Taking off a gang of cutters to put in a paper washer at the far end is expensive and uncertain. Expansion collars have done much to remedy this, but there are a few cases where an expansion collar cannot be used—between the halves of an interlocking cutter, for example. There is a way of making the cut larger without dismantling a gang. This way is shown in Fig. 6, which represents the halves of an interlocking side milling cutter. The little steel wedge *W* is driven between the parts *C*, spreading them the required amount; *T* is a strip of tin, the soft metal layers increasing the "staying-in" properties of the wedge. DONALD A. HAMPSON

Middletown, N. Y.

A SUGGESTION FOR THE DESIGN OF CHAIN BLOCKS

The writer believes that inventors and designers of chain blocks have overlooked an opportunity in not having designed a type especially for the use of erectors and small shops or power plants not provided with cranes. For such uses, it is necessary to frequently shift a chain block from one point to another in order to place it over the piece to be lifted. In doing this, the principal difficulty lies in getting the block down from one place and up in another. Much time is lost, because it is the heaviest part of the block which must be lifted and placed at the top, while the light part, the hook end, stays on the floor. It would seem that it would be possible to change this so that the light part, which one man could easily carry, would be placed at the top, and the heavy part of the block would be at the lower end. The only objection seems to be that in handling a load where there would not be sufficient head room to hang it far enough below the block, and where it extended too far horizontally, one might not be able to work the hand chain, but such cases would occur so rarely that they would hardly need to be considered.

It is also frequently a great convenience to be able to use a chain block for horizontal pulling, but the chain guides on the blocks generally made are not adapted for this purpose. It would be easy, however, to shape some hand chain guides so that they would take care of that chain, and a lug to peel the load chain from the slack side of its sheave would be sufficient for that chain.

A new device for chain blocks in such a building as a power house is to stretch a wire rope permanently as high under the roof trusses as possible and across the building. On this wire is put a light trolley with a grooved wheel about 6 inches in diameter, and from the bottom of the trolley is hung a chain block. The small wheel rolls freely enough so that the trolley can be moved on the rope, but not so freely that it will run away on a down grade. Some sag, of course, is required in the rope; otherwise, it woud be placed under too high a stress initially, and there would be nothing left for the handling of the load. The installation the writer has in mind is in a building 40 by 105 feet, having a height of 22 feet under the trusses. Three ¾-inch ropes are stretched lengthwise so as to have four feet of sag. With them, one man handles anything in the building weighing less than a ton. Four or five men were often required for the same pieces, before the ropes were put up. F. D. BUFFUM

Ellsworth, Pa.

CHAIN CASES FOR AUTOMOBILE TRUCKS

The remarks made by Mr. W. F. Schaphorst and C. P. W., in the April issue of MACHINERY lead me to further defend the practice of uncovered chains. I would not dispute that, theoretically, cases are an advantage, but there are some things which are theoretically correct that are not adopted commercially, because the advantages gained do not outweigh the disadvantages. I believe this to be true of chain cases.

The recent exhibitions of commercial cars seem to bear out this statement. Only a small number of models exhibited were equipped with chain cases. The *Power Wagon*, a Chicago automobile periodical, recently published a review of the mechanical features of 381 models. Of this number, only twenty-three had chain cases and seventy-seven were shaft-driven, which means that only about fifteen per cent of chain-driven cars are equipped with chain cases. Mr. Chester S. Ricker says in the *Horseless Age* in an article entitled "A Review of the Recent Automobile Shows": "On most trucks the chains are exposed, but upon several they are enclosed, as on the Sampson and on the Lozier." Mr. A. C. Woodbury, in the same journal of January 31, states: "A year ago one of the things that looked most promising was what seemed to be a general movement toward enclosed chains for the rear wheels of the larger trucks. The movement seems to have fallen flat, for although the Lozier is fitted with a sheet steel case and the Sampson has retained it, there is, on the whole, a smaller proportion of chain cases than last year."

An instance where chain cases would have proved a disadvantage was forcibly called to my attention after my first article was written. I was sent out to supervise the replacing of a rear axle that after years of service had broken on the road. The truck was jacked up, the axle replaced, and all the adjustments made on the road. If the truck had been provided with chain cases they would have had to be strong enough to support a seven-ton load or they would have been crushed.

In regard to the skill of drivers, it may not be out of the way to refer to the transcontinental trip made by the Saurer and Packard trucks. In this case the drivers were competent to negotiate roads of every description, without any appreciable injury to their chains. Yet, how many chain cases would have been broken on this trip if the trucks had been provided with them? I do not think it logical to compare sprocket chains and gears. A small obstruction will prevent a gear from turning, whereas, a sprocket will turn even with rather severe obstacles in the way.

I believe that a campaign of advertising the proper methods of mounting chains would lead to a more general use of chain cases. It is apparent that, at the present time, the campaign for chain cases is not being carried on by the chain manufacturers so much as by the salesmen of internal gear drives, worm drives, and other enclosed forms of drives, who are calling the attention of the public to the theoretical advantage of chain cases.

Brooklyn, N. Y. JOHN F. WINCHESTER

ESTIMATED COST OF MAKING MECHANICAL DRAWINGS

The following method may be used for determining the average cost of producing mechanical drawings. Assume that

A = average number of drawings of a given size produced in one year by one man,
B = number of square inches per drawing,
C = number of working days in the year,
D = draftsmen's rate of wage per hour,
E = working hours per day.

Then the labor cost per square inch of drawing equals $\frac{CDE}{AB}$.

In the same way the average cost per square inch of tracing and checking is determined. The cost of drawing paper and tracing cloth per square inch is also calculated. The total cost of the completed tracing per square inch equals the sum of the unit drafting, tracing, checking and paper costs. From this the average cost of any tracing of a given size can easily be determined.

In a drafting-room where the work consisted of assembly and detail drawings of punches and dies, jigs and fixtures, and tools in general, it was found that one draftsman could complete 262 drawings in 306 eight-hour working days. The draftsman's rate was fifty cents an hour. The size of the drawings was 16 by 23 inches. Hence the cost per square inch of the drawings was found as follows:

$$\frac{306 \times 8 \times 0.50}{262 \times 16 \times 23} = 0.0127 \text{ dollar.}$$

The cost per square inch of the tracing work was found in the same way to be $0.0054, and for checking $0.004. The cost

per square inch of drawing paper and tracing cloth was found to be \$0.0005. Hence the total cost per square inch of the completed tracing will be:

$$0.0127 + 0.0054 + 0.004 + 0.0005 = 0.0226 \text{ dollar,}$$

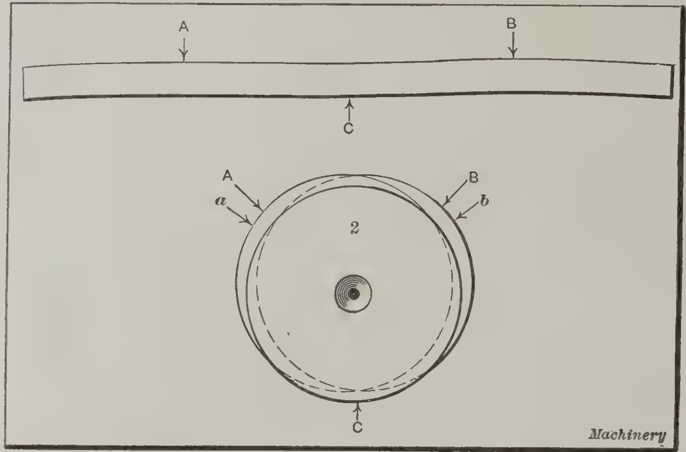
or the total cost of producing a drawing 16 by 23 inches within its borders would be: $16 \times 23 \times 0.0226 = 8.32$ dollars.

The cost of blueprints can, of course, be easily determined, and is quite independent of the cost of drawing, depending upon the number of blueprints required from each drawing. To all of these costs must be added a certain percentage for "overhead expense," if the absolute cost of the drawing is to be determined.

Cicero, Ill. E. A. Peterson

STRAIGHTENING SHAFTING

In the March, 1912, number of Machinery, an interesting article on straightening shafting, by Mr. J. W. Brandle, was published. Having had some fifty years' experience, the writer would like to say a few words on this subject. The accompanying engraving shows a two-inch rough shaft, 10 feet long, which is bent at two places about 2 feet 6 inches from each end. There is also a bend in the middle. After having "chalked" the shaft, it is found that the chalk marks are located as at A, B, and C. The beginner usually has trouble



Indicating Method of Straightening Shafting bent in Three Places

in straightening a shaft of this kind. He applies pressure at the points indicated by the chalk marks, the result being that the shaft is bent too much toward the opposite side. The proper method is to shift the marks a trifle as to a and b as indicated in the engraving, the shifting being perhaps about ten degrees. Pressure is then applied first at a and then at b. This throws the three bends into one direction, so to speak—that of the bend at C. Pressure is then applied at this place and the shaft will soon be found straight enough to clean up.

Birmingham, Ala. W. B. Odell

METHOD OF DIMENSIONING DRAWINGS

The Taft-Peirce Mfg. Co., of Woonsocket, R. I., issues the following rules for its draftsmen.

"If a limit can be permitted above and below the dimension, specify the limit thus: ±, giving the amount of limit tolerated. If a limit can be permitted below the dimension only, specify it thus: —, giving the amount of limit tolerated. If a limit can be permitted above the dimension only, specify it thus: +, giving the amount of limit tolerated.

"Fractions: Unless limits are specified, common fractions are capable, in the main, of a wide variation of limitation. For the purpose of fixing a standard, however, it shall always be understood that if a fraction is not accompanied by a limit, a minimum limit of ± 0.010 inch is permissible.

"Fractions that must be held closer than this must be accompanied by a specified amount of limit."

In order to make it unnecessary to give limits in all instances on the drawings, it is understood that two-place decimals have no limits added in case a tolerance of ± 0.005 inch is permissible. A three- or four-place decimal should be used only when absolutely necessary. If the tolerance is not added, a limit of ± 0.0015 inch is permissible. Dimensions to be accurate to three or four decimal places should be marked "exact."

Worcester, Mass. H. P. Fairfield

A MULTIPLYING ATTACHMENT FOR AN INDICATOR

In Fig. 1 is shown a multiplying attachment which the writer has used with an indicator of the type shown in Fig. 2. The principles employed might be interesting to the readers of Machinery. The device needs very little explanation. It will be sufficient to say that the area of the large plunger A, which is applied to the work, is ten times the area of the small plunger B, which, when the instrument is attached to the indicator proper, bears against the working anvil of the indicator. The cavity between these plungers is filled with heavy oil or grease of the best quality. The movements of the plungers

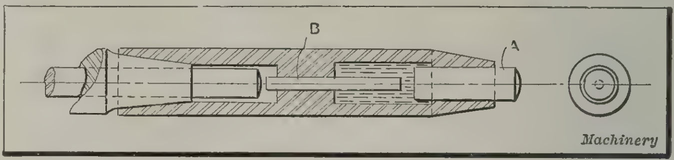


Fig. 1. A Multiplying Attachment for the Indicator shown in Fig. 2

are in inverse proportion to their displacement areas, and, therefore, any movement of the large plunger is transmitted to the indicator proper, multiplied ten times.

It was the writer's practice to true up work such as buttons, etc., as accurately as possible with the indicator minus the attachment, which would be within 0.001 inch. Then by attaching the multiplier this error would read on the dial of the indicator as 0.01 inch. Thus when this error was again corrected to read 0.001 or 0.002 inch, the writer knew the work to be accurate within 0.0001 or 0.0002 inch. Needless to say such accuracy can only be obtained with the use of a machine having very true bearings, and set on a very solid foundation.

The writer cannot forebear mentioning that he has had considerable amusement owing to the fact that he did not at once disclose the secret of the innermost mechanism of the device. The unique and learned explanations of the complicated mechanism it was supposed to contain, and the compliments to a mechanic capable of arranging so much mechanism of a com-

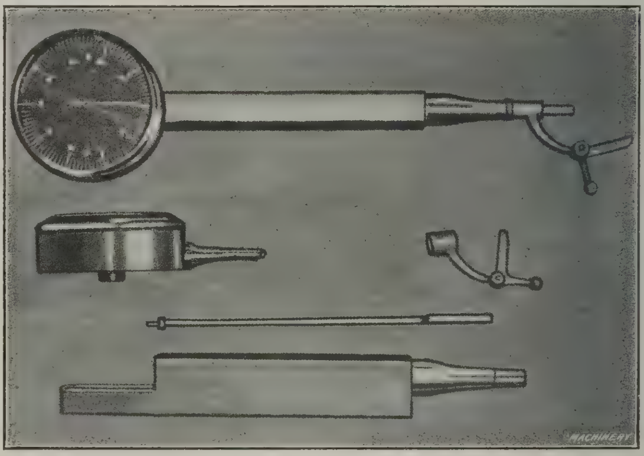

Fig. 2. Indicator to which the Device in Fig. 1 was attached

plicated, delicate nature in so small a space, were very entertaining indeed.

In making one of these attachments, considerable care should be taken to have the plungers fit properly. If they are too loose, the oil leaks out and destroys the accuracy, and if too tight, they will not work properly. T. Covey

LEAD HAMMERS FOR SHOP USE

The lead hammer is an indispensable tool in the modern machine shop. Before the advent of finely finished jigs and fixtures, when the tools for interchangeable manufacturing consisted of some old straps and boiler plate taken from the scrap heap, the machinist generally pounded the work on and pounded it off again. This process became a habit, and even yet, we frequently see some drill press hand raising the lid of a nice jig with a machinist's hammer. Some shops still build jigs without any regard to looks or finish, but the

majority of them recognize the fact that a nice looking tool will be more carefully handled and last longer than one that is not given a good finish.

Fig. 1 shows the detail of a lead hammer we make for our own use, which has saved our jigs from being all battered

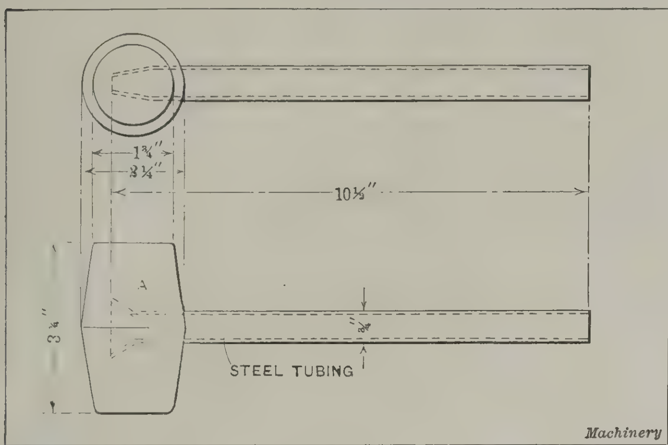

Fig. 1. Details and Proportions of Lead Hammers

up, besides giving the men something to hammer with when a steel hammer would not do. The handle is made of ¾-inch steel tubing, flattened at the end as shown at *A* to keep the mallet part from slipping off. The mallet part is made of 60 parts lead, 30 parts tin and 10 parts antimony. This makes a good general-purpose hammer, but should a softer one be

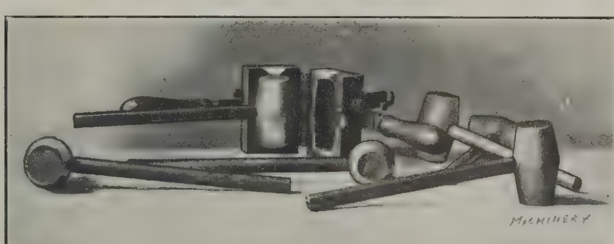

Fig. 2. The Molds for Casting the Mallet Part of the Hammers—Some Mallets fitted with Handles

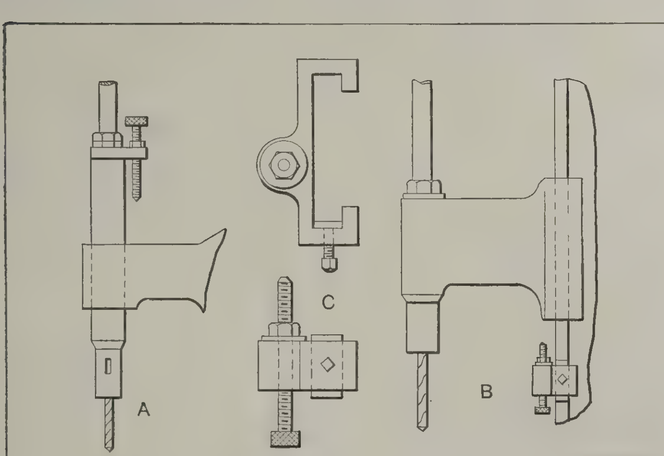
required, add a little more lead. The molds for producing the mallet part of the hammer are illustrated in Fig. 2, where some completed hammers are also shown. G. W. LINN

Indianapolis, Ind.

STOPS FOR DRILLING MACHINE SPINDLES AND HEADS

It seems strange that none of the new drilling machines possesses a drilling stop. I have noticed in a large machine shop from 10 to 20 drilling machines in daily use and not one



Adjustable Stops for Drilling Machine Spindles and Heads

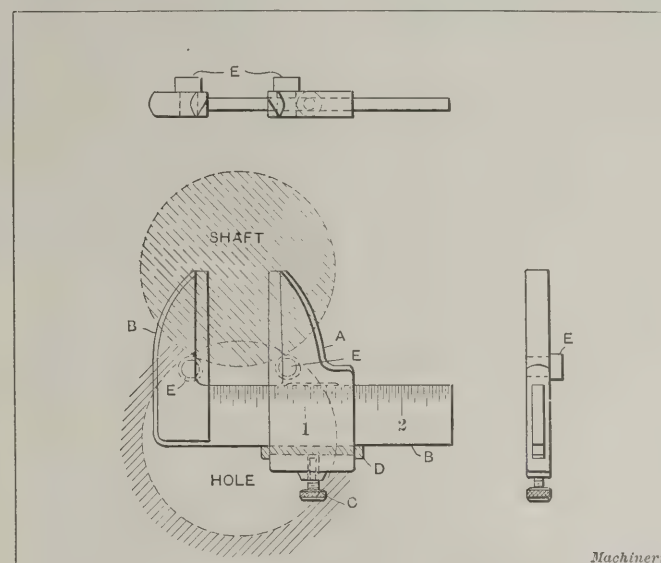
of them has even a respectable stop. The accompanying illustration shows stops for the spindle and also for the head. At *A* is shown a stop which can be applied to the spindle of a sensitive drill, while at *B* is a stop for a movable head, located on the column. An enlarged view of the stop at *B* is shown at *C*. To gage a hole for depth, set the point of the set-screw to a sizing block when the point of the drill is in the same plane as the top face of the work.

Brighton, Mass. F. RATTEK

MARKING-OFF GAGE FOR KEYWAYS

The accompanying illustration shows a handy gage for marking off keyways in hubs of pulleys, gears, etc., and at the ends of shafts. The illustration shows the gage applied to both a hub and a shaft.

The jaw *A* which moves along the bar *B* is set to the required width of keyway by means of the graduated scale on the bar, and locked by tightening the screw *C* on the gib



A Marking-off Gage for Keyways in Hubs and Shafts

D. The gage is then applied to the hub or shaft as shown, the hardened pins *E* being held against the sides of the hole, or shaft, while the keyway is being marked off. The gage has a capacity for shafts up to 6 inches in diameter.

J. M. L.

MAKING PISTON RINGS—A CRITICISM

The writer takes exception to some of the methods described in the article: "Making Piston Rings" in the April, 1912, number of MACHINERY. It is stated that the rings are turned eccentric, and then a parting or cut-off tool is used and the first ring is cut off within 1/64 inch. This must mean that 1/64 inch thickness of metal is left at the thin side, but how much stock would then be left at the other side? Again, does it produce good results to use a cut-off which generally chatters and take a finishing cut at the same time? Do not the rings give trouble by breaking off before they are cut way through?

Some firms scrap their rings if they are 0.0015 inch out of parallel. Do the rings made by the method described come as close as that? The writer does not like the milling practice mentioned. It is said that clamps are not required because of the snug fit. In that case it seems that it would be difficult to put them on quickly. It is also mentioned that they can be held with the fingers, but that seems to be a rather dangerous practice. The question of safety is being agitated at the present time so much that one can not indorse any practice that tends to lead away from the safest possible methods.

Milwaukee, Wis. W. BUTZLAFF

STATING PROPORTIONS

In a contemporary I see recommended a mixture of "55 parts tin, 45 parts zinc and 1 ounce of bismuth." Does the author mean 55 ounces of tin, or 55 pounds?

Very often we see mixtures or alloys recommended, in which every figure given is a factor of 5 or some other prime number. Why say "25 to 35" when "5 to 7" is more simple? Everyone speaks of an "8 to 1 gun-metal"; that is much more readily kept in the head than "16 to 2" or "40 to 5." Why not in all other cases use the most simple factors?

Dresden, Germany. ROBERT GRIMSHAW

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

MIXING BEESWAX WITH ALUMINUM SOLDER

C. E. L.—A formula for aluminum solder was published in the January, 1912, number which I have tried with very unsatisfactory results. In attempting to mix the beeswax with molten tin and zinc I came near causing a bad fire. The beeswax was apparently entirely consumed, and just what benefit it is to the mixture, I cannot understand.

A.—The contributor of the receipt assures us that the formula is quite correct, being exactly as given to him by the originator, and as such has been used for a number of years. Care must, of course, be taken to prevent the beeswax from taking fire by keeping the heat of the mixture as low as possible, consistent with its remaining in the molten state. Should the heat become too great, the ladle can be lifted from the fire, and in fact it is advisable to remove it from the fire when adding the beeswax, which should be inserted in small pieces, one at a time. If, however, the mixture does take fire it is an easy matter to put a cover over the pot and smother out the flame. It might be thought that the pine stick mentioned would catch on fire, but if the metal is kept at the proper heat, neither the stick nor the wax will be fired. The originator of the formula particularly recommended the use of the pine stick.

FROSTED OR CORRUGATED GLASS FOR FACTORIES

E. H. B.—I am a constant and appreciative reader of MACHINERY and admire the way it handles mechanical topics. I would be glad to see a discussion of the merits of frosted glass in the windows of factories employing skilled labor.

A.—The advisability of the use of frosted glass in the windows of factories employing skilled labor is a question of general interest. We are not in favor of frosted or corrugated glass for small floors. The effect is depressing, having a tendency, we believe, to cause eye strain. In large factories, however, the conditions are different. The dimensions of floors are great enough to allow the workers to change the focus of their eyes by looking at distant objects and the mental stimulus of the outside world is not required so much in the large shops, as there is a variety of action within to be seen. Corrugated or frosted glass can be used advantageously with clear glass in small shops, placing the corrugated glass on the sunny sides and the clear glass on the shady sides. The light from the sunny side is diffused by the glass and that coming from the shady side is diffused by reflection. To obtain a large flood of diffused light should be the object of the plant designer. The use of frosted glass to prevent men from looking out, does not appeal to us. If the shop conditions are right little time should be wasted by men staring out of the windows. Discussion is invited.

SEASONING CAST IRON FOR MACHINES

R. L. S.—Is there any practicable method or process for "seasoning" cast iron which does not require taking roughing cuts and then allowing the castings to stand for several weeks or months to prevent warping after finishing? Our system is to bore or plane castings in the rough and let them stand for some time to take whatever shape they will. They are then put back on the machines and finished. This method is costly, and during the busy season is too slow, and besides it is not entirely satisfactory as we often find that the parts change shape after finishing even though seasoned several weeks.

A.—The change of shape of castings after machining is due to readjustment of internal stresses thrown out of balance by the removal of the surfaces. These forces set up by irregular cooling of the metal in the foundry may be partially eliminated by reheating. Tumbling, rapping and repeated dippings in hot water have an accelerating tendency, but so far as we know the cheapest and most effective method is that commonly pursued by the machine tool builders, *i. e.*, taking roughing cuts off the parts to be finished and then letting the castings stand for several weeks or months to season. Then little change takes place, as the internal stresses have been largely neutralized by the effect of alternate heating and cooling due to variations in temperature. Any suggestions from readers as to ways and means of cheaply accelerating the seasoning process will be appreciated.

CONDUCTIVITY OF WROUGHT-IRON PIPE

F. C. P.—In connection with the design of a cooling apparatus for oil, in which the oil is cooled from a temperature of 100 degrees F. to 60 degrees F. by circulating through a coil placed in a water bath, it is required to find the approximate number of British thermal units (B. T. U.) that will pass through the walls of a 1¼-inch iron pipe, per hour, per square inch of radiating surface, for each degree difference of temperature of the liquid inside and outside of the pipe.

A.—The coefficient of conductivity of iron, that is, the quantity of heat in therms (252 therms = 1 B. T. U.) that will pass through one square centimeter of surface, one centimeter thick, in one second, per each centigrade degree difference in temperature, is (for temperatures here dealt with) on an average 0.165. Transforming this to English units, the quantity of heat in B. T. U. that will pass through one square inch of surface, one inch thick, in one second, for each degree F. difference in temperature is

$$\frac{0.165 \times 2.54 \times 2.54 \times 5}{252 \times 2.54 \times 9} = 0.00092 \text{ B.T.U.}$$

As 1¼-inch wrought-iron pipe has a thickness of 0.140 inch, the quantity of heat that will pass through its walls per square inch of surface per hour for each degree F, difference in temperature equals:

$$\frac{0.00092 \times 60 \times 60}{0.14} = 23.6 \text{ B.T.U.}$$

LOCATION OF VALVES IN PIPES

R. J.—Should valves be placed with the pressure on top or underneath the valve in main steam lines or in boiler feed pipes? What practice is followed in the United States Navy? The writer was somewhat surprised upon consulting two engineers engaged in power plant construction to hear directly conflicting opinions on the positioning of valves in these pipes.

A.—The engineer-in-chief of the Bureau of Steam Engineering, Navy Department, states that the requirements of the machinery specifications on locating valves in main steam and boiler feed pipes with reference to whether the pressure is above or below the valve are as follows: "All high-pressure steam valves over six inches diameter, except boiler stop valve, will have flat faced seats, with the pressure on the back of the valves, and will be so designed that the stuffing-box may be packed while under pressure. High-pressure steam valves six inches diameter, and below are installed to close against the pressure, in order that the valve stem may be packed when the valve is closed. In the feed system there is a feed check valve and stop valve on each boiler. These two valves are in the same casing, the stop valve being between the check valve and the boiler, opening against the boiler pressure and so fitted that the stuffing-box may be packed when pressure is on the boiler. The remaining valves in the feed system are gate valves, except the suction and discharge valves at pumps, which are stop valves, except where the connections are such that water may run to the bilge in case valves are left open, under which conditions stop lift check valves, so arranged that they may be kept off their seats when desired, are fitted."

METAL PAINT TO WITHSTAND ALCOHOL

Replying to the question by S. J. B., in the April number of MACHINERY, for a paint for brass vessels which will successfully withstand the action of diluted alcohol, the writer wishes to say that years ago, during his apprenticeship as a nautical instrument maker, a paint made of white zinc and pure turpentine was used, two coats of which was applied. White japan was also used, the objects afterward being baked in an oven. This, however, was more expensive. The instruments so painted were liquid ship compasses, and the liquid consisted of rectified spirits of wine reduced 50 per cent with distilled water.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

THE MELLING-NORTHRUP DIE-SINKING MACHINE*

The superiority of drop forging over casting for certain classes of work is well known, but the cost of making dies of intricate shape has impeded the progress of this art to a considerable extent. It has been necessary in connection with a great deal of die work, to rough out certain impressions with a chisel by hand, and then scrape and "type" the impression to a finish. When the impression is deep and narrow, this work of chipping, scraping and typing will be found to be slow and difficult. Many devices and attachments for both the milling machine and the ordinary die-sinking machine, have been devised to eliminate chipping and the difficult hand work. Some of these attachments are very

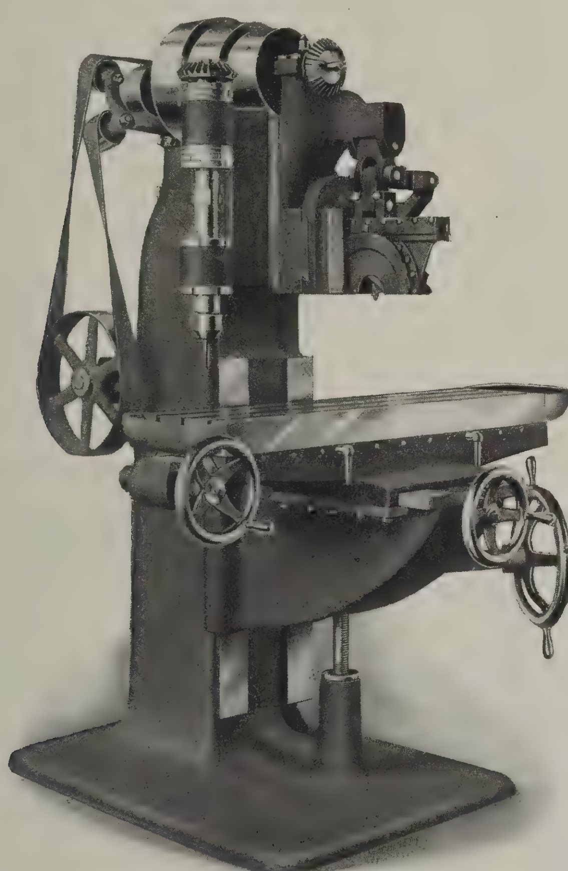

Fig. 1. Die-sinking Machine manufactured by Melling-Northrup Co.

ingenious and have been of inestimable value to the die-sinker. When not more than two types have to be sunk in a die, it is the usual practice for the die-sinker to use a chisel and type, because the work can be accomplished much cheaper and quicker in this manner, as it takes considerable time to set up a cherrying attachment. Having worked as a die-sinker for about ten years and experienced the need of an improved device for this work, Mr. Herman Melling of Melling-Northrup Co., Jackson, Mich., set about to design a machine which would meet all the existing requirements of drop-forge die-sinking. After considerable experimenting with different attachments and devices for this work, he conceived the idea of building a machine which would be suitable both for routing and cherrying.

The machine, which is shown in Figs. 1 and 2, does away with the necessity of typing most dies, so that the impression can be completed without resorting to any chipping or typing. The machine is of the column-and-knee construction, and the aim has been to make it heavy and rigid enough to eliminate chatter. The knee has a vertical adjustment on the column, which is effected by hand-wheel *A*. The table is long and wide, and is traversed by hand-wheel *B*. Lateral adjustment of the table on the knee is obtained by hand-wheel *C*. All movements of the saddle and table are effected by hand, no automatic feeds being employed to confuse the workman and make the machine more difficult to operate. These hand-wheels are all in convenient reach of the operator, and the table, saddle and knee are equipped with lock levers.

This machine is so arranged that it can be used for cherrying out an impression in a die, and also as a vertical milling or routing attachment, and both devices can be brought into operation without resetting the work. The vertical milling head *D* carrying the routing cutter *E*, is hinged at *F*, and is held to the column, when in the working position, by two bolts *G*. This vertical milling head can be swung out of the way by simply removing the bolts *G*, when it is necessary to use the cherrying cutter. The vertical milling spindle is driven from the cone pulley *H* through miter gears *I*, and it runs in solid, taper, phosphor-bronze bearings. The thrust, instead of being taken on the lower journal, is transferred to the upper journal, in order to equalize the friction on both bearings and, consequently, prevent them from heating excessively under heavy cutting action. The spindle can be locked by a spring-actuated wrench, which fits over a flattened portion of the spindle, when it is desired to hold the latter rigidly to remove the routing cutter.

Construction and Operation of the Cherrying Head

We now come to the most interesting part of this machine, namely, the cherrying device. This consists essentially of a segment head *K*, which carries a cherrying cutter *L* having teeth on half of its periphery and sides, the latter being beveled at an angle of 7 degrees, which takes care of the draft necessary in the dies. The axis of the die-sinking cutter *L*, is located in line with the axis of the segment head *K*, the latter being oscillated by a rack *M* which, in turn, is operated by a lever *N* and crank arm *O* (see also Fig. 3). This arm is free to slide in a bronze box *P*, which is fastened to the cam-wheel *Q*. The cam-wheel *Q* is rotated by a pulley *R* (Fig. 3), which, when it is desired to use the cherrying attachment, is pinned to a collar fastened on the main driving shaft by a spring-plunger *S*. The belt runs over idler pulleys *T* and onto a lower pulley *U* which drives the cam-shaft and cam-wheel.

The cherrying cutter *L* cuts into the impression when the rack *M* (see Fig. 5) is on the return stroke. Owing to the eccentric location of bronze box *P* on cam-wheel *Q*, a quick-return movement for the cutter is obtained, the cutting being done on the slow movement of the eccentric, or, in other words, when box *P* is at the bottom and farthest from the rockshaft *V*, Fig. 3. As shown in Fig. 1, the cherrying head slides in another slide which, in turn, is mounted on the face of the column and can be moved in a lateral direction. Connected with the cherrying head by a toggle joint, is a link *Y* (Fig. 4), which, in turn, is fastened to a bellcrank A_1, shaft B_1 and cam-lever C_1. Located on the lower end of cam lever C_1, is a roll which runs in a groove cut in cam-wheel *Q*. This cam transmits an oscillating movement to the cam lever, which operates the toggle, thus raising and lowering the cherrying head. This action, as can be seen, will remove the cherrying cutter from the impression on the back stroke, owing to the relative positions of the eccentric crank *P* and the operating portion of the groove in the cam-wheel.

When the cherrying cutter is to be sunk down into the die to produce an impression the exact duplicate of its own shape, it is not necessary that it be relieved on the sides, but when it is necessary to make an impression much longer

* For information previously published in MACHINERY on drop-forge die-sinking, see "Drop-Forge Die-Sinking," July, August and September, 1911, and articles there referred to; "Making Duplicate Drop Forging Dies" and "Compound Trimming Die," July, 1911, engineering edition; "Tempering Drop Forging Dies," January, 1908, engineering edition. See also MACHINERY'S Reference Series, No. 45.

than the width of the cherrying cutter, the cutter on being returned for the next stroke must be relieved or else it would be dulled very quickly and would not produce a good finish. This relief is accomplished in a very interesting manner. As can be seen in Fig. 4, bell-crank A_1 is formed into a yoke in which a stud D is held. Sliding on this stud and also on

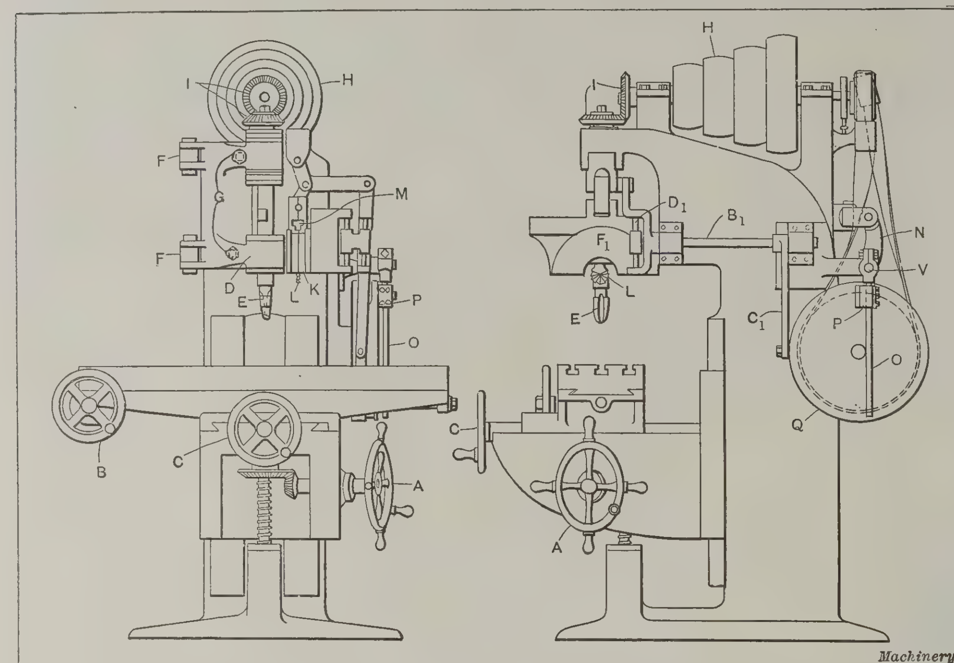

Fig. 2. Front and Side Elevations of the Melling-Northrup Die-sinking Machine

a second stud E_1, held in lugs cast integral with the slide in which the cherrying head is mounted, is a yoke F_1. This yoke is provided with a lug in which a spring plunger is held, the latter fitting in a series of drilled holes in the cherrying head slide. Now by changing the position of this yoke relative to the center of the cam-shaft B_1, the desired movement of the

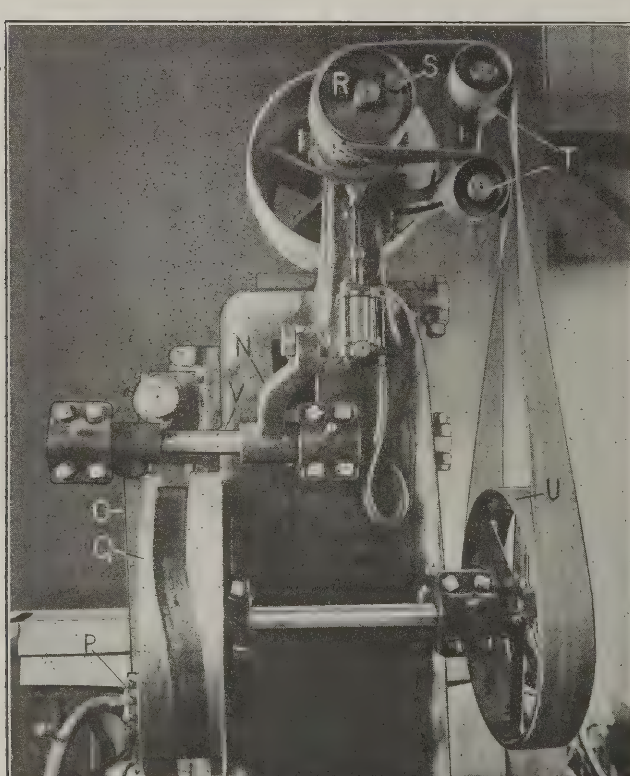

Fig. 3. Rear View showing Drive for Cam-wheel and Compressed Air Pump

cherrying head slide can be obtained. When the plunger is in direct line with the center of the shaft B_1 no movement at all will be transmitted to the slide, and when the plunger is shifted to a position above or below the center, a corresponding movement is given to the slide, so that the cutter is relieved to allow it to return free and without roughing up the work.

The action transmitted to the cherrying head by means of this toggle-joint motion and sliding yoke, is clearly indicated in Figs. 6 and 7. In Fig. 6 the toggle joint is shown in the position it occupies after being operated by cam Q; hence the cutter L has been raised and relieved from the bottom of the impression. The spring plunger G_1, as can be seen, is located above the center of the cam-shaft, and, consequently, has relieved or drawn the cutter away from that portion of the die in which it was working. In Fig. 7 the toggle joint is shown straightened out, in which position the cutter would be at work. Of course, while the toggle joint is straight, no side relieving movement is given to the cherrying cutter L.

A little device that will be appreciated by most die-sinkers is a small air pump which is operated from the cone-pulley driving shaft by an eccentric, as shown in Fig. 3. The compressed air is carried to the front of the machine through flexible tubing. This tube passes through holes drilled in the frame of the machine and is held, when not in use, in a spring socket H_1 as shown in Fig. 4. With this simple little device, it is possible for the die-sinker to always keep his work free from chips and dirt.

The Cherrying Cutters

In Fig. 8 is shown a representative group of die-sinking and routing cutters. The routing cutters A, as is the usual practice, are made with but two cutting edges. They are relieved on the sides, ground on the ends, and are somewhat similar

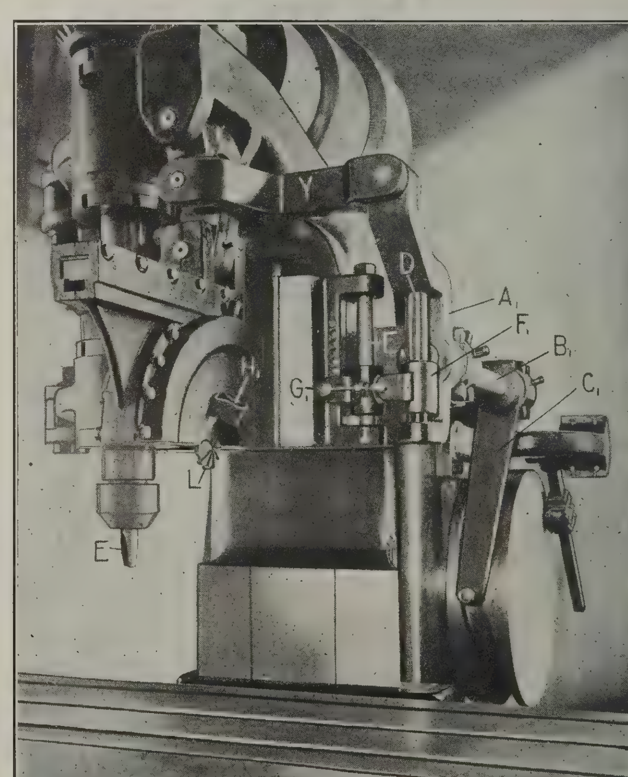

Fig. 4. Front View showing Relieving Mechanism for the Die-sinking Cutter

in shape to twist drills. Of course, this type of cutter would only be used for roughing purposes. When any special shape is to be reproduced, a cutter would be made to that shape. The cherrying cutter shown at B has six teeth and cutting edges on the sides that extend to the center or axis. The

teeth, as has been previously mentioned, are backed off on the periphery and sides, and are also tapered on each side to an angle of 7 degrees, this being the angle of draft usually allowed in drop-forge dies.

It has been found from actual experience that, irrespective of the diameter, six teeth will give the best satisfaction. These cutters are made from drop forgings, and are milled on a special fixture, which is an exact duplicate, as far as the

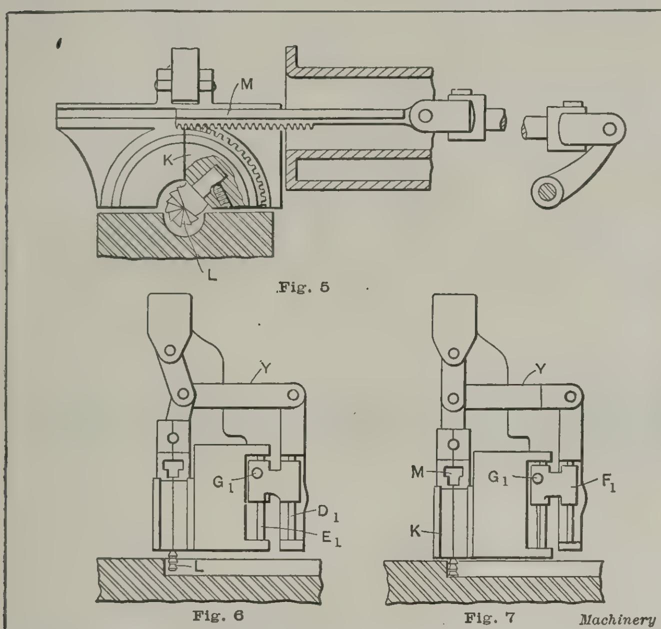

Fig. 5. Section of Cherrying Head showing how it is operated. Fig. 6. The Cutter in the Relieved Position. Fig. 7. The Cutter at Work

radius is concerned, of the segment head in the cherrying attachment. Owing to the construction of this die-sinking tool, and the attachment in which it is used, it is possible to cut in to the center and completely mill an impression without doing any chipping or typing. Cutters have been made ranging in diameter from ¼ inch to 3 inches.

Work Done by Melling-Northrup Die-sinking Machine

In Fig. 9 is shown a die block which has been used for testing the machine. The rapidity with which the majority

Fig. 8. A Representative Group of Routing and Cherrying Cutters

of these impressions have been sunk is marvelous, considering the time that it takes a man to do this work by hand. The impression *A* is 1½ inch in diameter and ¾ inch deep, and the width of the impression is 5/16 inch. This impression was sunk in 7½ minutes, without previous roughing operations. The smaller hole *B*, which is 1 inch in diameter, was formed in 3 minutes. This test block is made of the regular crucible steel used for drop-forge dies and contains from 0.40 to 0.50 carbon.

The small block shown to the right, has an impression *C* sunk in it which is 3 inches in diameter, and the width of the narrowest part is only 5/16 inch. This impression was made in 45 minutes, which includes roughing with the routing attachment. A die-sinker would certainly have difficulty in producing a similar impression with a chisel or by any other means, on account of the great depth and small space in which he would have to work. If this hole had been sunk with an ordinary cherrying cutter, it would still be necessary to do a little hand work, as the ordinary cherrying cutter does not cut clear to the center, and, consequently, does not finish the impression. On holes much larger than 1½ inch in diameter,

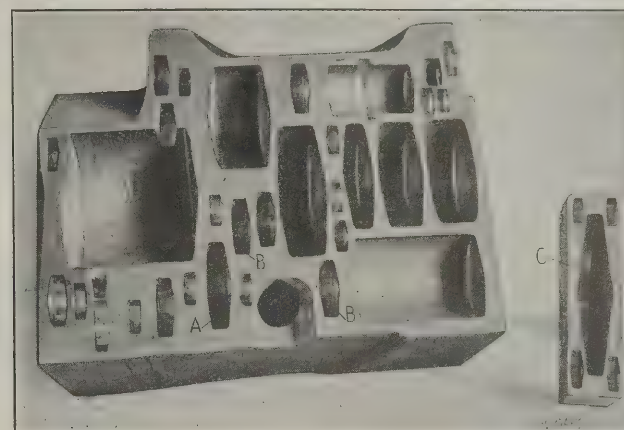

Fig. 9. A Drop-forge Die-block used in Testing the Capacity of the Machine for Sinking Holes quickly

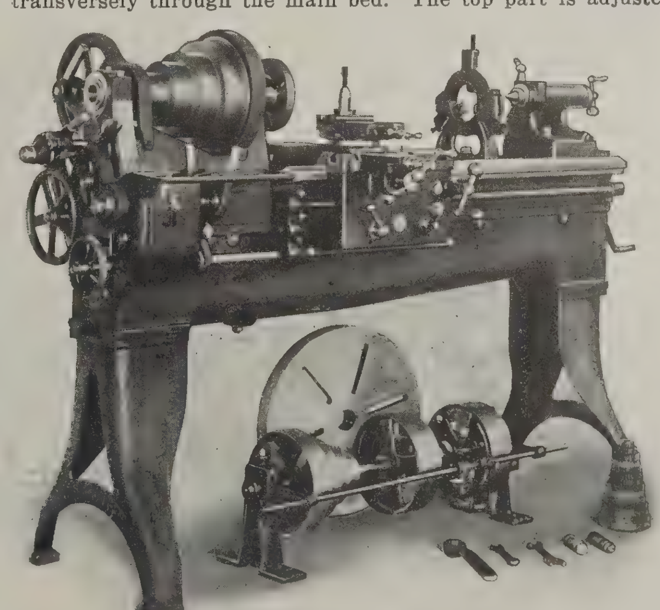
it is always best to rough out the impression with the routing cutter, as this will relieve the cherrying cutter of considerable hard work.

The first machine built by the Melling-Northrup Co. was sold to the Baker Drop-Forge Co., Jackson, Mich. Other machines with some changes are now in process of manufacture.

BARNES EXTENSION-BED GAP-LATHE

The Barnes Drill Co., 814 Chestnut St., Rockford, Ill., is now building a 14–24-inch gap-lathe which embodies a number of improved features. The feed changes are effected by quick change gear boxes giving six variations ranging from 0.007 to 0.049 inch. The bed is of a broad, deep pattern and well braced. The top and main beds are fitted together by a dovetailed construction which permits the top section to be firmly held in any position by means of clamp bolts which extend transversely through the main bed. The top part is adjusted



Barnes 14-24-inch Extension-bed Gap-lathe

for varying the width of the gap by a screw and crank at the tailstock end.

The headstock is of a heavy design, and the spindle has a diameter of 2 15/16 inches in the front bearing. A 1 9/16 inch hole extends through the spindle so that 1½ inch stock can be

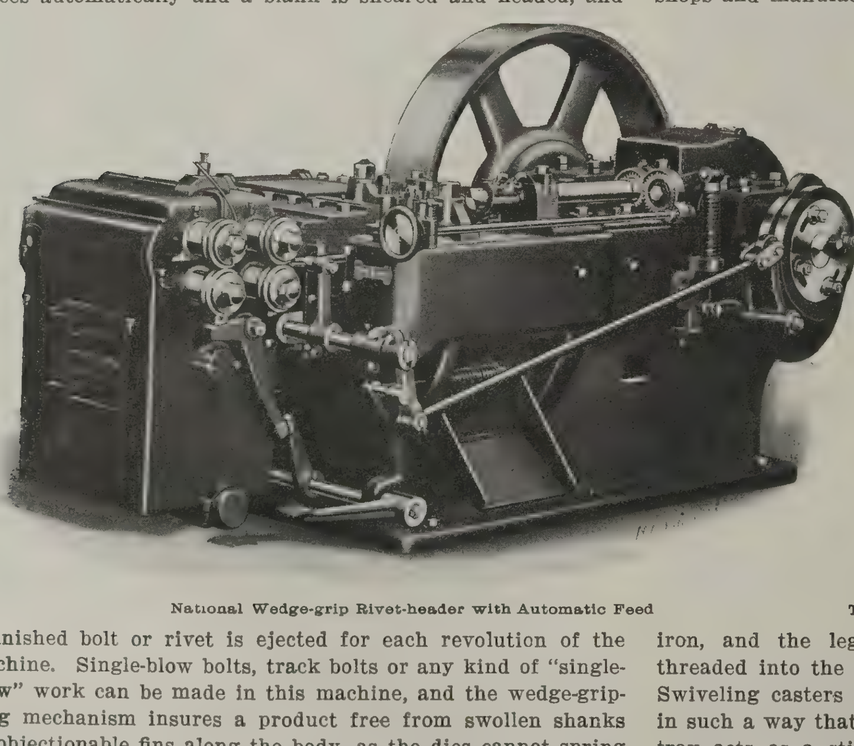
inserted. The spindle runs in split bronze bearings which are carefully scraped and fitted. The cone pulley has four steps, the diameters of which are 4, 6, 8 and 10 inches, and the width 2⅛ inches. By means of the back-gears which have a ratio of 11 to 1, eight spindle speeds are obtained. The cone can be quickly locked and unlocked for direct or indirect driving, by means of a push-pin and without the use of a wrench. The tailstock is of the offset type.

The carriage is extended in front to provide a firm support for the tool when turning large diameters. The carriage has a long bearing on the front V and a flat bearing at the rear. It is fed by a splined screw and can quickly be clamped to the bed for cross-feed work. A taper attachment is secured to the back of the carriage and turns any taper up to 2¾ inches per foot.

This lathe has a swing over the bed of 14½ inches, a swing over the carriage of 10 inches, and a swing through the gap of 24 inches. The sizes of the front and rear bearings are 2 15/16 by 3 7/16 inches and 2 1/4 by 2 3/4 inches, respectively. The diameter of the tailstock spindle is 1 13/16 inch. The feed-screw is one inch in diameter and has eight threads per inch, Acme standard. The maximum distances between the centers with 5½ and 7½ foot beds, when the gap is closed, are 36 and 60 inches, respectively. When the bed is extended the maximum distances between the centers are 54 and 96 inches, respectively. This lathe can be equipped with a motor-drive, if desired.

NATIONAL RIVET-HEADER WITH AUTOMATIC FEED

The National Machinery Co., Tiffin, Ohio, is manufacturing a wedge-grip, rivet-header equipped with a new design of automatic feed. In the operation of this machine, long rods in mill lengths are taken from the finishing rolls while on the initial heat (or they are re-heated in special long furnaces) and when the rod is started into the feed rolls by the workman, it advances automatically and a blank is sheared and headed, and a finished bolt or rivet is ejected for each revolution of the machine. Single-blow bolts, track bolts or any kind of "single-blow" work can be made in this machine, and the wedge-gripping mechanism insures a product free from swollen shanks or objectionable fins along the body, as the dies cannot spring or give during the upsetting operation.

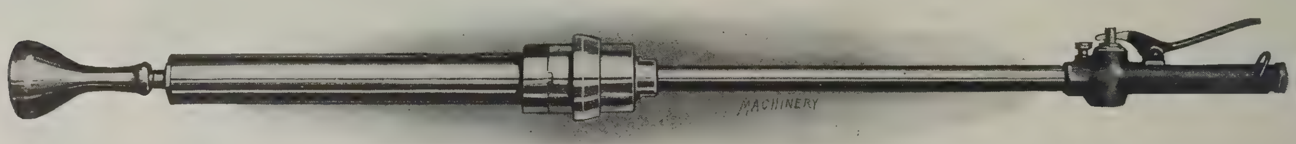


National Wedge-grip Rivet-header with Automatic Feed

The feed rolls are made of chilled castings and they are water-jacketed, in order to maintain an even temperature and insure a minimum wear on the feeding surfaces, so that a positive and uniform feeding movement is obtained. A new type of stock gage is employed which is designed not only to allow rapid and minute adjustments while the machine is in operation, but also to eliminate "spring" and thus secure uniformity in the work produced. The output of this type of header is said to be from 50 to 100 per cent larger than is obtainable on the hand-feed machine, and, owing to the accuracy and uniformity in feeding, a better quality of work is secured on the automatic-feed header. This machine is built in 1-, 1¼- and 1½-inch sizes.

CLEVELAND SAND RAMMER

The Cleveland Pneumatic Tool Co., Cleveland, O., has brought out a new molders' sand rammer. This rammer, which is illustrated herewith, is pneumatically operated and is made in different styles and sizes, adapted for general foundry work or for bench or core ramming. All sizes are equipped with either a round or grooved rod, as preferred, and with a butt and pein. The use of the groove is to prevent the rod from turning when the rammer is in operation, except at the will of the operator.



Pneumatically operated Sand Rammer manufactured by the Cleveland Pneumatic Tool Co.

These rammers are light in weight, operate at high speed and with practically no vibration. The piston-rods are packed with a special design of packing which prevents dirt from getting into the piston chamber and cutting the working parts. The floor rammer, which is the type shown in the illustration, has an exhaust deflector which prevents the exhaust air from blowing onto the operator, as well as on others who might be working with him.

THE BADGER TOOL RACK

The tool rack illustrated herewith is designed for machine shops and manufacturing plants. The trays are made of cast iron, and the legs, which are of 1-inch round steel, are threaded into the top tray and pass through the lower trays. Swiveling casters with 4-inch wheels are fastened to the legs in such a way that they will not become detached. The lower tray acts as a stiffener for the legs and, when the rack is assembled, it is strong and serviceable. Any number of trays

Tool Rack for Machine Shops and Manufacturing Plants

can be furnished, and drawers can be supplied if desired. The standard racks are made with 20- by 25-inch trays and have a total height of 36 inches. If a stationary rack is wanted, ¾-inch pipe legs with floor flanges are furnished.

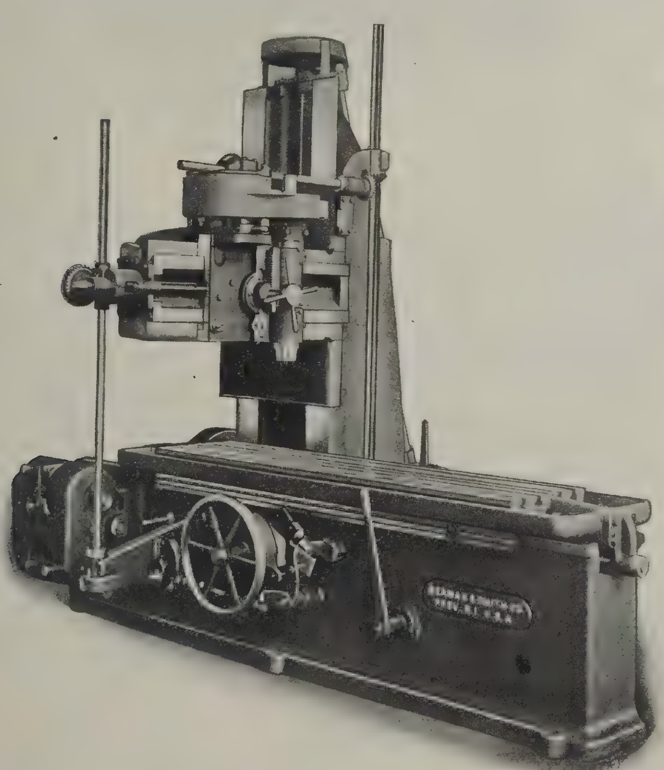
These racks are especially adapted for use in connection with machine tools, as they can readily be moved about. They can also be used in place of "tote" trucks for conveying products from one tool to another and from one department to another. The weight of a crated rack is approximately two hundred pounds. These racks are manufactured by the Wisconsin Foundry & Machine Co., 623 E. Main St., Madison, Wis.

BEAMAN & SMITH MILLING MACHINE

The vertical-spindle milling machine shown in the accompanying engraving is a recent design built by the Beaman & Smith Co., Providence, R. I. This machine is of the open-side construction, and is capable of handling a large variety of work. The horizontal bed of the machine has attached to it an upright that carries an overhanging arm or cross-rail. The spindle is carried by a saddle which, in turn, is mounted on the overhanging arm and has a horizontal feeding movement. The work table is provided with a rapid power movement, available in either direction and varying from 9 to 26½ feet per minute. The table is operated by a screw which engages a revolving bronze nut, and the thrust is taken by ball bearings.

The feed for the table is positive and operates in either direction. The required changes are obtained by a geared feed-box which is conveniently located at the left end of the bed, as the illustration shows. There are nine changes of feed, ranging from 1 inch to 8½ inches per minute, and the arrangement is such that the feed can be varied independently of the spindle speed. The table is equipped with an automatic stop for disengaging the feed at any predetermined point.

This machine is driven by a 4-inch belt which operates on a four-step cone pulley. Eight spindle speeds are available, varying from 14½ to 140 revolutions per minute. The spindle is of crucible steel and runs in boxes of hard bronze. It has a



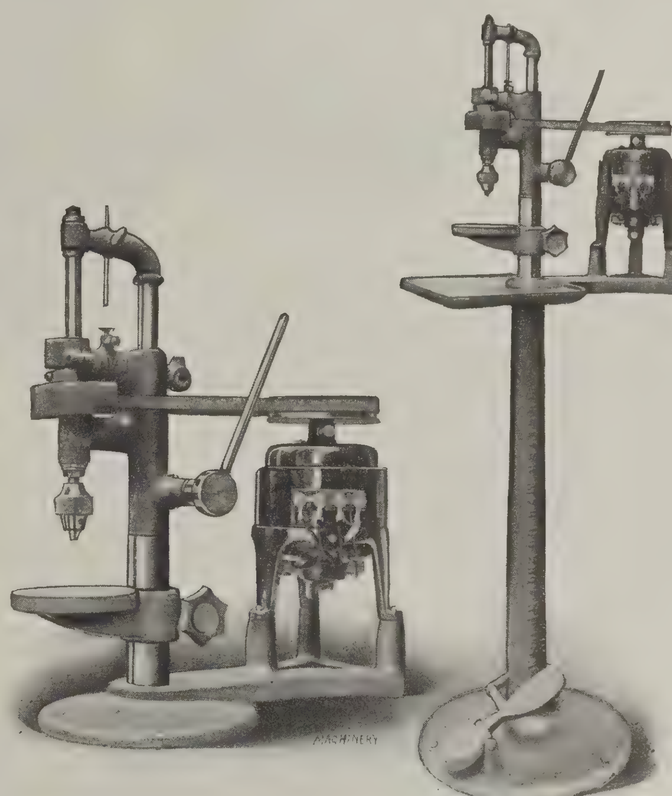
Beaman & Smith Open-side Vertical-spindle Milling Machine

tapered end 3 inches in diameter, for attaching face milling cutters, and also a No. 11 Brown & Sharpe taper hole for receiving cutter shanks and arbors. The spindle has a 6-inch independent vertical adjustment and a horizontal movement of 22 inches on the overhanging arm. There is a hole through the center of the spindle for a retaining bolt. The respective diameters of the two spindle bearings are 3 1/4 and 2 9/16 inches, and the length, in each case, is 4½ inches.

The cross-rail or overhanging arm is very substantial and proportioned to best resist the strains to which it is subjected. It has a vertical power movement for adjustment on the upright, varying from 11 to 32 inches per minute. The work table is 18 inches wide, 6 feet long, and has a feed and rapid power movement of 6 feet 9 inches. The distance from the end of the spindle to the top of the table can be varied from 0 to 36 inches. The weight of the machine is approximately 13,000 pounds.

LANGELIER MOTOR-DRIVEN SENSITIVE DRILLS

The Langelier Mfg. Co. of Providence, R. I., has recently designed a new line of motor-driven drilling machines of the sensitive type. These are made in two sizes and for either bench or floor use, as shown by the accompanying illustration.



Langelier Sensitive Drilling Machines of Bench and Floor Types

The smaller size has a capacity for drills up to 7/32 inch, and the capacity of the larger size is for drills up to ⅜ inch in diameter. The machine shown to the left in the illustration is the No. 1 bench type, and the machine to the right is the No. 1 stand or floor drill. These machines are driven by ⅛ horsepower motors, and they can be obtained either with or without the motor.

The motor drives the drill spindle by an endless belt at a speed of about 2000 revolutions per minute. The spindle "floats" inside of a sleeve which is continuous through the two spindle bearings, and the driving pulley is keyed to this sleeve and not to the spindle. This feature gives great sensitiveness and adapts the machine for precision work. This form of drive also obviates any jerking of the spindle, no matter how tight the driving belt may be, and spindle wear is practically eliminated. A belt guard is placed over the spindle pulley to prevent the belt from hitting the operator in case of breakage.

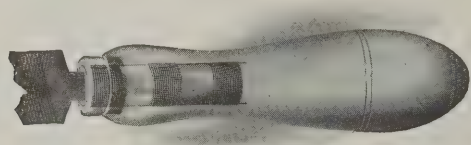
The feeding of the spindle of either a bench or stand drill can be effected by a hand-lever at the side of the column or by a foot-treadle connecting with a rod passing inside of the column. The drill table has a vertical adjustment of 4⅝ inches and it can be swung to one side, if desired. Each of these machines is equipped with a depth gage, which is a valuable feature when drilling duplicate parts, especially if the holes must be drilled accurately to a given depth. This gage

consists of a vertical rod which passes through the spindle frame and can be locked in any position by a winged nut. The lower end of the rod strikes a hardened, fine-pitch knurled screw, by means of which very minute adjustments can be made. A binding screw at the side locks the vertical screw after it is set to the required height.

All of the running parts of these machines are designed for taking up wear and for replacement, if necessary. The weight of the No. 1 bench drill with a motor attached is 50 pounds, and the bench space is 20 by 12 inches. The weight of the No. 1 stand drill with a motor is 100 pounds, and the floor space 20 by 16 inches.

OSGOOD FILE AND TOOL HANDLES

The J. L. Osgood Tool Co., 121 Erie County Bank Bldg., Buffalo, N. Y., has added to its line of indestructible file and tool handles, the type shown herewith. This handle has a steel-bound inner core to prevent splitting, and it is made in six different sizes, having lengths varying from 4 to 5⅝ inches. The smallest size is intended for files from 2 to 4 inches in length, and the largest size, for files from 14 to 20 inches in length. This company has also brought out a line of screw-driver and toolmakers' handles. The latter have a a tough wood core reinforced by a steel tube, and the grip is made of soft, flexible cork.



Osgood File Handle with Steel-bound Center Core

ROBERTSON POWER HACK SAW

The power hack-saw machine shown herewith, is a recent design being manufactured by the W. Robertson Machine & Foundry Co., 32 Greenwood Pl., Buffalo, N. Y. The general construction of this saw is clearly shown by the illustration. The surfaces of the bed are milled true, and the base of the head is machined to fit into housings formed on the bed, which gives a solid construction. The frame is supported on a finished steel arm and has a long bearing provided with ample lubrication.

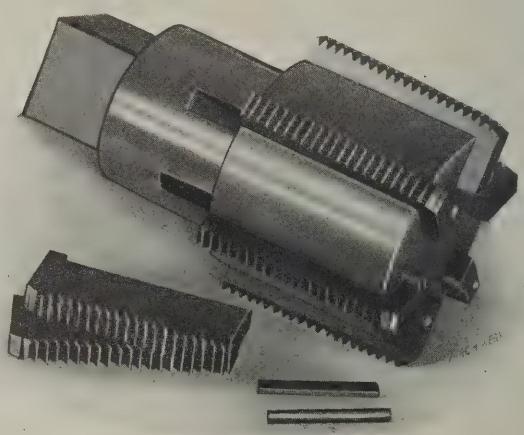
Power Hack-saw made by W. Robertson Machine & Foundry Co.

The frame is mounted and driven so as to insure a true cut and it takes either 10-, 12- or 14-inch blades. The saw cuts on the draw stroke, and there is a mechanical release on the return stroke. The machine is equipped with an automatic stop. The vise is strongly constructed and all surfaces are milled true. It is secured to the bed by two bolts and can be swiveled to 45 degrees. The position of the vise is indicated by degree graduations. This machine has a capacity of 6 by 6 inches, and the net weight is 250 pounds.

WINTER BROS. INSERTED-CHASER TAPS

Winter Bros. Co., of Wrentham, Mass., in developing a line of high-speed taps, found, that for sizes above 2 inches diameter, the cost of the steel increased to such a point that it more than offset the increased production obtained as the result of the superior qualities of high-speed steel. The inserted-chaser style of tap was developed to solve the cost problem. After numerous trials in different shops, the simple style of inserted-chaser tap which was first designed proved both economical and satisfactory.

This tap, one size of which is shown herewith, has a body made of machinery steel, or, in the case of very large sizes, of cast iron, and the chasers are held in slots, the sides of which are parallel. Before these slots are milled in the body, holes (which ordinarily have a diameter of 3/16 inch) are drilled in such a location that the inner sides are flush with the bottom of the slots, and the centers are 1/32 inch ahead of the sides of the slots. When the latter are milled, two-thirds of each hole is left, and into these holes the chaser binding pins are inserted.



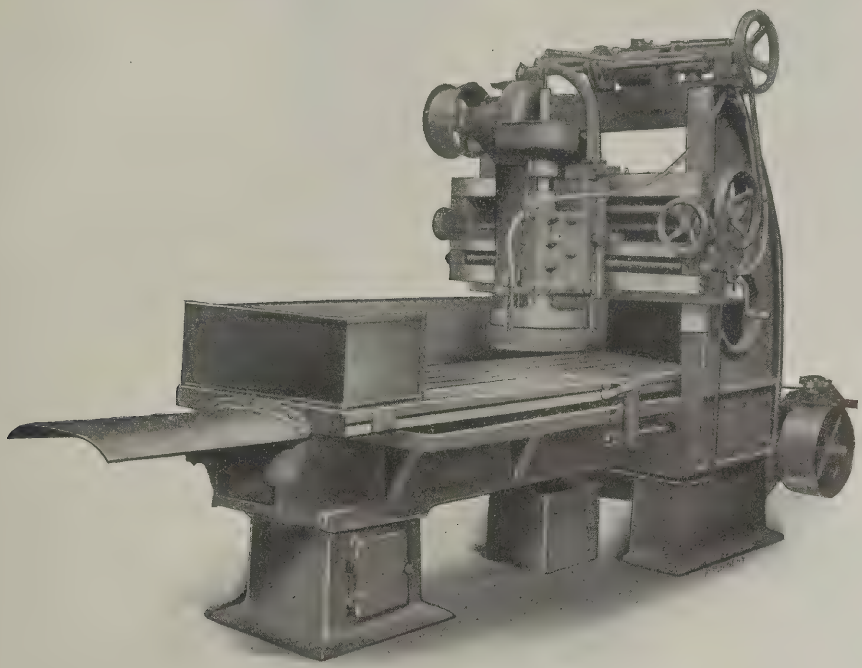
Tap having Inserted Chasers or Blades

The chasers are made of flat stock with parallel sides, and the bottom is milled off, thus leaving a shoulder about ⅛ inch high near the front end, as shown in the illustration. In assembling the tap, this shoulder is set against the end, thus locating each chaser accurately. Near the bottom of the front or cutting side of each chaser, a surface is milled, having an angle of 16 degrees to the rest of the face. The binding pins have one side flattened, and when they are driven in place, this flat side bears against the angular surface, which holds the chasers firmly against the ends and bottoms of the slots. The pins are made of straight pieces of drill rod or screw stock and they are an easy fit in the round hole, but a driving fit when the chasers are in place. It is not necessary to drive the pins very hard or insert them for any great distance. The chasers are removed by driving them out endwise, which also removes the pins.

The cost of a new set of high-speed steel chasers is less than that of a carbon steel tap for sizes above 2 inches diameter. For sizes as large as 4 inches diameter the cost of a complete inserted-chaser tap with high-speed steel blades is less than that of a carbon steel tap, and a new set of chasers costs only about one-third as much as a solid tap of carbon steel. When the same number of threads per inch is used for different diameters, the chasers are said to be interchangeable for diameters varying as much as 6 inches. Special pipe taps have also been made which work satisfactorily with duplicate chasers, for all sizes from 2½ inches up to 12 inches.

VERTICAL GRINDING PLANER WITH MOVABLE HEAD

The vertical planer-type grinder illustrated herewith is designed for grinding a large variety of work. The wheel-head on this machine is mounted on a heavy and substantial cross-rail, and has a cross movement of 36 inches. It is traversed back and forth by a screw and the crank handle seen at the right-hand end of the cross-rail. The wheel spindle has a quick hand motion, vertically by means of the large handwheel shown, and a slow or feeding motion is effected by the smaller handwheel at the front of the cross-rail, which operates through a worm and worm-gear that can easily be disengaged.



Vertical Grinder of the Planer Type

The wheel-head travels on the modern narrow guides, and has bearings of generous proportions. The wheel-head proper is of the same general design and size as that used on the Springfield-Brandes vertical grinding planer, which was illustrated in the department of New Machinery and Tools for December, 1910. The wheel is 16 inches in diameter and is driven by an accurately planed pair of bevel gears, one being of cast iron and the other of rawhide. All the high-speed bearings are either of the self-oiling or sight-feed type. The end thrust bearings are all provided with ball bearings.

The drive for traversing the table is something like a planer drive, except that the motion is transmitted through a worm and worm-gear and a large coarse-pitch screw operating in a nut 15 inches long. The machine is equipped with a pump and all necessary attachments, and lubricant can be applied either through the spindle or from the outside of the wheel. It is also equipped with a large water guard which surrounds the table to confine the spray. This guard is made in two sections. The front section is shown removed, and it can readily be taken out and put back, by sliding it in from the top and clamping with thumb-nuts.

This machine has a capacity for grinding widths up to 30 inches and lengths up to 7 feet. The weight is 13,450 pounds. It is built by the Springfield Mfg. Co., Bridgeport, Conn.

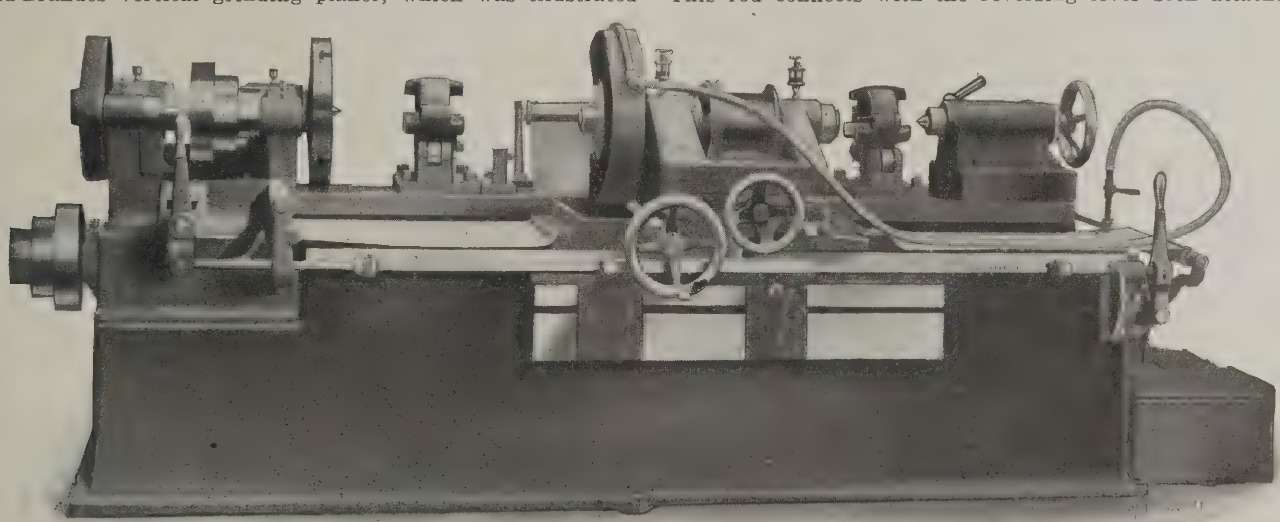
SPRINGFIELD SPECIAL ROLL GRINDER

The Springfield Mfg. Co., Bridgeport, Conn., has designed a special grinder for grinding concave rolls by means of a former. This former is located directly under the handwheels at the front of the machine, as will be seen by referring to the accompanying illustration. It is somewhat similar in construction to a lathe taper attachment and is provided with an adjustment.

In operation, the intermediate slide on which the wheel-head is mounted is forced against the former by a heavy spring. The operation of grinding is practically automatic, although the grinding wheel is fed by means of a small handwheel. The wheel face is curved slightly, as this is necessary in order to reproduce the curve of the former. The two rests seen on each side of the wheel-head are to permit revolving the rolls on their own journals. These rests are adjustable.

The machine is also designed to do internal grinding. The internal attachment is shown in place, directly beyond the wheel. It is driven by a belt which runs over a pulley that forms part of the main driving pulley for the grinding wheel. This internal attachment is removed when the machine is to be used for either straight or curved grinding.

The wheel carriage is reversed automatically by ordinary trip-dogs, which are mounted on a rod at the front, as shown. This rod connects with the reversing lever seen attached to the speed-box at the left. When this lever is in a neutral position and the smaller lever seen to the right is set against the retaining drum, the mechanism remains idle and the wheel-head can be traversed by hand, the movement being transmitted by a revolving nut operating on a stationary screw.



Special Machine designed for Grinding Concave Rolls

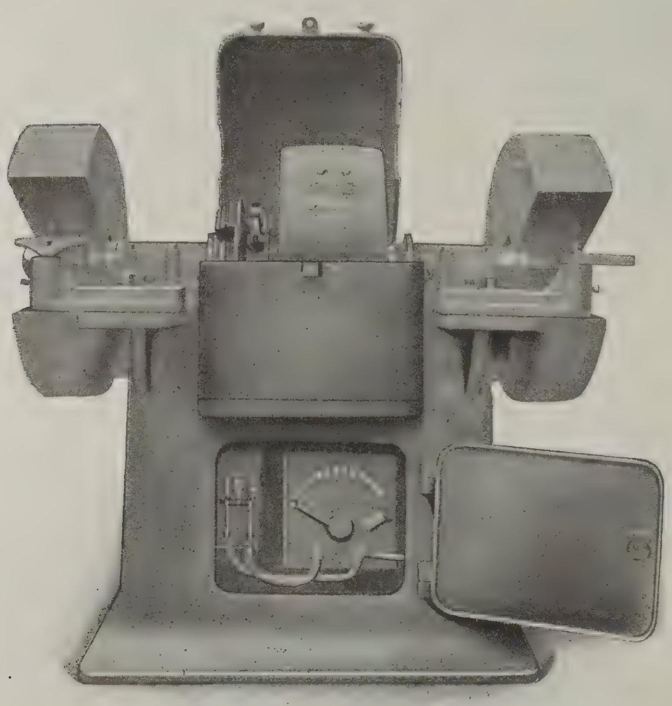
This machine has a capacity for grinding rolls 12 inches in diameter and 4½ feet long. It is equipped with a pump and water attachment for wet grinding, and the matter of lubrication and protection of exposed parts has received careful at-

tention. The wheel-head ways, as will be seen, have covers which are attached to automatic rollers that wind and unwind as the wheel-head traverses back and forth. The weight of this machine is 7250 pounds.

SPRINGFIELD MOTOR-DRIVEN GRINDER

The direct-connected motor-driven dry grinder shown in the illustration has been designed by the Springfield Mfg. Co., Bridgeport, Conn., as a standard for direct-current motors. The aim has been to adapt it, as far as possible, to standard motors, and the only thing that is special, as far as the motor is concerned, is the shaft. The motor is mounted on a rigid base and it is enclosed with a dust-tight case. The upper half of this case is hinged so that it can easily be thrown back to the position shown, either for inspection, adjustment or cleaning, and it is held in the closed position by a bolt. The case is bored out to fit finished projections on each of the boxes, and, as the joint is ground, the case is practically dust-proof.

The grinder is designed to take two hoods, as shown. These are made so as to enclose practically the entire wheel, with the exception of the portion which must be left exposed



Direct-connected Motor-driven Dry Grinder

at the front. The hoods have an outer plate which can readily be removed when it is desired to change the wheels. These hoods can also be connected with an exhaust system, which is desirable where such a system is installed. The starting controller is mounted on a slab inside of the base and is as close to the front as possible, for convenience in operating. The spindle bearings are of generous proportions and are of the self-oiling type. At present, these machines are made in three sizes suitable for wheels having diameters and widths of 12 by 2 inches; 18 by 2 or 3 inches and 24 by 3 or 4 inches.

GARDNER POLISHING STAND

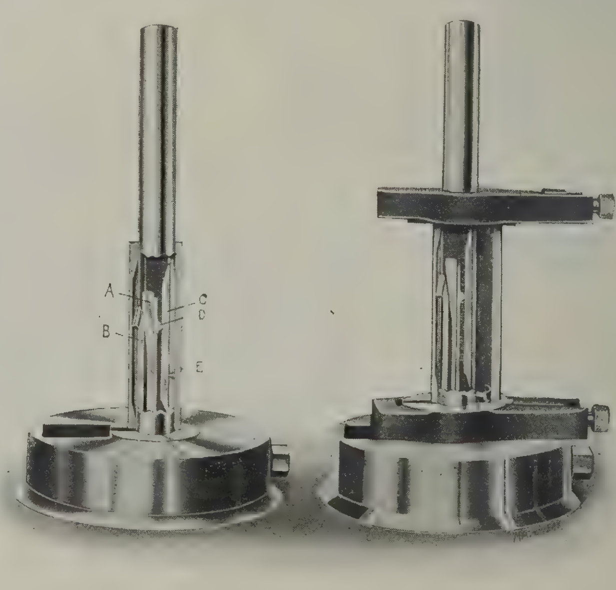
A ball-bearing polishing stand has been put on the market by the Gardner Machine Co., Beloit, Wis. This machine, which is shown herewith, is fitted throughout with ball bearings. The diameter of the spindle at the bearings is 2 inches and it tapers down to a diameter of 1¾ inch. The arbor is 1¼ inch in diameter and forms a shoulder for the 4½-inch wheel collars. The spindle extends 15 inches on each side of the base and is 39 inches from the floor. The spindle pulley is 5 inches in diameter and has a 4½-inch face. The two radial ball bearings are encased so as to be completely protected from dust or grit, and they are lubricated by a light grease contained in compression grease cups. Spacing collars are furnished when wheels of various widths are required. The countershaft hangers have ball bearings. The tight-and-loose pulleys are 8 inches in diameter and have 5½-inch faces. The loose pulley is fitted with two radial ball bearings. The

Gardner Ball-bearing Polishing Stand

driving pulley is 18 inches in diameter, and when it runs at 750 revolutions per minute, the machine is driven at a speed of 2700 revolutions per minute. This polishing stand is known as the No. 3 size. Its weight, complete with the countershaft, is 600 pounds.

KEYSEATER ATTACHMENT FOR CUTTING OIL GROOVES

Mitts & Merrill, 843 Water St., Saginaw, Mich., have brought out an attachment for cutting oil grooves, which can be applied to the keyseaters built by this company. The accompanying sectional views show the working parts of this device and how it is operated. Referring to the left-hand view, part *A* is the feed wedge, *B* is the cutter, and *C* is the pattern of the oil groove to be cut. This pattern is fastened to the back of the groove in the post which forms a support for the work. Part *D* is a follower-bar having a knob or projection on the



Sectional Views of Mitts & Merrill Keyseater Attachment for Cutting Oil Grooves

rear side, which follows the pattern and guides the cutter, thus forming an oil groove corresponding in shape and length to the pattern. The bushing *E* represents the work, and the form of the completed oil groove, as well as the way it is reproduced from the pattern, is clearly shown.

When the attachment is in operation, the cutter *B* and the follower-bar *D* travel together in a line parallel to the pattern.

The feed wedge *A* is operated in the usual manner for feeding the cutter into the work. The cutter has an automatic relief on the return stroke. The work is chucked by means of bushings similar to those used for keyseating. The view to the right shows the attachment equipped with expansion bushings for chucking work that varies in diameter.

With this device, as regularly furnished, oil grooves up to 3/16 inch deep can be cut. A groove 4 inches long and 1/8 inch deep can be cut in one minute, which includes the time required for chucking and removing the work. The No. 1 size will cut grooves 1/8 inch deep in holes 1 inch in diameter and larger. The No. 2 size is adapted for grooves 3/16 inch and holes 1 1/2 inch in diameter and larger.

BRYANT HOLE- AND FACE-GRINDERS

The Bryant Chucking Grinder Co., of Springfield, Vt., has designed two new chucking grinders, one of which has a single spindle and the other two spindles. These machines are being built in addition to the three-wheeled chucking grinder which was illustrated in the November, 1909, number of MACHINERY, and they are intended for chuck work which requires only one

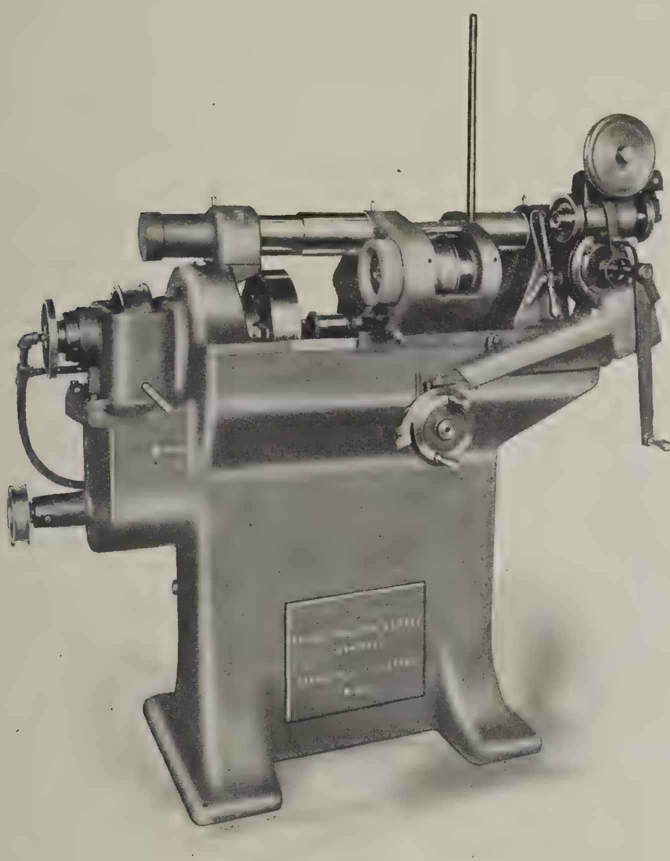


Fig. 1. Two-spindle Face- and Hole-grinder built by Bryant Chucking Grinder Co.

or two grinding operations at a single setting. A front view of the two-spindle type is shown in Fig. 1, and Fig. 2 is a rear view of the single-spindle machine. The former is especially adapted to that class of work which has to be ground internally and faced, as both operations can be performed successively and rapidly.

The design of these machines has been simplified as far as possible, in order to give a maximum output for the grinding of duplicate parts within a limited range. Provision is made only for those adjustments which are actually needed in general practice. The average machine tool is ordinarily provided with an assortment of speeds, feeds, and adjustments which are necessary to meet the conditions for work within its range, but when such machines are used on duplicate work in manufacturing, usually only one or two of the many feeds, speeds, and adjustments are needed.

These new hole- and face-grinders, as the illustrations show, are a decided departure from conventional designs, particularly in regard to the method of mounting the wheel-slide. Instead of the usual flat or V-shaped ways, the wheel-slide is held in position and traversed in hardened and ground cylindrical bearings which are located above the grinding wheels, and are further protected by brass telescoping sleeves which make them grit- and dust-proof. These bearings, the general arrangement of which is clearly shown by the longitudinal section Fig. 4, give a smooth even traverse to the wheel-slide and insure its permanent control and alignment. These bear-

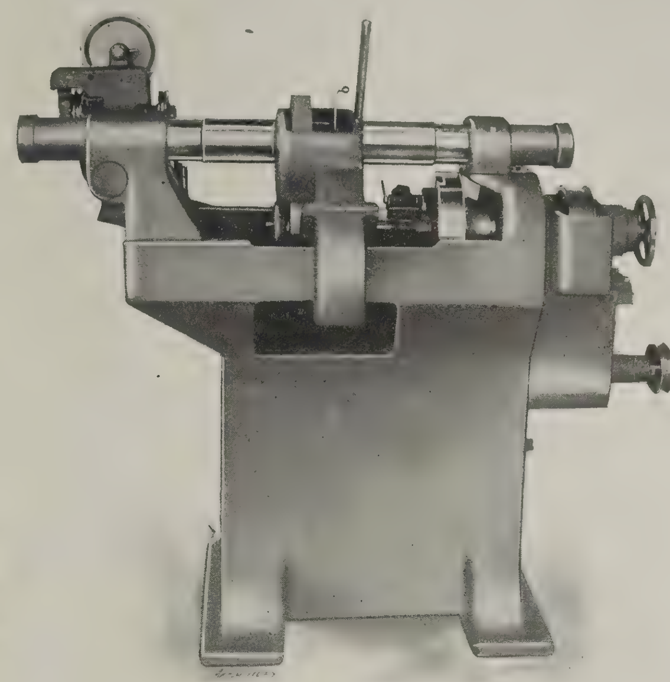

Fig. 2. Rear View of Single-spindle Internal Grinder

ings are not only used for the longitudinal traverse, but they enable the wheel-slide to be given a radial swinging motion, which furnishes the cross-feed for diameter control. This radial motion, when a grinder is equipped with two wheels (one for hole and the other for face grinding), is used for locating either spindle in the operating position; whereas, with the single-spindle grinder, this motion is employed to swing the wheel out of the working position when necessary.

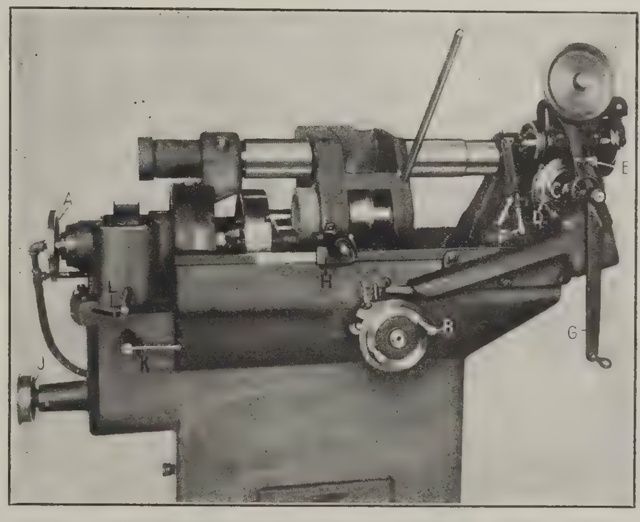

Fig. 3. Two-spindle Machine with Wheel-slide set for Face-grinding

The wheel-slide, in either case, can be moved easily and quickly.

The hand lever seen attached to the wheel-slide, is used for moving the facing wheel into position. Fig. 1 shows the wheel-slide set for hole grinding, and Fig. 3 shows the cup-wheel set for end facing. The work-holding chuck is operated by handwheel *A* (Fig. 3) at the left end of the spindle, which is connected with the chuck as shown in the sectional view Fig. 4. The handwheel *B* (Fig. 3) seen at the front of the machine, is for the diameter control, and the way this wheel imparts a radial swinging movement to the grinding wheel slide, is shown by the cross-section, Fig. 5. A circular arm *E*

is bolted to wheel-slide *S* and projects into a pocket under the water pan. The lower or inner end of this arm rests against feed-screw *F* and is held in this position simply by the arm's weight and the pull of the driving belts. There is no vibration of this arm, as it simply pushes against the feed-screw.

The wheel-slide is traversed longitudinally by a belt which passes over the three grooved pulleys seen at the right-hand end of the machine. The two smaller pulleys rotate in reverse directions and are alternately connected through a clutch mechanism with a worm engaging with worm-wheel *C*. This worm-wheel, in turn, rotates a pinion shaft and pinion meshing with a circular rack on the wheel-slide, as shown to the right in Fig. 4. On the side or front face of worm-wheel *C*, are mounted the reversing stops *D* for controlling the wheel travel. The reversal of the wheel-slide can also be effected by the hand lever *E*. Lever *F* is used for disengaging the power traverse, and the long lever *G* is for moving the slide back and forth by hand.

The cross-feed is equipped with an automatic trip mechanism having suitable adjustment. A diamond holder is located at *H* for truing the grinding wheels. The cooling water is supplied by a pump driven by pulley *J*, and the piping is so arranged that the water can be conveyed to the work either through the spindle or by a flexible pipe attached to the wheel carriage. The flow of water is controlled by lever *K*, which is within convenient reach. The work-head of this machine has an angular adjustment for grinding tapers up to 30 degrees included angle. The position of the head is shown by graduations on the segment-shaped base *L*, and the method of clamping the head is clearly shown by the illustration.

This machine has a capacity for grinding holes up to 10 inches in diameter and 6 inches in length, and the chuck will hold parts having a maximum diameter of 12 inches. There are three work speeds of 150, 225 and 300 revolutions per minute, and variations of wheel traverse of 20, 30, and 40 inches per minute. The wheel-spindle driving shafts are mounted in ball bearings of the enclosed type and require only occasional oiling. Either the single- or double-spindle machines are furnished for power or hand operation.

The equipment of the two-spindle grinder consists of a 12-inch chuck; a facing spindle with a 6-inch cupwheel; an assortment of grinding wheels to cover internal and face grinding on both hard and soft metals; a diamond holder and diamond; water pump and connections; a countershaft and suitable wrenches. The floor space occupied by the machine is 3 by 6 feet, and its approximate weight, 2000 pounds.

The principal features claimed for a grinder of this type are as follows: Better control and greater rigidity for the wheel-slide; hardened and ground wheel-slide bearings, which are grit- and dust-proof; quick and accurate operation; elimination of any vibration or error such as might result from faulty fitting and adjustment of the cross-slide; a housing that partly confines the water and spray; and uniform lubrication due to the cylindrical wheel-slide bearings.

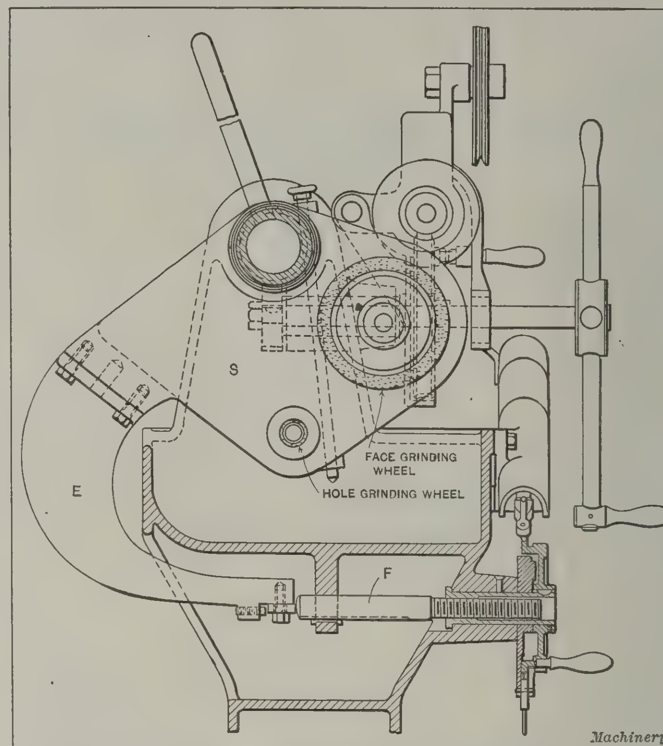

Fig. 5. Cross-section showing Cross-feed Control for Wheel-slide

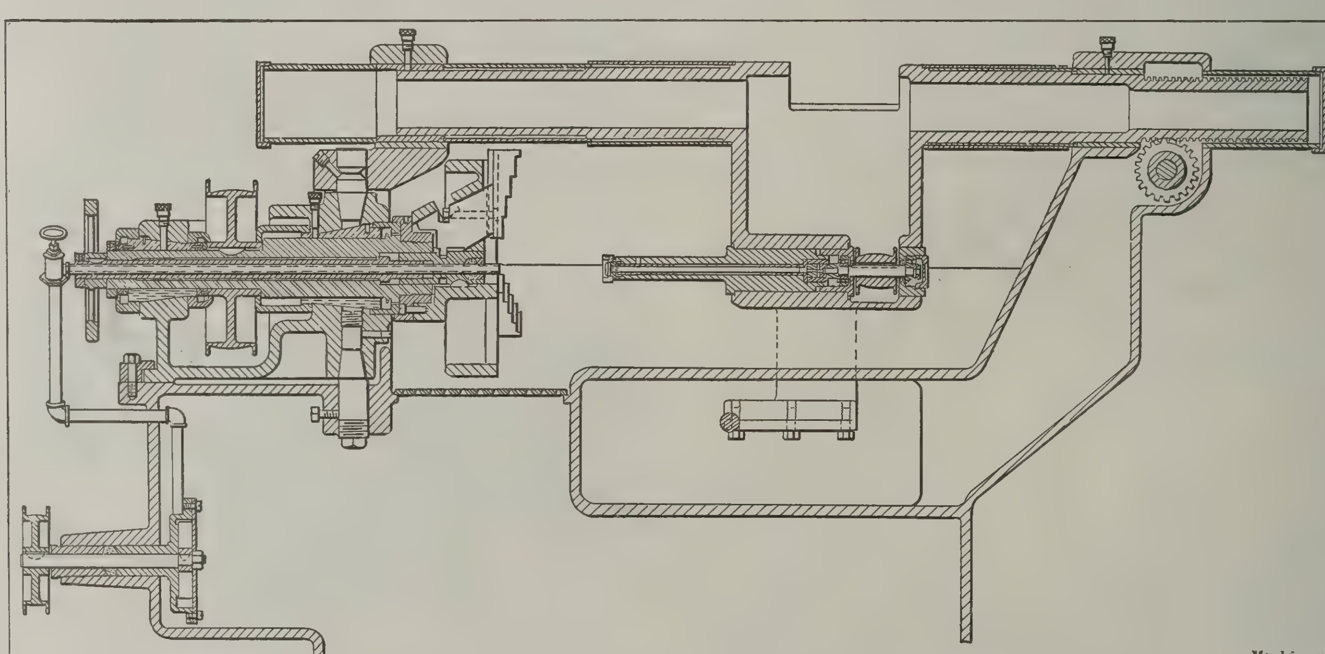

Fig. 4. Longitudinal Section of Bryant Chucking Grinder

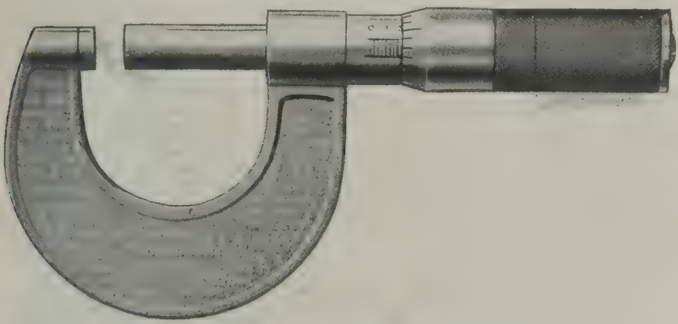
FRICTION THIMBLE FOR SLOCOMB MICROMETER

Most mechanics are familiar with the friction or ratchet stop which is applied to some micrometers for the purpose of securing the same degree of pressure when measuring. Some machinists have what is called a "heavy feel" and others a "light feel," and when a micrometer without a ratchet or friction stop is used, variations in diameter are sometimes the result, when duplicate parts are measured by different men. This is overcome by the ratchet or friction, which slips when more than a certain amount of pressure is applied, thus preventing the measuring screw from turning farther.

The J. T. Slocomb Co., Providence, R. I., is applying a friction thimble or stop to the Slocomb micrometers (when so

ordered) which is so arranged that it can be operated by the same hand which holds the micrometer. By referring to the accompanying illustration, it will be seen that this friction thimble is the same size as the regular knurled thimble, and it extends forward to about the center of the micrometer handle. This device consists chiefly of a coiled, flat, German silver spring the inner end of which is attached to a washer clamped to the end of the thimble by a shoulder on the



Slocomb Micrometer equipped with Friction Thimble

central screw. The outer end of the spring slides around inside of a large bore in the outer revolving part, the arrangement being such that when the thimble is turned to the right, the device slides over the spring, but when turned to the left, the friction uncoils the spring, thus causing it to drive positively in this direction.

There are no parts liable to get out of order, and the spring will not wear and thus lose its tension. This stop gives a smooth forward action and a movement that is fully as positive in a reverse direction. The friction thimble can be used when the micrometer is opened to its full capacity, and the screw can, of course, be operated without using the stop, when desired.

NEW MACHINERY AND TOOLS NOTES

Knurling Tool: Edgar T. Ward & Sons Co., Boston, Mass. Knurling tool with capacity for diameters up to ¾ inch. Three knurls are applied to the work, thus giving a good support, and the holder has a hollow handle which contains an extra set of knurls.

Drilling and Tapping Machine: Taylor & Fenn Co., Hartford, Conn. Radial drilling machine having two heads. One head is for drilling and the other, which is equipped with a reversing mechanism, can be used for tapping. The speeds of each head can be varied independently, if necessary.

Metal Saw: Peter Bros. Mfg. Co., Algonquin, Ill. Abrasive metal-saw designed primarily for the tool-room, for cutting off high-speed or other tool steels. The cutting wheel is 8 inches in diameter and 1/16 inch thick. It has a capacity for square bars up to ⅞ inch, and angles, channels, tees, etc., up to 1¼ inch.

Electric Hammer: Electro-Magnetic Tool Co., Chicago, Ill. Electric hammer having a motor of the series type and brush-holders attached to the tool casing so that the motor-head can readily be removed. Ball bearings are used throughout, and the hammer is equipped with a magnet which acts as a flexible clutch to prevent transmitting the strain and jar to the gears and motor.

Knurling Tool: Alert Tool Co., 221 N. Broad St., Philadelphia, Pa. Knurling tool having three knurls, thus giving a three-point contact which prevents bending or straining the work. By means of a winged nut, the knurl-holder is adjustable for pieces varying from 0 to 1¼ inch in diameter. This holder is applicable to all types of machines, such as engine lathes, bench lathes, etc.

Lathe: Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass. New line of motor-driven lathes with from 13- to 30-inch swing. The headstock is designed to permit placing all the gearing at the forward end or close to the spindle nose, and the rear end is arranged for the motor, which is placed low to avoid top-heaviness. The headstock covering encloses all gears. The lathe has double back-gears which are shifted by a lever at the front.

Pipe Bender: Wallace Supply Co., 108 N. Jefferson St., Chicago, Ill. Pipe bender so designed that the wall of the pipe is supported where the bend is made, thus eliminating any distortion or flattening. A radius of 14 inches or more is recommended for pipe as large as 2 inches, but the machine has been successfully used for a radius as small as 9 inches on 2-inch pipe; 8 inches on 1½-inch pipe; 6 inches on 1¼-inch pipe, and 4 inches on 1-inch pipe.

Milling Machine: Kearney & Trecker Co., Milwaukee, Wis. Vertical milling machine known as No. 2½-B. This machine is similar in construction to the No. 1½ size illustrated and described in the February, 1912, number, but has a greater capacity. The table has a feed of 30 inches and a cross-feed of 15 inches. The vertical feed and the greatest distance from the end of the spindle to the top of the table is 20½ inches. The working surface of the table is 14 by 47 inches, and the diameter of the rotary table, 17¼ inches. There are eighteen speed changes ranging from 15 to 360 revolutions per minute, and twelve feed changes which vary from ½ to 16 inches per minute. The net weight of the machine is 5200 pounds.

Portable Drill: Cincinnati Electrical Tool Co., 652 Evans St., Cincinnati, Ohio. Two sizes of portable, universal drills for operating on either direct or alternating current. One size will drill holes up to 3/16 inch in steel or hard wood, or 3/8 inch in soft wood, and the other size has a maximum capacity for 1/4 inch holes in steel or hard wood, and 1/2 inch in soft wood. The motor armature is equipped with ball bearings. The gears are enclosed and run in grease, thus protecting the electrical parts from dust and grease. The body of these drills is made of aluminum, and the outside diameter is about 4 inches. The weights of the two sizes are 7½ and 8½ pounds, respectively. A spade handle and a straight handle are furnished.

Milling Machine: Gooley & Edlund, Syracuse, N. Y. Single-purpose milling machine designed for form and gang milling in connection with the manufacture of guns, automobiles, typewriters, sewing machines, and similar parts. The frame of the machine is a single casting having two uprights joined by an arch at the top and cast integral with the base. The inner faces of these uprights have dovetailed ways, to each of which the heavy bed is fitted. The bed can be rigidly clamped to the uprights by four ⅞-inch bolts. The front upright contains an adjustable sleeve bearing which acts as an outboard support for the cutter arbor. The table has a screw feed and a quick-return handwheel operating through a rack and pinion. Eight changes of feed are provided. The maximum distance from the center of the arbor to the surface of the table is 12 inches. The table is furnished in lengths of 32, 38 and 44 inches, as may be required, and it has a width of 10⅛ inches.

JOINT MACHINERY DEALERS' CONVENTION

The joint triple convention of the National Supply and Machinery Dealers' Association, the Southern Supply and Machinery Dealers' Association, and the American Supply and Machinery Manufacturers' Association was held in Norfolk, Va., at the Monticello Hotel, May 13-15. The National Supply and Machinery Dealers' Association was called to order by President W. L. Rodgers of the Pittsburg Gage & Supply Co., Pittsburg, Pa.; the Southern Supply and Machinery Dealers' Association by S. M. Price of the S. M. Price Machinery Co., Norfolk, Va.; and the American Supply and Machinery Manufacturers' Association by Willard Parker, president. The program included an address on "Workmen's Compensation," by F. C. Schwedtman; "Motion Study," by Charles S. Miller; "Accident Prevention and Relief," by F. C. Schwedtman and James A. Emery; "The Modern Machinery Supply Jobber a Necessary Adjunct to the Manufacturers," by W. T. Dodd; "Cost of Handling Small Orders in Broken Package Lots and Remedies Proposed" and "Resale Prices in Their Present Status," etc.

NEWARK INDUSTRIAL EXPOSITION

Newark Industrial Exposition, Newark, N. J., was held under the auspices of the Board of Trade of the city of Newark, May 13 to 25 in the First Regiment Armory, its object being to advertise the industries and advantages of the city. Newark has a population of 365,000 and with the immediate surrounding towns 565,000. It has a wharf frontage on the Passaic River of 10½ miles, and is served by the Pennsylvania, Lackawanna, Lehigh Valley and New Jersey Central Railroads. The exposition comprised 196 concerns who showed a great variety of machinery and products valued at over $1,000,000, produced in Newark. It was attended by thousands of interested visitors. Among the exhibitors were Gould & Eberhardt, makers of shapers and gear cutting machines; Newark Gear Cutting Machine Co., maker of gear cutting machines and cut gears; Zeh & Hahnemann, makers of screw, crank and hydraulic presses; Crocker-Wheeler Co., maker of electric generators and motors; A. & F. Brown, makers of transmission machinery; Garvin Machine Co., maker of milling machines and other machine tools.

GRINDING THIN ALUMINUM CASTINGS

The Gardner Machine Co., Beloit, Wis., recently completed a grinding test on some peculiarly shaped aluminum castings which, owing to the thinness of the sides that required grinding, presented some rather interesting difficulties owing to the distortion caused by the heat generated. These aluminum castings are used for making automobile horns, and Fig. 1 of the accompanying illustrations, shows how the flat sides were ground between two disk wheels on a No. 14 Gardner grinder.

As the sides of the casting were only about 1/16 inch thick, they could not be ground in the usual way because the thin sides were heated so quickly and bulged out to such an extent that the metal, in some cases, was ground entirely through near the center, before the other parts of the surface were finished true. In all cases, the sides were decidedly convex

Fig. 1. Grinding Thin Aluminum Castings on a Gardner Two-wheel Disk Grinder

after the metal had become cool, showing that they had expanded or bulged because of the heat, which caused an excessive amount of stock to be ground away from the center; consequently, when a casting cooled and resumed its natural shape, the sides were convex.

The idea was conceived of filling the hollow castings with cold water, and this was carried out as shown in Fig. 2. The open end or pipe was plugged with a cork of suitable size. The casting was then filled with water and placed in the hinged wooden holder shown in Fig. 2. The upper half of

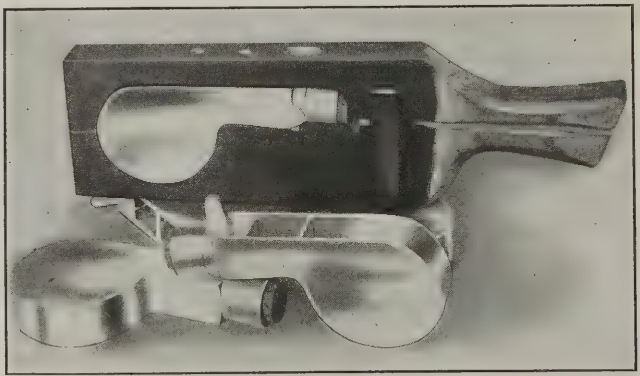

Fig. 2. Holder for Aluminum Castings

this holder was provided with a felt pad which pressed down, thus covering the rectangular opening in the casting and preventing the water from jarring out during the grinding operation. It was found that the water absorbed the heat and equalized its distribution so thoroughly that no further trouble was encountered from warping. The samples were ground to accurate dimensions, and finely finished flat surfaces were formed at the rate of 60 to 75 castings per hour.

BROACHING A CONNECTING-ROD END

The method of finishing the end of an engine connecting-rod by broaching is illustrated in Fig. 1. The hole is 2¼ inches wide by 4½ inches long, and the end of the rod is 1⅞ inch thick. This rectangular opening is finished by broaching in from four to five minutes, the time depending somewhat upon the facilities for handling the work. The end of the

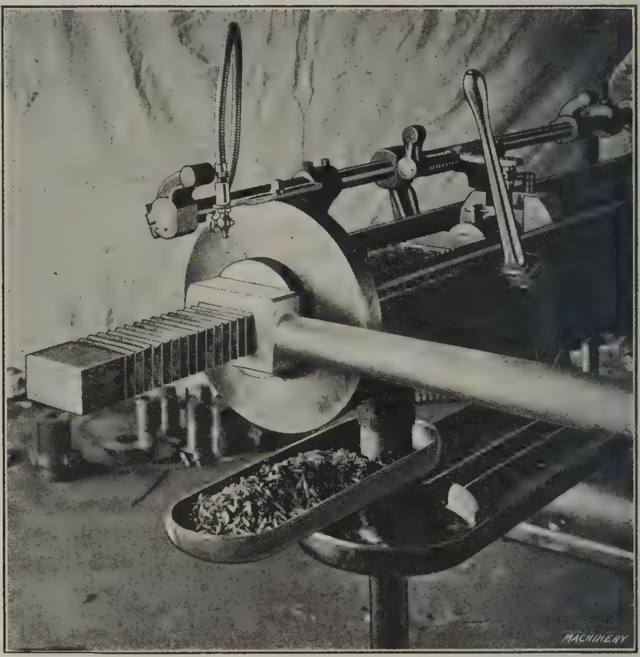

Fig. 1. Broaching Connecting-rod End in Lapointe Machine

rod prior to the broaching operation, is either blocked out by jig drilling as indicated at *A*, Fig. 2, or a rough hole is formed by forging. The full lines in these sketches show the rough surfaces in each case, and the dotted lines, the finished hole.

For broaching an opening of this size, two operations are required; one for roughing and one for finishing. The roughing broach removes the greater part of the metal and

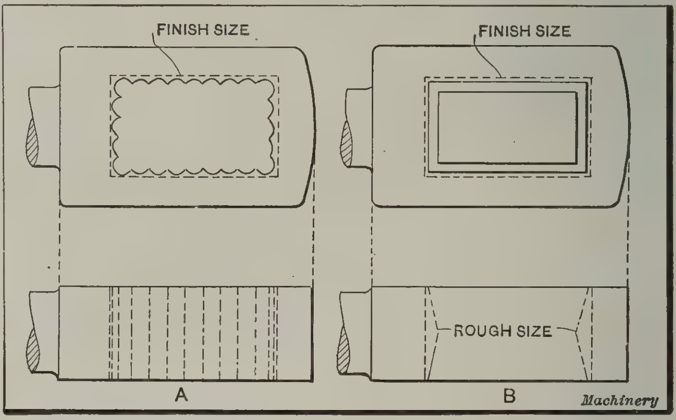

Fig. 2. (A) Rod End Blocked Out by Drilling. (B) Rod with Forged Hole

enlarges the hole to within 1/16 inch of the required size, there being 1/32 inch left on each of the four faces for finishing. The starting end of the finishing broach fits into the hole made by the roughing broach. These broaches are made of a solid piece of steel and are approximately 48 inches long.

As each of these rods weighs from three hundred to four hundred pounds, they are usually handled by means of a hoist. The end of the rod to be broached is supported by the broach itself, and the opposite end rests on a suitable stand. In this way, the work is held parallel or in position to bring the finished hole in alignment with the rod. The broach operates in a fixed position and finishes the hole according to the way the rod is set. After the support is properly located, any number of pieces can be broached without further adjustment, the holes produced being uniform in size and in alignment with the rod. The broaching machine used for this work is built by the J. N. Lapointe Co., Marlboro, Mass.

SEMI-ANNUAL CONVENTION N. M. T. B. A.

The tenth semi-annual convention of the National Machine Tool Builders' Association was held at the Hotel Chalfonte, Atlantic City, N. J., May 16-17. While the representation of the concerns having membership was only about sixty, their seeming indifference was not justified by the work the association has done this year, as was apparent from the report of the committee that worked in Washington to modify the drastic provisions of the Underwood tariff bill which, if passed, will place machine tools on the free list.

Mr. E. P. Bullard, Jr., of the Bullard Machine Tool Co., in welcoming the members as president of the association, referred to the great value of the body when an emergency, like the proposed bill, arose. The industry, through its appointed representatives, could act practically as a unit before the congressional committees and win recognition that probably would be denied to individual manufacturers seeking to protect their interests.

Mr. James H. Herron was introduced as the general manager of the association instead of permanent secretary, the name of the position originally proposed. The fact that the constitution of the association requires the secretary to be a member made the change necessary. Mr. Herron, who will devote his entire time to the work of the association, outlined his views in the paper "What can the Association do for its Members?" in which he spoke of working for the common good, revising nomenclature, the importance of standardization, the protection of gears and other dangerous parts of machine tools, the collection of statistics, keeping technical indexes for the benefit of members, and cost keeping. Reference was made to the indefiniteness of the present system of designating the nominal capacity of engine lathes and it was suggested that something be done that would show in the nominal rating what the lathe will swing over the carriage and between the centers. Other excellent suggestions were made that merit the serious attention of the members.

Mr. W. A. Viall of the Brown & Sharpe Mfg. Co., read the report of the membership committee in the absence of Mr. C. A. Hoefer, chairman. Eleven concerns were proposed for membership as follows:

A. D. Quint, Hartford, Conn.
Landis Machine Co., Waynesboro, Pa.
Hisey-Wolf Machine Co., Cincinnati, Ohio.
Grant Mfg. & Machine Co., Bridgeport, Conn.
Geometric Tool Co., New Haven, Conn.
Gooley & Edlund, Syracuse, N. Y.
Joseph T. Ryerson & Son, Chicago, Ill.
Langelier Mfg. Co., Providence, R. I.
Baird Machine Co., Bridgeport, Conn.
Armstrong-Blum Mfg. Co., Chicago, Ill.
Acme Machinery Co., Cleveland, Ohio.

The following consolidations and changes of membership names were reported:

Stoever Foundry & Mfg. Co., Myerstown, Pa., to Treadwell Engineering Co., Easton, Pa.

Grant & Wood Mfg. Co., Chelsea, Mich., to Flanders Mfg. Co., Pontiac, Mich.

Miami Valley Machine Tool Co., Dayton, Ohio, to Conover-Overkamp Machine & Tool Co., Dayton, Ohio.

Fay Machine Tool Co., Philadelphia, Pa., to Jones & Lamson Machine Co., Springfield, Vt.

F. E. Reed Co., and Prentice Bros. Co., of Worcester, to Reed-Prentice Co., Worcester, Mass.

The membership has been increased by seven, making the total 173.

Mr. D. M. Wright of the Henry & Wright Mfg. Co., reported on standardization of machine tools, and counseled that no radical moves be made without giving them very careful consideration and obtaining the opinions of every member of the association affected by the proposed changes. The matter of revising the nomenclature of the trade was discussed, particularly the term "machine tool" which the courts have decided has a much broader significance than the machine tool builders generally believe. In view of the ambiguity, Mr. Wright offered a resolution to the effect that the name of the association be changed to "American Metal Working Machinery Constructors' Association." The resolution was referred to the executive committee.

Mr. C. Wood Walter of the Cincinnati Milling Machine Co., chairman of the committee on prices charged to educational institutions, made no definite recommendations but pointed out the inconsistency of the common practice of machine tool dealers in dealing with educational institutions as compared with the practice of all other concerns, such as builders, plumbers, publishers, etc. The latter, of course, obtain full prices, and it seemed that all interests would be best served by making the rule universal and letting the individual members make their contributions to the cause of education direct instead of in the form of rebates on the prices of equipment.

Mr. Walter also reported on the fight against placing machine tools on the free list before the Senate committee, in the absence of Mr. F. A. Geier, the president of the Cincinnati Milling Machine Co. It was pointed out that although the subject is by no means settled and adverse legislation may be passed, either in the form of the Underwood bill or the Cummins bill, the machine tool builders, through their representatives, have placed on record their arguments against unjust discriminations and the prospects are reasonably bright for a tariff of twenty-five per cent as against no protection at all, as originally proposed in the Underwood bill.

The paper "How can the Mechanical Journals be made of the Most Value to their Patrons?" by Mr. Fred E. Rogers, editor of MACHINERY, was read in the second session (see engineering section of this number), following which Mr. Charles E. Hildreth of the Whitcomb-Blaisdell Machine Tool Co., presented "What has the Future in Store for Us?" accompanied by a large chart on which the fluctuations of pig iron prices for the past eighty-five years had been plotted. From this chart the prospects for the next six years can be predicted if the observed cycles in the past are reproduced. The signs of the times and known conditions existing with the railroads seem to confirm the indication of the chart that an era of heavy pig iron consumption and general prosperity is close at hand, if it has not already begun.

The third session was given up entirely to meetings of the lathe, sensitive drilling machine, boring machine, gear cutting machine, grinding machine, hand screw machine, radial drilling machine, planing machine, milling machine, shaping machine, vertical drilling machine and turret lathe committees.

In the last session Mr. Charles E. Carpenter of E. F. Houghton Co., spoke on "The Value of the House Organ as an Advertising Medium." He outlined the history of the *Houghton Line* and the principles observed in its conduct, without giving conclusive statements as to the value of house organs to manufacturing concerns generally. The fact was made plain that, to be successful, a house organ must have a good organization, including editorial writers of exceptional ability and that the circulation list must be carefully selected.

The question of admitting the makers of woodworking machinery had been submitted to letter ballot, and the vote was against their admission, the opinion being that the woodworking machinery makers have to meet so many conditions out of common with those of the machine tool industry that there would be confusion and lack of harmonious action.

The committee on standardization was made permanent. Mr. L. P. Alford, editor of the *American Machinist*, reported on the progress of the investigation being made by the Bureau of Standards at Washington into the laws governing the behavior of metals beyond the limit of proportionality up to and including rupture. It is within this zone that all metal working machines act in changing the shape of metals, but comparatively little has been done scientifically to deduce the laws of action.

* * *

HYDRAULIC PRESS—PULLEY REAMING MACHINE

The illustrations show two homemade tools in the plant of the Cleveland Planer Works, Cleveland, Ohio, the first being a portable hydraulic press and the second a pulley reaming machine. The hydraulic press consists of a wheeled base containing the ram and carrying the hand pump and two uprights with a cross-rail at the top. The ram will safely exert a pressure of 100 tons, and, of course, has sufficient capacity for assembling all ordinary press fits met with in machine tool building. It is used also for straightening shafts. Being portable, the press is taken to the work when it is more convenient than to transport the work to the press.

The pulley reaming machine consists of a low cast-iron base supporting the table and enclosing the reaming spindle which runs in an oil bath. The bevel gears and pulley shaft also are immersed in the oil bath, thus providing lubrication for all running parts from one reservoir, by a simple construction that is practically proof against leakage and drip. The table carries the pulley dogs, these being two stationary uprights on opposite sides of the spindle.

Fig. 1. Portable Hydraulic Press made and used by Cleveland Planer Works

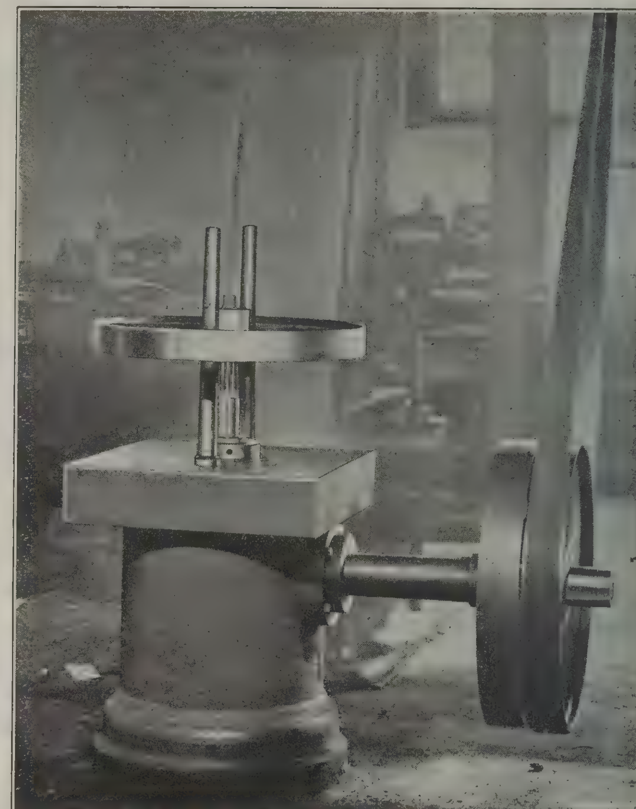

Fig. 2. Pulley Reaming Machine made and used by Cleveland Planer Works

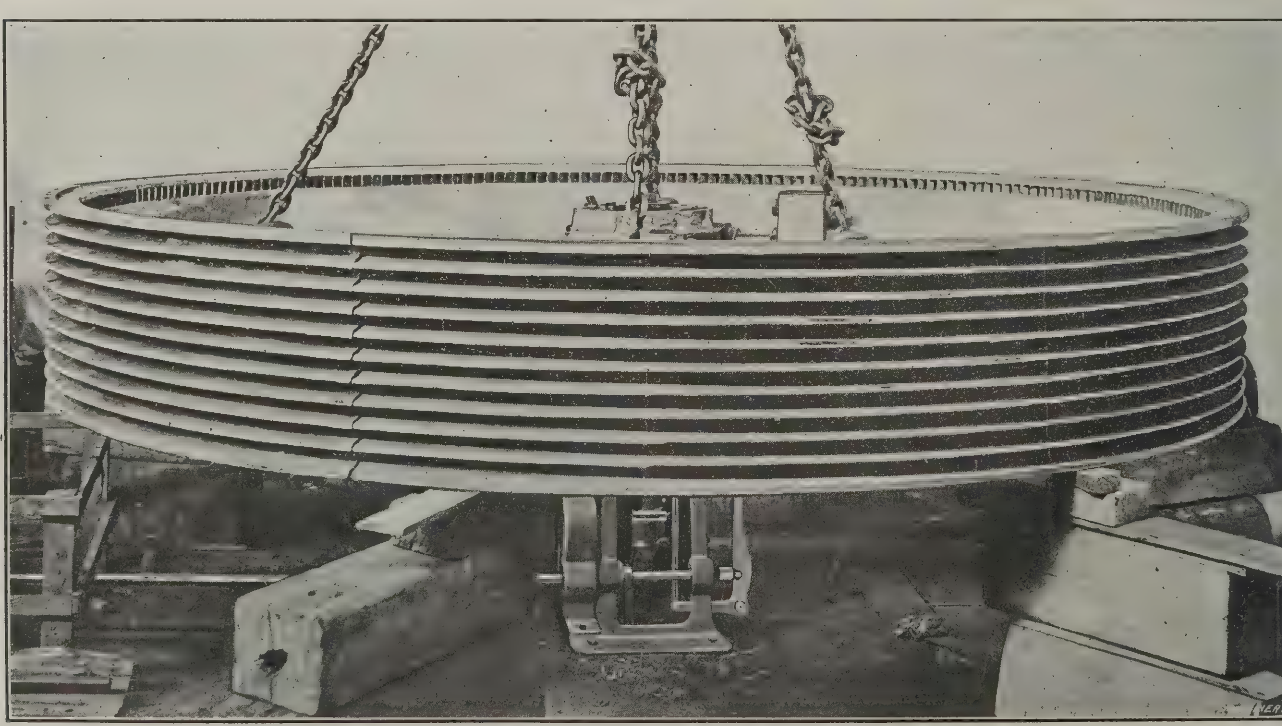
The reamers have square shanks fitting the square socket in the vertical spindle and enter the pulley bore from the under side. The pulley is restrained from turning by the two uprights or dogs and "feeds" down by its own weight only, the pressure of the spokes against the uprights tending to keep the feed from being too rapid.

KEYSEATING LARGE PULLEY IN AN INDIAN SHOP

The keyseating job illustrated herewith is of considerable interest because of the great difference between the size of the pulley and the machine. The casting is a large rope pulley which weighs ten and one-half tons, whereas the keyseating machine weighs only about one ton. The keyway cut is 2½ inches wide, and the machine used for cutting it was built by Mitts & Merrill, 843 Water St., Saginaw, Mich. The cutting of such a large keyseat on a machine of this size, to the required degree of accuracy, is made possible by the method of supporting the work and guiding the tool. The bored hub fits over a vertical post which forms a part of the machine, and this



Cutting Keyway in Hub of 10 1/2-ton Rope Pulley

post is provided with a groove in which the cutter operates. The advantage of this construction is that the keyway is cut with reference to the bore, and the cutter has a positive and rigid support. Locating the pulley by the bore also makes it unnecessary to have the hub faced true, as far as cutting the keyway is concerned. This machine has a maximum stroke of nineteen inches and the stroke can be decreased to suit the length of the work. The cutter has a quick-return movement which is twice as fast as the cutting speed. It also has an automatic relief on the return stroke.

The photograph of this keyseating operation was received from Messrs. Burn & Co., Ltd., Bengal, India. This firm is said to be the largest engineering and shipbuilding concern in the Far East.

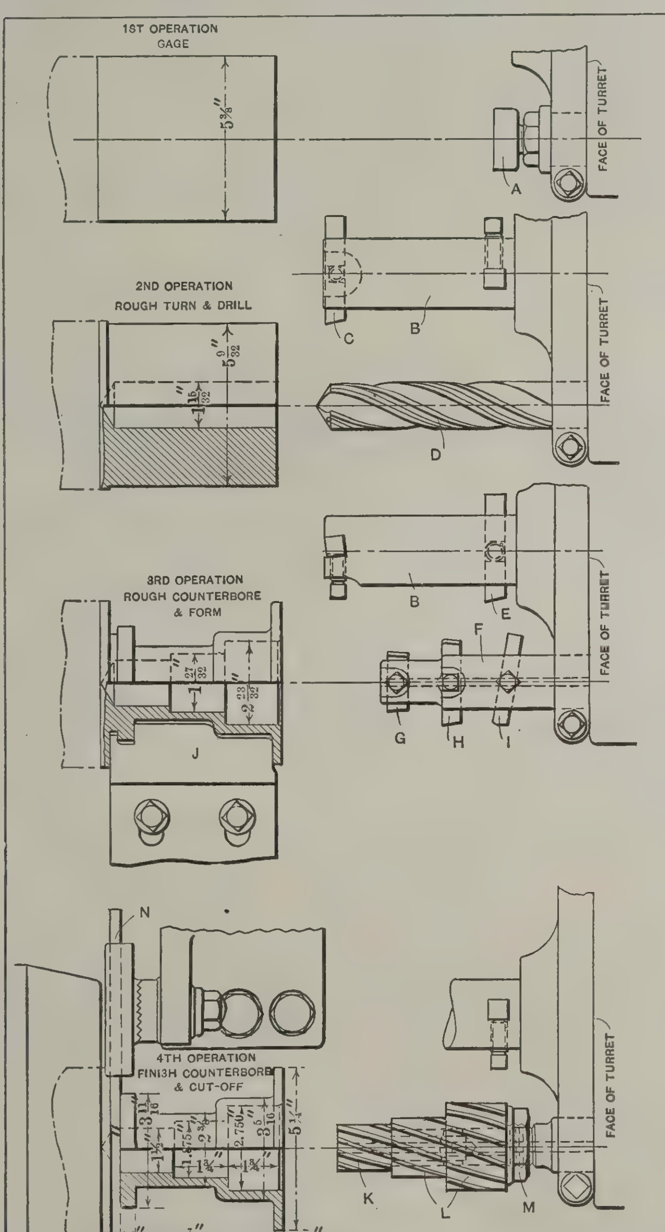
MACHINING CLUTCH HUBS IN A CLEVELAND AUTOMATIC

The different machining operations for producing motor car clutch hubs on a 6-inch standard model Cleveland automatic, are shown by the accompanying diagrams. These hubs are made of 14 point carbon, open-hearth steel and from rough bar



Successive Operations for Producing Motor Car Clutch Hub in Cleveland Automatic

stock. The first operation is feeding out the stock and gaging it to length by means of a stop-gage *A*, which is mounted in the No. 1 hole of the turret.

During the second operation, the entire length of the clutch hub is rough-turned by an overhanging turning attachment *B*. A central hole is also drilled with a 1 15/32-inch high-speed oil-feed drill *D*, which is carried in the No. 2 turret hole. The turning tool *C* is made from square stock, and the cutting edge is formed by simply grinding the end. The holder that carries this tool is fastened against the face of the turret and is clamped around the stems of all the other tools, which gives a very rigid support.

The third operation consists of rough-counterboring, chamfering, forming the outside, and finishing the periphery of the large flange at the outer end of the hub. The rough-counterboring is done by two tools mounted in boring-bar *F*, which is provided with an oil feed. The forward tool *G* bores a 1 27/32-inch hole and tool *H*, a 2 23/32-inch hole. The rear tool *I* chamfers the outer edge of the larger hole, as shown. The finishing tool *E*, mounted in the overhanging turning attachment *B*, takes a finishing cut over the large flange. The flat forming tool *J*, which is mounted on an adjustable toolpost on the front of the cross-slide, forms the outside of the clutch hub at the same time that the tools previously referred to, are in operation.

The fourth operation is that of finish-counterboring. The tool for this work is of a three-step form, provided with an oil feed. This counterbore is not made of one piece, but is composed of three separate tools. The advantage of this construction is that if one tool wears out before the rest, it can be replaced, whereas, if the entire tool were solid, it would be difficult to grind and expensive to reproduce. The smallest part *K* has a taper shank with a tang similar to an end-mill. The part *L* is locked by a square key and is backed up by a nut *M*; it has longitudinal adjustment to compensate for grinding the front faces.

The cutting-off operation, which comes next in order, starts before the work of the finishing counterbore is completed, and the cutting off is half finished at the time this counterbore is withdrawn; then the cutting-off tool severs the piece from the bar.

The time for each of these operations is as follows: 1. Gaging to length (takes place during the idle movement of the machine). 2. Drilling and rough-turning, 9 minutes. 3. Rough-counterboring, forming and finishing large flange, 12 minutes. 4. Finish-counterboring, 4 minutes. 5. Cutting off, 4 minutes 26 seconds. Idle movement of machine, 50 seconds. Total time for each hub, 30 minutes 16 seconds.

These clutch hubs are machined accurately to size and require very little extra work after being severed from the bar. The actual labor cost is about five dollars per hundred. The simple design of tools used for these operations is an important feature, especially in the production of pieces of this kind in large quantities. Forming tool *J* is a high-speed steel tool and both ends are the same, although the engraving only shows one end. With this arrangement, if one end is worn to such an extent that it needs replacement, after a large number of parts have been made, it is simply necessary to turn the tool around and use the opposite end. The cutting-off tool is a strong, straight blade, which can be adjusted in a few minutes after grinding, and all of the tools are rigidly mounted.

* * *

The American Society of Engineer Draftsmen held its regular monthly meeting in the Engineering Societies Bldg., May 16. A paper was read by Mr. R. E. Boehck of Evansville, Ind., on "The Development of Logging Machinery," and Mr. F. F. Nickel of the Worthington Pump Co. delivered a lecture on "Practical Applications of the Slide Rule." The meeting was especially interesting on account of the fact that Miss Marie Oberlander, student of architectural drawing at Teachers College, Columbia University, was admitted to junior membership. Miss Oberlander is the first woman to be elected as a member of the society.

* * *

Within the past decade concrete has become one of the most important of building materials, but unless properly mixed with standard materials it is hardly ever satisfactory. Mr. Leonard C. Wason, president of the Aberthaw Construction Co., states that in his opinion five per cent taken out of the proper cost of a concrete building decreases its value one-half.

SEVENTEENTH ANNUAL MEETING OF THE N. A. M.

The National Association of Manufacturers held its seventeenth annual meeting at the Waldorf-Astoria, New York City, May 20-22. At the first session the reports of the various committees, including those on consular reform, bankruptcy, merchant marine, and union labor were presented. One of the most valuable features of the convention was the exhibition of safety appliances and the special motion picture exhibit which illustrated in a clear and interesting manner the methods of accident prevention. The exhibition of safety appliances consisted of a large number of working models, and two thousand photographs lent to the society for the occasion by the Wisconsin State Industrial Commission and the U. S. Steel Corporation. A model ten feet long of an ocean liner with full lifeboat equipment was exhibited by the Hamburg-American line, and a full-sized installation of a submarine bell signaling system, with both sending and receiving apparatus, was shown.

Four films of moving pictures relating to accident prevention were shown, the first being of the general dramatic moving picture type, illustrating the disregard of safety appliances which is frequently met with among experienced workmen, and showing the fatal results. Another film showed the practical application and use of safety appliances on many machines in the plant of the Brown & Sharpe Mfg. Co., Providence, R. I. These pictures illustrated probably better than could have been done by any other means the need for, and the application of, effective guards on machine tools. Incidentally, one was impressed with the great field for moving pictures for educational purposes, not only as regards accident prevention, but as regards machine operation in general.

Another film showed methods adopted in large factories for safeguarding the employes in case of fire. Typical fire drills were exhibited showing hundreds of employes forming in line in perfect order and descending the fire-escapes from the third and fourth stories of a factory building. Since the deplorable Triangle Waist Factory fire, in New York City, fire drills have been made compulsory by law in the state of New Jersey, and these moving pictures were taken under actual working conditions at the regular fire drills. An interesting feature mentioned in connection with this exhibition of pictures was that in the case where fire drills are inaugurated, it is highly important to have an organized system for keeping the employes together and in order after they have left the building until they are ready to enter the building again, so that there may be no unnecessary loss of time. This applies to the fire drill as well as to an actual fire, which might be put out in a few minutes. In one case, it was stated that, in a factory employing eight hundred girls, the fire drill proved a success, as far as leaving the building in order was concerned, but no provision had been made for the method of re-entering the building, and it took several hours to again collect the working force! An interesting film submitted by the North German-Lloyd Steamship Co. showed a life-boat drill on board one of their liners.

There is a good reason for dwelling so long upon this exhibition of moving pictures, as it seems beyond question that accident prevention and the safeguarding of life and limb of industrial workers has become a matter to which all associations of manufacturers and engineers must give due attention. At the same time, there is probably no more effective means to illustrate to both the employers and employes the causes of accidents and the means for their prevention, than is offered by the moving picture machine. To the National Association of Manufacturers is due considerable credit for having given so much attention to this subject, and for having cooperated with the moving picture film makers in producing films of this character.

During the second day of the convention, one of the main addresses was that by Mr. John Kirby, Jr., president of the association. His address was largely devoted to a bitter and uncompromising attack directed partly against the initiative, referendum and recall, and partly against the National Civic Federation and the labor unions. Mr. Edward S. Beach read a paper on the "Influence of Patent Laws on the Development of Industries," in which he defended the present patent laws and voiced his objections to the provisions for compulsory working contained in two bills now before congress. One manufacturer, commenting upon the paper, stated that he believed that the bills containing clauses for compulsory working secured to the inventor all that was intended to be secured by the patent law, and that such provisions did not involve additional hardship to inventors. Addresses were also made by Mr. James A. Emery, on "Legislation and Business," and by Mr. Franklin H. Wentworth on "Fire Prevention."

During the afternoon session, May 21, papers were read by Mr. Frank E. Law, on "Workmen's Compensation for Accidents," and by Mr. Walter E. Edge, on "Workmen's Compensation." Mr. Henry Weismann read a paper on "Immigration, Its Value to the Country, Past, Present and Future."

During the last day of the convention, addresses were made by Mr. Irving T. Bush, on "Currency Reform"; by Mr. M. L. Stewart, on "Trade Possibilities of the Philippine Islands and the Far East"; by Mr. W. M. Benney, on "The National Association of Manufacturers and its Work for Export Trade," and by Mr. C. A. Conant, on "The Panama Canal in Relation to Commerce and Transportation." Moving pictures showing the progress on the Panama Canal were shown. A banquet was held on the evening of May 22, which marked the conclusion of the convention.

The following officers were elected for the year: President, John Kirby, Jr., Dayton, Ohio; secretary, George S. Boudinot, New York; treasurer, A. B. See, New York; assistant treasurer, J. P. Bird, New York.

* * *

CONSOLIDATION OF THE HORTON CHUCK COMPANIES

S. E. Horton Machine Co., Windsor Locks, Conn., and E. Horton & Son Co., of the same place, manufacturers of lathe chucks, have been consolidated through the sale of stock owned by Ezra B. Bailey to interests affiliated with Stoddard Ellsworth Horton, the president and treasurer of the S. E. Horton Machine Co. Mr. Horton will be president, treasurer and general manager of the combined companies.

The E. Horton & Son Co. was started sixty-two years ago by Eli Horton, the inventor and patentee of the first geared universal chucks. Mr. Horton developed original methods of manufacture and made his product known for excellence throughout the manufacturing world. His grandson, S. E. Horton, was identified with the E. Horton & Son Co. beginning 1891 and was superintendent of the plant from 1896 to 1905. He left the company a few years ago and organized an independent company of which he was president and treasurer. The consolidation of the Horton chuck companies will make conditions favorable for a much stronger and more effective business organization.

* * *

REORGANIZATION OF THE WALTHAM WATCH TOOL CO.

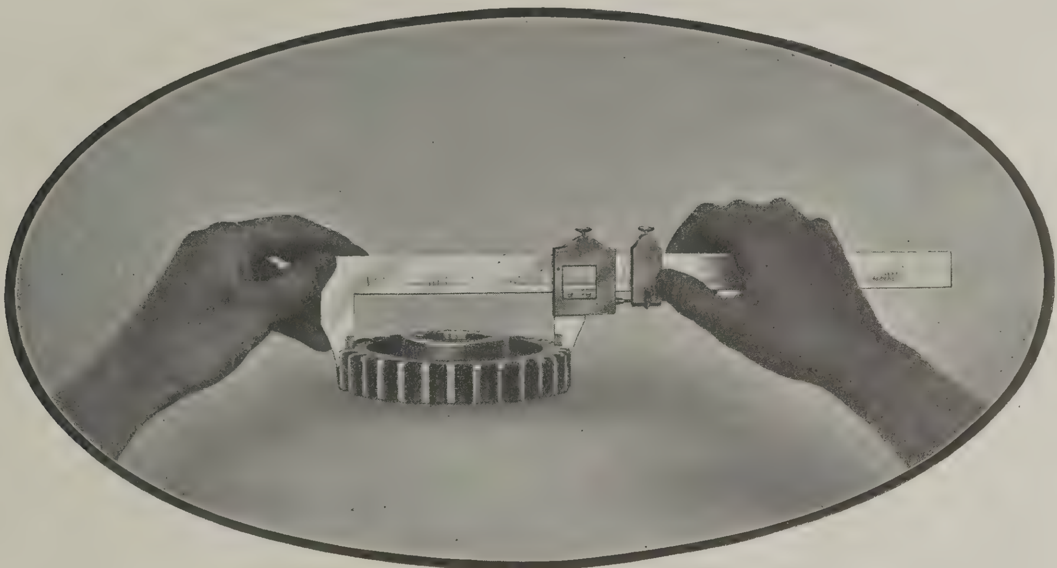
The Van Norman Machine Tool Co., Springfield, Mass., is a new corporation organized to take over the business and property of the Waltham Watch Tool Co., of that city. The authorized capital stock is $400,000, and the incorporators are: Frank H. Page, Clarence J. Wetsel, Charles E. Van Norman and Fred D. Van Norman, all of Springfield. Mr. Page, who is president of the National Equipment Co., will be president of the reorganized company; Mr. Wetsel, formerly manager of the Baush Machine Tool Co., of Springfield, will be treasurer; Charles E. Van Norman, vice-president; and Fred D. Van Norman, secretary. The Van Normans founded the Waltham Watch Tool Co. about eleven years ago, in Waltham, Mass.

The company will continue to manufacture the Van Norman milling machines, universal bench lathes, bench milling machines, internal grinding machines and other tools and accessories that have become well known during the past few years.

* * *

When springs are used for producing certain movements in quick succession, the strength of the springs should be from two to three times what would be required to produce the same movements at a slow speed.

A new adaptation of an old tool for determining accurately the depth of gear teeth



VERNIER CALIPER NO. 687

Measuring the bottom diameter of gears provides an accurate check on the cutting operation and insures the duplication of any desired standard.

This tool, therefore, is found especially valuable in the Automobile Shop for measuring automobile transmission gears, and in fact for measuring the bottom diameter of any gear where it is impossible to use our regular vernier calipers on account of the thickness of the jaws.

Outside of the measuring jaws this tool is exactly like our 12" vernier caliper, and can be used as such.

Write for further information.

BROWN & SHARPE MFG. CO.

PROVIDENCE, R. I., U. S. A.

PERSONALS

George B. Pickop, formerly master mechanic of the American Hardware Co., has entered the employ of the Universal Screw Machine Co., Hartford, Conn., as general superintendent.

Henry G. Dreses, president of the Dreses Machine Tool Co., Cincinnati, Ohio, sailed for Europe May 25. Mr. Dreses will make a tour of European manufacturing countries in the interests of his concern.

C. A. Nourse has resigned as general superintendent of the American-LaFrance Fire Engine Co., Elmira, N. Y., to become superintendent of the Reed-Prentice Co., of Worcester, Mass. He assumed his new duties June 1.

George Bradshaw has been appointed general safety agent of the New York Central & Hudson River Railroad Co. He will have his headquarters at New York, reporting to the general claims attorney and to the general manager.

Douglas T. Hamilton, associate editor of MACHINERY, has been made Western editor with headquarters in the Monadnock Block, Chicago, Ill. Mr. Hamilton will travel in the machine tool building territory west of Pittsburg and Erie.

H. W. Kreuzburg, president of the Champion Tool Works Co., Cincinnati, Ohio, sailed May 25 on the *Cincinnati* for a four months' trip in Europe in the interests of his company, taking in Great Britain and the Continental manufacturing countries.

J. C. Dufresne, formerly in charge of the speed and rate setting departments of the Providence Engineering Works, Providence, R. I., has resigned to become factory engineer and mediator for the Aurora Automatic Machinery Co., Aurora, Ill.

J. E. Fries, engineer with the Cutler-Hammer Mfg. Co., Ampere, N. J., has been transferred to the San Francisco office as Pacific Coast engineer, where he will be able to render prompter service to the rapidly growing business of the company on the Pacific Coast.

Duncan H. Macdonald has resigned as general manager and superintendent of the Southern Engine & Boiler Works, Jackson, Tenn. Frank W. Milbourn has been elected to succeed Mr. Macdonald as general manager, and H. M. Harris has been appointed superintendent.

Emile A. Tordet, manager of the Italian branch of Fenwick Freres & Co., of Paris, Turin, Liege, etc., is on a two-months' business trip in the United States to visit the firms represented by his concern in Italy. His address while in the United States is care of Brown & Sharpe Mfg. Co., Providence, R. I.

W. S. Quigley has withdrawn from the Rockwell Furnace Co., New York City, of which he was vice-president and general manager since the formation of the company. Mr. Quigley has formed the Quigley Furnace & Foundry Co., 50 Church St., New York, to carry out some advanced ideas in furnace construction.

Ezra B. Bailey of Windsor Locks, Conn., who recently sold out his entire interest in E. Horton & Son Co., of Windsor Locks, had been connected with the company for thirty-two years. He became treasurer and general manager of the company in 1880 and has been in the chuck business longer, with one exception, than any other man now engaged in it.

George I. Keyes (W. P. I. '97) has retired from the management of the Reed Foundry Co., Worcester, Mass., with which he was connected since it was first established in 1901. For the present Mr. Keyes will take a much needed rest and vacation. He was formerly a member of the firm of Keyes & Woodbury, Worcester, Mass.

John Harland Nelson has been elected professor of applied mechanics by the trustees of the Worcester Polytechnic Institute, Worcester, Mass., to succeed the late Prof. Edward L. Hancock. Prof. Nelson has been at the head of the department of applied mechanics, Case School of Applied Science, Cleveland, Ohio, for the past three years, and is a graduate of the South Dakota State College.

A. Bradley Burgess (W. P. I. '01) has been appointed general manager of the Standard Plunger Elevator Co., Worcester, Mass. Mr. Burgess, upon graduation from the Worcester Polytechnic Institute, became an estimating engineer, following which he filled the positions as sales manager, local manager and now that of general manager. Since he assumed control, the main offices have been removed from 115 Broadway, New York, to Worcester. The treasurer's office of the company will remain in New York.

W. H. Sherwin, for the past ten years Northwestern representative of Joseph T. Ryerson & Son, Chicago, located at Minneapolis, has resigned his position, and will become general manager and vice-president of the Alberta-American Ornamental Iron Co., of Redcliffe, Alberta. This concern is successor to the American Ornamental Iron & Steel Co., of Minneapolis, Minn., a well-known concern that is moving its entire plant to Redcliffe where it expects to add to its already large equipment and thus put the concern in a position to handle the business of that rapidly developing country.

John W. Hill, mechanical engineer, has resigned from the Brown & Sharpe Mfg. Co., Providence, R. I., to become sales engineer with the Bantam Anti-Friction Co., Bantam, Conn. Mr. Hill has a wide experience as mechanical engineer, having been connected with the General Electric Co., Westinghouse Electric & Mfg. Co., and the American Locomotive Co., at Providence. He was also associated several years ago with Mr. W. S. Rogers, president of the Bantam Anti-Friction Co., at the Watervliet Arsenal, in the design of heavy machinery for building the big guns for coast defense purposes, and is, therefore, well equipped for the position he now holds.

* * *

OBITUARY

Hugh Addison Reed, president of the Baird Machinery Co., Pittsburg, Pa., and one of the most prominent machine tool men in the Pittsburg district, died at his home 1232 Sheffield St., N. S., April 25, aged fifty-eight years. Mr. Reed was a native of Pittsburg, having been born in the old city of Allegheny, and spent his entire life in that vicinity. Although he had not been in good health for the past year, his death came as a shock to his many friends. He was one of the first to represent the machine tool business in Pittsburg, becoming interested in it at an early age. Mr. Reed was a member of the Engineers' Society of Western Pennsylvania, and Technischer Verein, and was well known by the machine tool builders throughout the country.

* * *

COMING EVENTS

June 12-14.—Annual convention of the American Railway Master Mechanics' Association at Atlantic City, N. J.

June 17-19.—Annual convention of the Master Car Builders' Association at Atlantic City, N. J.

June 17-22.—First annual gas engine show under the auspices of the National Gas Engine Association in the Auditorium, Milwaukee, Wis. Albert Stritmatter, secretary, Cincinnati, Ohio.

June 27-29.—Summer meeting of the Society of Automobile Engineers, Detroit, Mich., Hotel Pontchartrain, headquarters. Coker F. Clarkson, secretary, 1786 Broadway, New York.

July 9.—Annual convention of the American Railway Tool Foremen's Association in Chicago. H. L. Miller, secretary of the supply association, 835 Monadnock Bldg., Chicago, Ill.

August 20.—Annual convention of the International Railroad Master Blacksmith's Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7.—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; Hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

NEW CATALOGUES AND CIRCULARS

RICHARD DUDGEON, Broome and Columbia Sts., New York, manufacturer of hydraulic jacks, hydraulic punches, and roller tube expanders. Booklet entitled, "Some Mathematical Recreations."

GEM MFG. Co., Pittsburg, Pa. Catalogue No. 6 of steel and brass oilers, torches, oil carriers, tallow pots, flue scrapers, foundry chaplets, loose pulley lubricators, flexible shafts, portable drills, center grinders, clamp spindles, universal joints, electric polishing machines, stop clutches, etc.

CONOVER-OVERKAMP MACHINE & TOOL Co., Dayton, Ohio (successors to Miami Valley Machine Tool Co.). Catalogue of lathes and No. 1 grinder comprising 14-inch standard lathe; 16-inch standard lathe; 16-inch lathe, double back geared; plain turning lathe; and universal cutter and tool grinder, illustrating applications to various forms of cutters.

EGBERT R. MORRISON, Sharon, Pa. Circular of the "Morrison" water-tube boiler of the type consisting of cylindrical shells connected by water-tubes, there being two shells above and two below connected by tubes and surrounded by brick work which is provided with baffle-plates insuring thorough circulation of the hot gases over the heating surface.

ROCHESTER BORING MACHINE Co., Rochester, N. Y. Sixteen-page catalogue, 8 by 10 inches, on floor type and table type boring machines. The machines are illustrated and details of construction are shown in line illustrations and halftones. Special tables and attachments are also shown.

ROCKFORD DRILLING MACHINE Co., Rockford, Ill. Booklet entitled "Jigging and Tooling." This booklet illustrates and describes how the Rockford gang drills built by this company may be used to best advantage in manufacturing work. A number of examples from practice giving detailed data of possibilities in production form the basis of the contents.

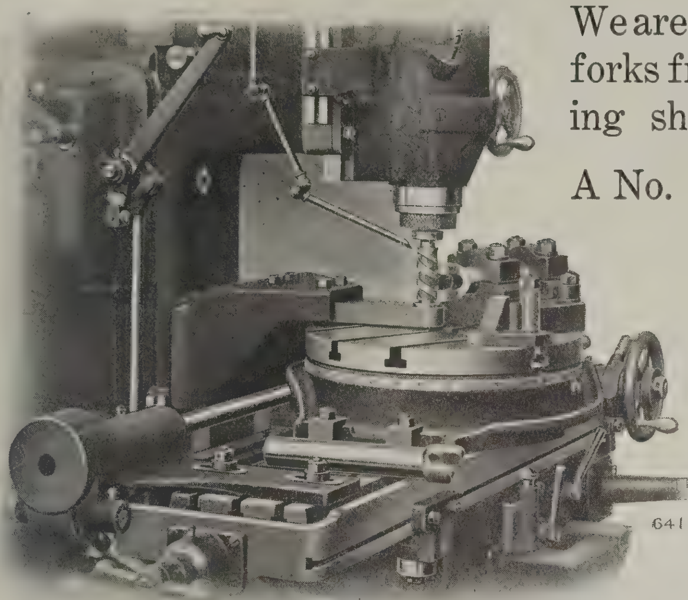
E. T. COPELAND Co., 100 William St., New York. Booklet entitled "Circulation of Water in Steam Boilers," containing a general treatise on circulating devices and especially on the Copeland patent automatic circulating system, describing its general construction, how it works, what it accomplishes, etc. The text matter of the booklet is clearly illustrated by engravings.

HESS-BRIGHT MFG. Co., 2111 Fairmount Ave., Philadelphia, Pa. Pamphlet entitled "Ball Bearings in Woodworking Machinery," illustrating a large variety of woodworking machinery to which ball bearings have been successfully applied; also showing the approved construction of ball bearing mountings adapted to the peculiar conditions in woodworking machinery.

HYATT ROLLER BEARING Co., Newark, N. J. Miniature bulletin 400 C of twenty pages on roller bearing line shafting boxes. Data of tests made by the United Shoe Machinery Co., showing a large saving in power, are included; also data on a test made by the American Can Co. A price-list is given of Hyatt standard line-shaft bearings and extra heavy main shaft bearings, and dimensions of Hyatt standard boxes, etc.

MAKUTCHAN ROLLER BEARING Co., 1541-42 McCormick Bldg., Chicago, Ill. Catalogue of roller bearings and roller bearing hangers. The principle of the Makutchan roller bearing is illustrated and described and tables of sizes and price lists of roller bearings, roller bearing hangers of various types, and thrust ball bearings are given. A number of halftone illustrations are included, showing views of installations where the Makutchan bearings are used.

Time Per Piece—7 Minutes

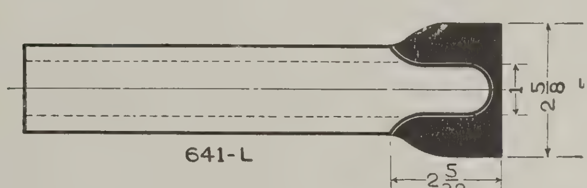


We are now cutting our universal shaft forks from solid steel bars. The drawing shows them ready for milling.

A No. 3 Vertical with a 20" Circular Attachment forms up the outside at one setting and at one cut.

This is possible because all feeds are set and controlled from the front of the knee without stopping. A combination of table, cross and circular feeds is used.

Speed, 94 Revolutions.
Feed, 2 1-4" per minute.
Time per piece, 7 minutes.



The next operation consists of milling out the fork for the ball seat. There are two fixtures. While the operator is filling one, the other piece is being milled. Time for this cut, one minute.

You will notice that the cutter is different from the usual end mill—suggests some of our advanced ideas in cutter design.

We are pretty far ahead in everything that relates to milling.

Ask for our New Examples of Modern Milling Practice.

The Cincinnati Milling Machine Co.

Cincinnati, Ohio, U. S. A.

EUROPEAN AGENTS—Alfred H. Schutte, Cologne, Berlin, Brussels, Milan, Paris and Barcelona. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Sam Lagerlofs, Stockholm, Sweden. Axel Christiernsson, Abo, Finland. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow. CANADA AGENT—H. W. Petrie, Limited, Toronto, Montreal and Vancouver. AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne. JAPAN AGENTS—Andrews & George, Yokohama. CUBA AGENT—Krajewski-Pesant Co., Havana. ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Ayres.

SKINNER CHUCK Co., New Britain, Conn. 1912 catalogue and price list covering independent, universal and combination lathe chucks; drill chucks; planer chucks; faceplate jaws; drill press vises and reamer stands. A new line has been added to the products of this company, consisting of all-steel independent lathe chucks and all-steel faceplate jaws. The catalogue gives complete tabulated dimensions and price lists of all the tools illustrated and described.

LINCOLN-WILLIAMS TWIST DRILL Co., Taunton, Mass. Catalogue of carbon and high-speed steel twist drills, reamers and milling cutters; also arbors, disks, countersinks, mandrels, saws, sockets and sleeves, taps and dies. The catalogue includes a number of tables of general value on cutting speeds, decimal equivalents of listed sizes, dimensions of Morse taper shanks, dimensions of Brown & Sharpe taper shanks, drill feeds and speeds, melting points of the elements, and tap drill sizes.

WATSON-STILLMAN Co., 192 Fulton St., New York. Catalogue No. 83, entitled "Hydraulic Benders," covering 64, 6- by 9-inch pages, and illustrating and describing hydraulic and motor-driven rail benders; shaft straighteners for lathes; portable shaft straighteners; straightening presses; pipe benders; axle straightening presses; bar straighteners; hydraulic shaft straightening presses; plate straightening and forming presses; beam bending presses; strake benders; crank pin presses; bending jacks, etc.

EUGENE DIETZGEN Co., 214-220 E. 23d St., New York. Circular illustrating the "Dietzgen" economy box for storing blueprints, drawings, tracing paper, etc. The box is especially adapted for the storing and preservation of blueprint paper, the construction being such that light is excluded. Provision is made for measuring and cutting off the paper to the exact required length. This feature of economy means a substantial saving in almost any drafting-room using blueprint paper, tracing paper and other paper in rolls.

YALE & TOWNE MFG. Co., 9 Murray St., New York. Catalogue No. 12-D, 1912, of chain blocks, electric hoists, trolleys and cranes. This catalogue, containing 96, 6 by 9-inch pages, illustrates and describes in detail the various types of hoisting devices built by the company. Constructional features are plainly illustrated and carefully described and parts and details are numbered and named so as to make it easy to order duplicate parts. All dimensions necessary for preliminary layouts are included, making the book, in general, valuable for the designing engineering and manufacturer.

NATIONAL-ACME MFG. Co., Cleveland, Ohio. Booklet entitled "Parts for the Trade," illustrating a large number of specialties made on National-Acme automatic screw machines to customers' specifications and to order only. The parts shown comprise spark plugs, automobile engine parts, special screws and nuts, carbureter and magneto parts, sundry accessories, lubrication parts, motorcycle parts, heavy machinery parts, screws, bushings, nuts, etc., for speedometers, cyclometers, indicators, typewriters, phonographs, sewing machines, washing machines, hardware, tools, plumbing supplies, gas appliances, locomotives, cars, etc.

WESTINGHOUSE ELECTRIC & MANUFACTURING Co., East Pittsburg, Pa. Descriptive leaflets No. 2303, Direct-current Crane Motors; Nos. 2313, 2314, and 2315, Commutating Pole Mine Motors; No. 2368, Strap Wound Armature Coils of Westinghouse Railway Motors; No. 2370, Details of Railway Motors; No. 2376, Box Frame Interpole Railway Motor for use on 600- to 1200-volt service; No. 2377, Box Frame Interpole Railway Motor for Locomotive Work; No. 2393, Dynamotor-Compressor for 1200- to 1500-volt Direct-current Service; No. 2444, Equalizer Flywheel Hoisting Sets; No. 2464, Rheostats for Direct-current Motors.

STANDARD MACHINERY Co., Providence, R. I. Catalogue, eighth edition, on drop presses, comprising plain drop presses in eight sizes with hammers weighing from 60 to 800 pounds; power lifters for plain drop presses for 40- to 1000-pound hammers; automatic drop presses in eight sizes with hammers weighing from 50 to 1200 pounds. A valuable chapter on foundations is included illustrating the construction of approved forms. The company also builds trimming presses, roller bearing and plain bearing rolling mills, rotary swaging machines, wire-drawing machinery, roller bearings, ball bearings and special machinery.

J. H. WILLIAMS & Co., 61 Richards St., Brooklyn, N. Y. Catalogue of drop-forged wrenches for all uses, spanners, wrench sets for automobilists, "Ratcho" wrenches, lathe dogs of the safety and ordinary forms, C-clamps, machinists' clamps, strap clamps, external caliper gages (unfinished), machine balanced handles, toolpost fittings, thumb nuts, eye-bolts, swivels, hoist hooks, rope sockets, rod ends, yoke ends, shafting collars or bushings, key forgings, weldless pipe ferrules and flanges, chain pipe vises, chain pipe wrenches, crankshafts, connecting rods, valve stem forgings, levers, etc. The company makes drop forgings of iron, steel, copper, bronze and aluminum. The front cover of the catalogue is double, bearing on the front face a drop-forged engineer's wrench with the "flash." The second cover shows the trimmed wrench, the opening in the front cover having the effect of a trimming die used for removing the flash of drop-forgings. The design is unique and peculiarly appropriate.

WIENER MACHINERY Co., 50 Church St., New York. Catalogue of Ernst Schiess, Ltd., Dusseldorf, Germany, builder of heavy machine tools. This well-known German concern has built some of the largest machine tools in the world as, for example, a turning and boring mill with table 36 feet 1 inch diameter, weighing approximately 660,000 pounds. The catalogue illustrates the works' interior, erecting shop, heavy type roughing lathes, "sliding and surfacing lathe" for turbine shafts, turning lathe for turbine shafts, turning lathe for large turbine shafts and drums, weighing 732,600 pounds, heavy roll roughing lathe, hollow boring lathe, turning and boring lathe, turning and boring mill, portable boring mill, planing and milling machine, standard type planing machine, pit planing machine, transverse planing machine, shaping machine, triple slotting machine, combined slotting and drilling machine, universal radial drilling machine, horizontal boring and milling machine, cylinder boring machine, double punch press, bending machine, horizontal cold saw, etc.

CINCINNATI-BICKFORD TOOL Co., Oakley, Cincinnati, Ohio. Catalogue of "Cincinnati" heavy pattern upright drilling and tapping machines, comprising 20-inch high-speed sliding head drill, square or round table and hand or power feed, with or without tapping attachment, belt or motor drive; 21-inch stationary head, heavy pattern drill, with and without back gears, belt or motor drive; 21-inch sliding head, heavy pattern drill with and without tapping attachment; 24- to 42-inch regular heavy pattern drill, with and without tapping attachment, belt or motor drive; 24- to 36-inch, special pattern drill with geared tapping attachment; 20-inch high-speed sliding head gang drill, furnished with two to six spindles, each with or without tapping attachments and with or without power feed; and 21- to 42-inch heavy pattern gang drill with four spindles. The details of table equipment are illustrated; also right angle drive, belted motor drive, geared motor drive, motor and speed-box drive, friction back gear and tapping attachment, feed box, depth gage, automatic trip, etc.

TRADE NOTES

HILL, CLARKE & Co., INC., has removed its Philadelphia office from 512 Arch St., to 1011 Chestnut St.

CUTLER-HAMMER MFG. Co., Ampere, N. J., opened an office in the Title Insurance Bldg., in Los Angeles, Cal., April 1.

NILES-BEMENT-POND Co., removed its Chicago offices from the Commercial National Bank Bldg. to the McCormick Bldg., 332 S. Michigan Ave., May 1.

BROWN & SHARPE MFG. Co.'s drafting-room gave a minstrel show and entertainment for the benefit of the "League for the Suppression of Tuberculosis," May 3.

TOLEDO MACHINE & TOOL Co., Toledo, Ohio, has contracted for a three-story iron and brick building 90 by 115 feet which will be used in connection with the present business.

WILLIAM GANSCHOW Co., Chicago, Ill., gear cutter, has taken another floor in the building now occupied, adding new machinery and increasing the capacity one-third. The company has also fitted up a finely equipped office.

STANDARD ROLLER BEARING Co., 50th St. and Lancaster Ave., Philadelphia, Pa., recently purchased and installed over $100,000 worth of additional machinery equipment to increase its facilities for the manufacture of ball and roller bearings.

PHILADELPHIA GEAR WORKS, 1120-1122 Vine St., Philadelphia, Pa., has established a special automobile service for local customers, thereby shortening local delivery time considerably, and also enabling the company to quickly place cut gears in the express companies' care when ordered from out of town.

NORTON Co., Worcester, Mass., broke ground April 5 for a $100,000 administration and research laboratory building which will be situated between the present buildings and those of the Norton Grinding Co., facing on New Bond St. The new building is to be of brick, and will be three stories high, with a basement 98 by 157 feet.

BIGNALL & KEELER MFG. Co., Edwardsville, Ill., manufacturer of Peerless, Duplex and P. D. Q. C. pipe threading and cutting machines, emery surfacers, die grinders and rolling cutters, has made an exclusive sales agency arrangement with Manning, Maxwell & Moore, Inc., for the sale of its machines throughout all the Eastern states.

QUIGLEY FURNACE & FOUNDRY Co., 50 Church St., New York, has been formed by Mr. W. S. Quigley, formerly vice-president and general manager of the Rockwell Furnace Co., New York. The new company will carry out some advanced ideas in furnace construction and has secured the services of able furnace engineers who have been associated with Mr. Quigley for a number of years.

BILLINGS & SPENCER Co., Hartford, Conn., and Claire L. Barnes Co., Chicago, Ill., have discontinued the selling arrangements existing between them by mutual consent. In future the Billings & Spencer Co. will market its products of drop forgings and tools direct. During the past two years the company has more than doubled its manufacturing capacity, and its new plant at Dividend, Conn., devoted exclusively to the making of drop forgings, is now in full operation.

CINCINNATI ELECTRICAL TOOL Co., 652 Evans St., Cincinnati, Ohio, announces that it has just completed two sizes of universal drills which will operate on direct current as well as alternating current. Type OX2 will drill up to 3/16 inch in steel and hard wood and up to ⅝ inch in soft wood. Type OX3 will drill ¼ inch in steel and hard wood and ½ inch in soft wood. The armature runs in ball bearings, and the gears are enclosed and run in grease.

KELLY REAMER Co.'s stockholders held their annual meeting at the company's office in Cleveland, Ohio, April 20 and elected Wm. E. Kelly, W. A. Calhoon, H. J. Maxwell, O. H. P. Davis, E. B. Jessup, George Bauer and Thomas A. Torrance, directors, who elected the following officers for the year; president and general manager, Wm. E. Kelly; vice-president, W. A. Calhoon; secretary, H. J. Maxwell; and treasurer, O. H. P. Davis. The company reports a large increase in business during the past year.

JOSEPH TRACY and HENRY F. DONALDSON have associated themselves as automobile engineers to undertake consultation, research and development work, design and construction, laboratory and road tests, and have removed the office which Mr. Tracy has maintained for several years at 116 West 39th St., to 1786 Broadway (cor. 58th St.), New York. The testing laboratory in New Jersey, near New York City, will be maintained as heretofore, and its facilities will be increased by additional equipment.

STARK TOOL Co., Waltham, Mass., manufacturer of precision bench lathes and attachments, bench milling machines, watchmakers' lathes and fine tools completed its fiftieth year in business May 1. Since the business started it has not had a shutdown, lock-out or cessation of the regular work, beyond the regular yearly vacation of a week. The business was founded by John Stark who was succeeded by the present John Stark at his death. The company is the fourth oldest industry in Waltham, being antedated only by the Boston Mfg. Co., Davis & Farnum Co., and the Waltham Watch Co.

J. L. OSGOOD TOOL Co., 121 Erie Co. Bank Bldg., Buffalo, N. Y., recently took over the business of J. L. Osgood, manufacturer of Osgood's indestructible tool handles. Several new types of indestructible handles have been added; also a line of black diamond hand tools, and the "junior class" indestructible file and tool handles. These handles will not split, having a steel-bound inner core which resists the splitting action of the file tang. A line of screwdriver handles made on the same principle has also been added, having hard wood handles with steel reinforced core and transverse scores on the grip, making a strong and powerful handle.

W. ROBERTSON MACHINE & FOUNDRY Co., 32 Greenwood Pl., Buffalo, N. Y., is a new concern recently organized under the laws of the state of New York with $15,000 capitalization, $12,000 of which is paid in. The officers are: W. Robertson, president and manager; T. J. Reed, vice-president; F. H. Keil, secretary; and F. M. Robertson, treasurer. The company will manufacture machine tool specialties, including a complete line of power hacksaws for all kinds of metal cutting, and special drilling machines. It will also manufacture, to order, gray iron pistons, cast within 0.005 inch of finished size by a new process which insures the wrist-pin holes being absolutely round and to the dimensions specified in the drawings, and produces a balanced piston which is very essential for quiet and serviceable motors. Mr. W. Robertson, the president of the company, has been a successful designer of tools and appliances, having placed over 1600 of his power hacksaws on the market. He was formerly connected with the Frontier Iron Works of Buffalo, N. Y.

EARLE GEAR & MACHINE Co., Stenton and Wyoming Aves., Philadelphia, Pa., was recently awarded a contract for one of the most interesting features in connection with the operation of the locks of the Panama Canal, that is, the mechanism which controls the collapsible hand-rails on the top of the various gates, forty in number. When these gates are closed a standing rail on each side serves to prevent persons from falling into the water. As the gates are opened to permit the passage of vessels, these rails are automatically collapsed or folded by means of a unique driving mechanism, motor operated. The worms, gears and screws for this device incorporate some very interesting engineering features. All parts are exceptionally heavy and the design of the entire outfit has been made with a view to quick operation and accessibility. There are eighty sets—forty right-hand and forty left-hand. Each gate is approximately seventy feet long, and some idea of the rugged construction necessary can be gained from consideration of this dimension. The company, to which the contract was awarded, is a specialist in the manufacture of work of this character; it recently produced a large number of lock-working mechanisms for the New York state barge canal.

MACHINERY

Railway Edition for Locomotive Construction and Repair Shops

July, 1912

EIGHT-MOTOR ARTICULATED-TRUCK LOCOMOTIVES FOR THE NEW YORK, NEW HAVEN & HARTFORD RAILROAD

THIRTY-NINE heavy-service, electric locomotives are now being built by the Baldwin-Westinghouse combination for use on the New York, New Haven & Hartford R. R. between New York and New Haven. This is one of the largest consignments of electric locomotives ever constructed. The design adopted differs from any heretofore used for electric engines, in that thirty-six of the engines are arranged for single-phase service only.

A side view of one of these locomotives is shown in Fig. 1. Each locomotive has four twin motor driving units similar to the one shown in Fig. 3, there being eight motors in all. One of these motor units is mounted over each driving axle. This arrangement has proved very desirable for the following reasons: 1. The peripheral speed is a limiting feature in railway motor design. With two small motors it is possible to use a rotative speed of approximately twice that obtainable with one large motor. Each motor has, therefore, one-half the number of poles of practically the same size as would be required by one large motor of equivalent capacity. Hence, two of the small motors have practically the same number of parts, such as field coils, armature coils, and brush holders, as would be required by one large motor. 2. Each of the small motors has a diameter practically half of that of one equivalent large motor; hence a saving in weight and space results. 3. There is a further saving in weight because each small motor exerts but one-half the torque that must be exerted by one equivalent large motor; therefore a single gear meshing with the pinion of each motor can be used in place of the two gears necessary with a large motor of the same total capacity. 4. By the use of a single gear, the motor can be longer which permits of a more economical design. 5. The motor armatures are interchangeable with those used on the New

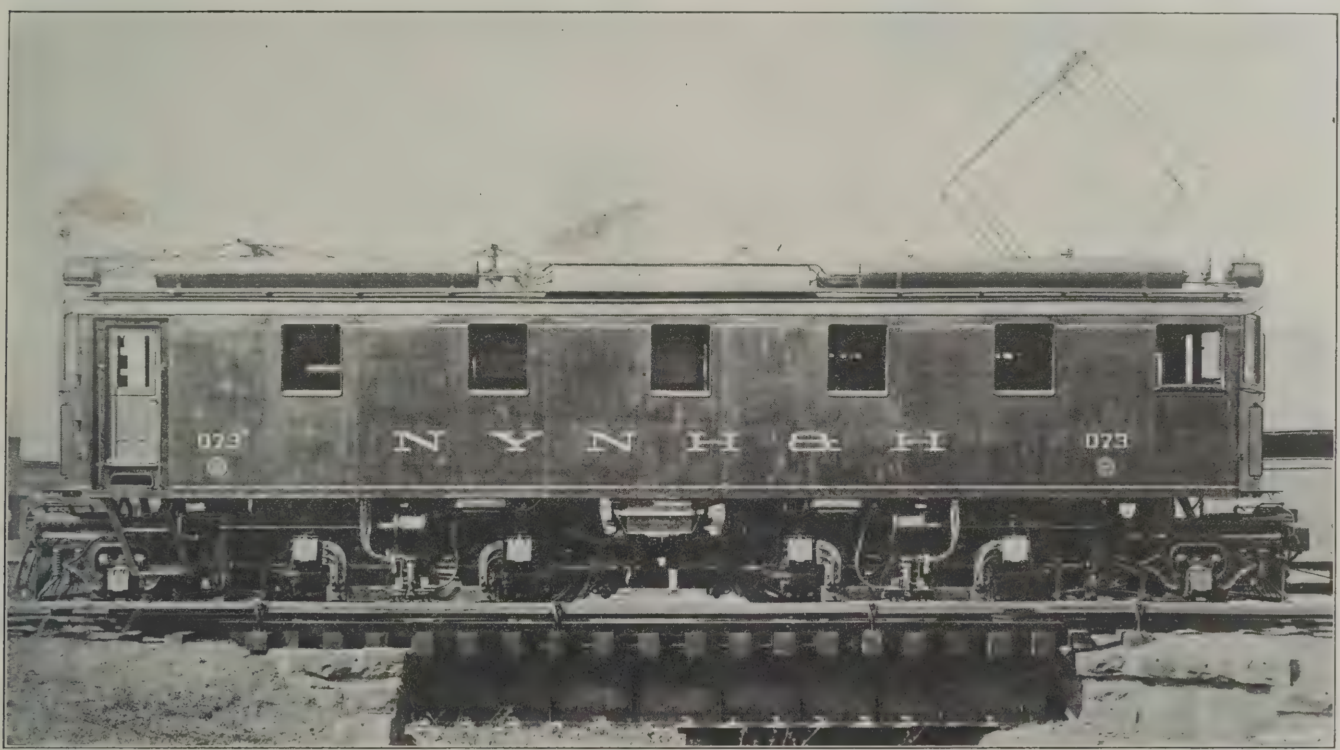


Fig. 1. Side View of Eight-motor, Articulated Truck, Electric Locomotive

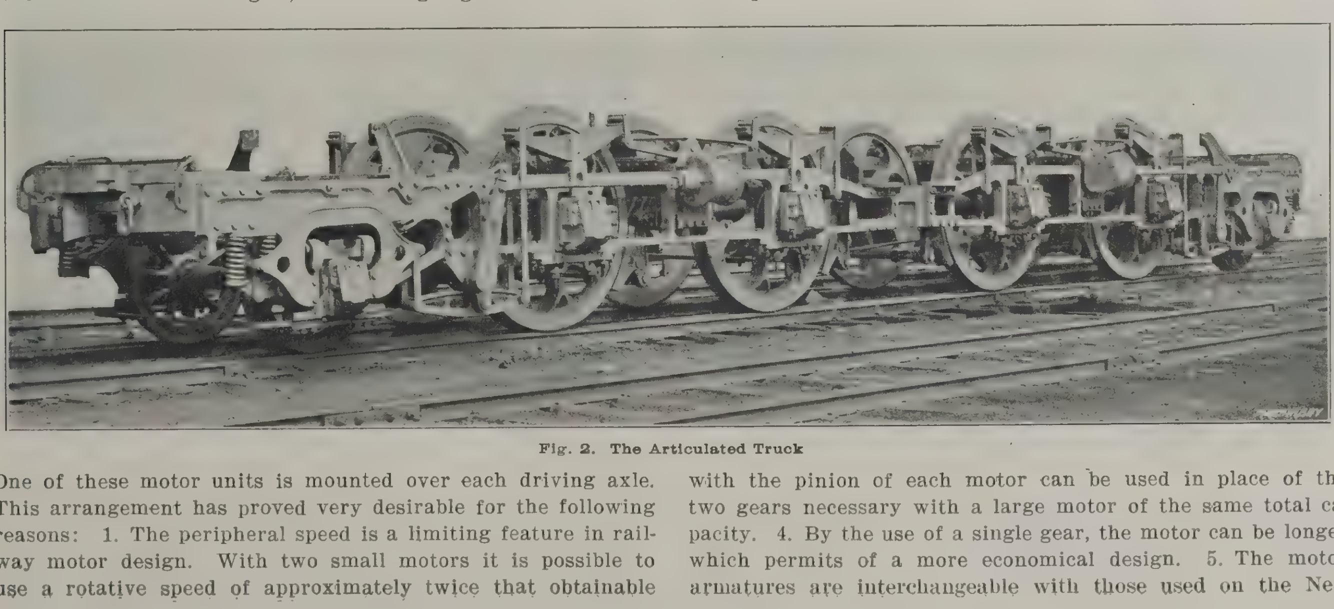

Fig. 2. The Articulated Truck

York, New Haven & Hartford and the New York, Westchester and Boston motor cars. 6. Finally, eight motors actually cost less than four having the same aggregate output.

These engines have an articulated running gear (Fig. 2)

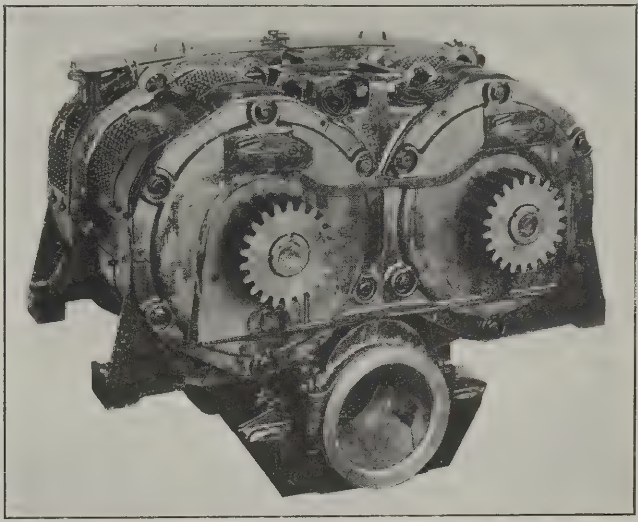

Fig. 3. One of the Twin Motor Units

which is very similar to that used for the 072 type New Haven locomotives. (The 072 engines were driven by four motors.) This running gear has proved very "easy running" as far as shock to the equipment in the locomotive cab is concerned,

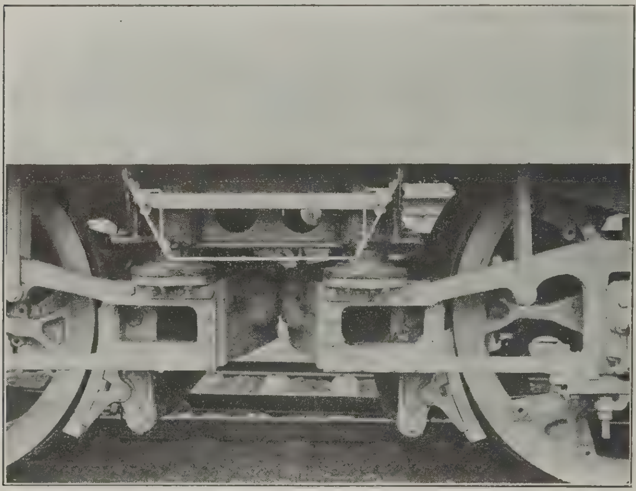

Fig. 4. Spring Buffers and Bumper Girders

which is one of the reasons why it has been used. The cab is carried by semi-elliptic and helical springs in series. This spring arrangement resembles, in general principle, at least, that which is employed for passenger cars.

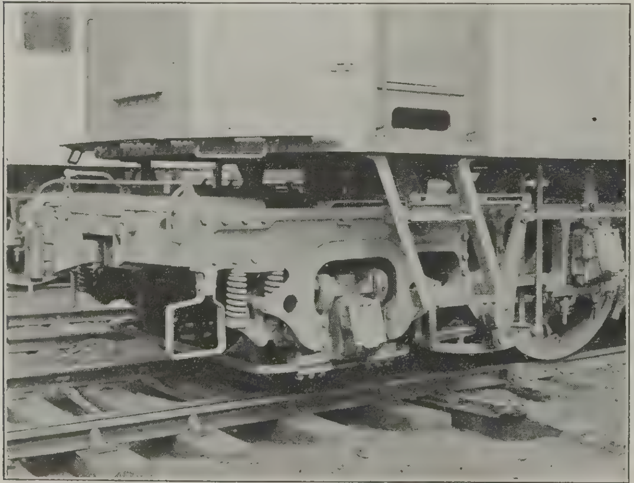

Fig. 5. The Rushton Truck

In general design and arrangement, all of the locomotives are the same, but the three bearing the road numbers 073 to 075, are for both alternating- and direct-current operation. They are intended for fast freight and heavy passenger service and are designed to handle a trailing load of 800 tons at a maximum speed of 45 miles per hour. When operating on single-phase alternating current, they take energy at 11,000 volts and 25 cycles, and on direct current at 650 volts.

Thirty-six of the locomotives are equipped for 11,000 volt, 25-cycle, alternating-current operation only. These are primarily for fast freight service, but will sometimes haul passenger trains. They are designed to handle a trailing load of 1500 tons at a maximum speed of 35 miles per hour, and to exert a maximum tractive force of 40,000 pounds.

The four pairs of driving wheels and two pairs of small leading wheels, are in two groups having outside frames.

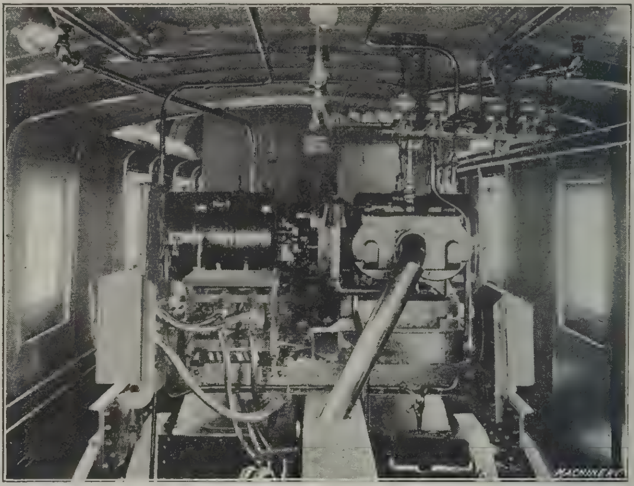

Fig. 6. View of Locomotive Interior showing Reverser, Air-duct to Main Motors, Motor-generator Set for Charging Storage Batteries and Operating Unit Switch Control, Air Compressor, Blower Motor, and Transformer in the Background

These cast-steel frames are four inches wide and are similar to those used in steam locomotive practice. The pulling and buffing strains are transmitted entirely through the truck frames which are braced transversely at the end of the trucks

Fig. 7. View of Cab Interior showing Engineer's Operating Equipment

and between the driving axles. The inside faces of the driving pedestals are tapering and are fitted with adjustable wedges. The pedestal binders are of cast steel.

The drawbar pull is transmitted from truck to truck by means of a drawbar adjusted to leave a ½ inch maximum clearance between the end ties or bumper-guides of the trucks

when all the slack is taken up. The truck cross-ties, which are attached to the inner ends of the trucks, are equipped with spring buffers (see Fig. 4) which assist in transmitting the buffing shocks from truck to truck. Midway between the driving wheels, the bar frame of each truck is braced transversely by a built-up structure on which the truck center-pin is mounted. The center-pin of one truck is allowed a limited longitudinal movement with reference to the cab under frame, to relieve the frame from pulling and buffing strains.

A two-wheeled truck of the Rushton type (Fig. 5) with outside journals, is arranged under each end of the locomotives and carries the small truck wheels. This truck is of the radial type, its frame being connected to the main truck cross-tie by two links which are so arranged in relation to each other that the intersection of their center-lines, if they were extended, would be on the center-line of the locomotive at the correct point for the truck radius-bar pin. This construction was adopted because the motors are so located that it is impossible to place the radius pin at its normal position on the center-line. A radial type drawbar, arranged to receive a housing for a Westinghouse friction draft gear, is mounted on each end of the engine. Thrust springs are provided to limit the lateral movement of the drawbar. The coupler shank is supported by a carrier iron which is bolted to the end bumper casting.

Each group of two pairs of driving wheels and a pair of truck wheels, is equalized on each side of the locomotive. The springs (see Fig. 2) are of the usual elliptic form and are mounted directly over their respective boxes. Helical springs support the truck frames at their outer ends. The equalizing beams are of cast steel. The weight of the cab is transferred to the truck frames through coiled springs, and the spring pocket plungers slide on the frame cross-ties when the engine is traversing curves. The thirty-six locomotives have a length between coupler faces, of 50 feet, and the driving wheels are 63 inches in diameter.

The eight single-phase, commutator type, series motors which drive each locomotive, have a capacity of 170 horsepower on a one-hour rating. The motors are grouped together in pairs, as shown in Fig. 3. The two motors of each pair (a right-hand and a left-hand motor) are bolted together so as to form a unit. Each pair of motors is provided with two axle bearings which carry a quill that is concentric with and surrounds the axle. A single gear is secured on one end of the quill and into this gear mesh the pinions keyed on the motor armature shafts. Mechanical connection between the quills and the driving wheels is effected through helical springs which are mounted between the driver spokes and the projecting arms provided on each end of the quill. A radial clearance of 1½ inch is provided between the inside of the quill and the driving-wheel axle, so that the drivers are free to follow irregularities in the tracks. This method of mounting relieves the axles of the dead weight of the motors and insures that the operation of the locomotive will be easier on the tracks.

A low deck is built over each pair of motors and doors are provided in the decks in such positions that free access to the commutators and armature bearings is afforded. Flexible leads of ample length to accommodate all movement of the motors relative to the cab, extend through insulating bushings in the floor and electrically connect the motors with the controlling apparatus.

The three locomotives arranged for operation on either alternating or direct current are provided with control equipment that can be used in either service. The pneumatically-operated control switches work in combination with a transformer and preventive coils when the locomotive is receiving alternating current, and in combination with grid resistors, when it is receiving direct current.

Each pair of motors is connected permanently in series. In alternating-current operation, the four pairs are connected in multiple and on direct current they may be connected two pairs in series or all four pairs in parallel. When operating on alternating current from the line at 11,000 volts, the energy passes through an oil circuit breaker to the primary of the main transformer and thence to the ground. A number of taps are provided on the secondary winding of this main transformer and are connected to the motor circuits through preventive coils, by means of the pneumatically-operated switches. There are twelve voltage steps on the transformer winding, nine of which are for running points.

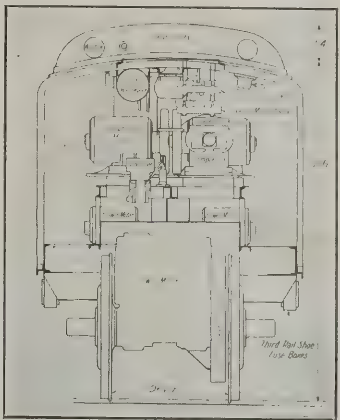

Fig. 9. Transverse Section

The pneumatic switches, used for operation on alternating current, are assembled in one group. This group is located close to the transformer. Reversal of the direction of rotation of the motors is effected by two pneumatically-operated drum-type reversers. Each reverser is so connected as to handle two pairs of motors. When the locomotives are on direct current, the control of the motors is accomplished by two other groups of pneumatically-operated switches which connect the pairs in series and in parallel, in combination with the resistors. The switches are arranged in a straight line with the resistors directly above them, so that the connecting leads between switches and resistors are of minimum length.

Fig. 6 shows the interior of a locomotive for single-phase operation. A master controller is located at each end of the cab as shown in Fig. 7. Two Sirocco-type blowers, for handling cooling air, are located in the center of the cab directly under the main transformer. These blowers draw air from the outside of the locomotive and discharge it through the main transformer, motors and resistors. This keeps the equipment at a moderate temperature even when operating under severe overloads. A double air-brake apparatus is provided on each locomotive. Two compressors each having a capacity of 50 cubic feet of free air per minute, are mounted within the cab

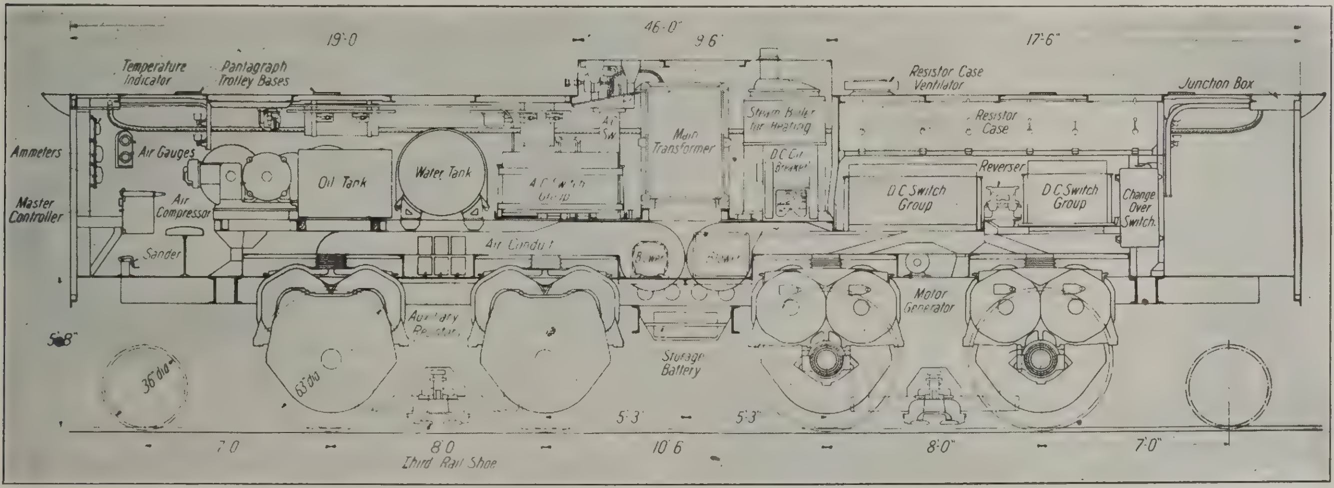

Fig. 8. Side Elevation of the Electric Locomotive

to supply air for the brakes and controlling apparatus. An oil burning steam-heater plant capable of supplying 800 pounds of steam per hour, is installed in the three alternating and direct current locomotives for the heating of passenger trains.

* * *

PIERCING AND EMBOSSING DIE

By ARON LAWRENCE*

The piercing and embossing die shown in Fig. 2 was designed to pierce eight holes in the periphery of the automobile head lamp front shown in Fig. 1, and at the same time to emboss an arch-shaped rib around the sloping neck portion. This rib or ledge is used to support the head of the lamp when assembled to prevent it from being buckled out of shape when polishing. The pierced holes are for attaching the front to the lamp body, and also for fastening the door hinge and catch.

Referring to Fig. 1, it will be seen that the punches for the body rivet holes in the small diameter or top portion of the front must have a considerably longer stroke than the punches for the hinge and catch holes. The base *A* of the die shown in Fig. 2, is a gray iron casting bored out in its upper central portion to fit the locating ring *B*, also made of cast iron. The ring *B* is fastened to base *A* with large screws and dowels. The piercing die bushings *C* and *D* are pressed into the locating ring *B*, and are made from hardened tool steel. The scrap from the punches passes in toward the center of the die and falls down through the opening to the bolster plate. The hardened tool-steel embossing punch punches are operated by the angular-faced lugs *I*, cast integral with the upper portion *T* of the die. The punch holders *G* are slotted out to receive a cross-pin *J*, which limits the length of the return stroke.

The lower punches *K* are similar in construction to those just described except that the punch carriers *L* are shouldered and are returned by means of helical springs *M*, held in counterbored holes in projecting bosses on the base *A*. The punches are limited in their outward travel by a pin *N* which works in an elongated slot in the base. This pin also serves to preserve the proper alignment of the angular end of the carrier *L* under the angular projections *I*. Oil holes are provided for the proper lubrication of the various plungers.

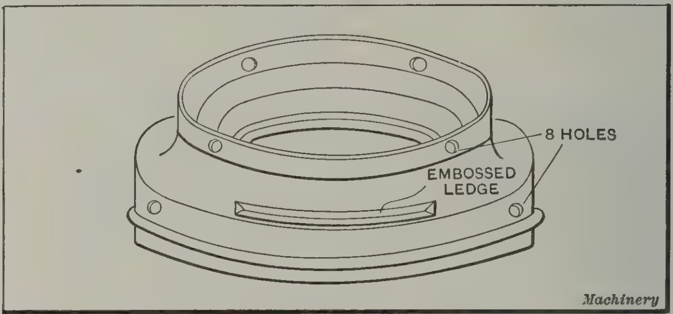

Fig. 1. Automobile Head Lamp Front

The embossing die *O* is of hardened tool steel, set into a cast-iron ring *P*, which slides vertically below the upper die member *T*, being guided by four steel pins *Q*, and limited in its travel by the shoulder screws *R*. A heavy rubber ring *S*, of sufficient resiliency to accomplish the embossing before further compressing, is introduced between the ring *P* and the casting *T*. Of course this rubber ring must be under initial tension or it will not operate properly.

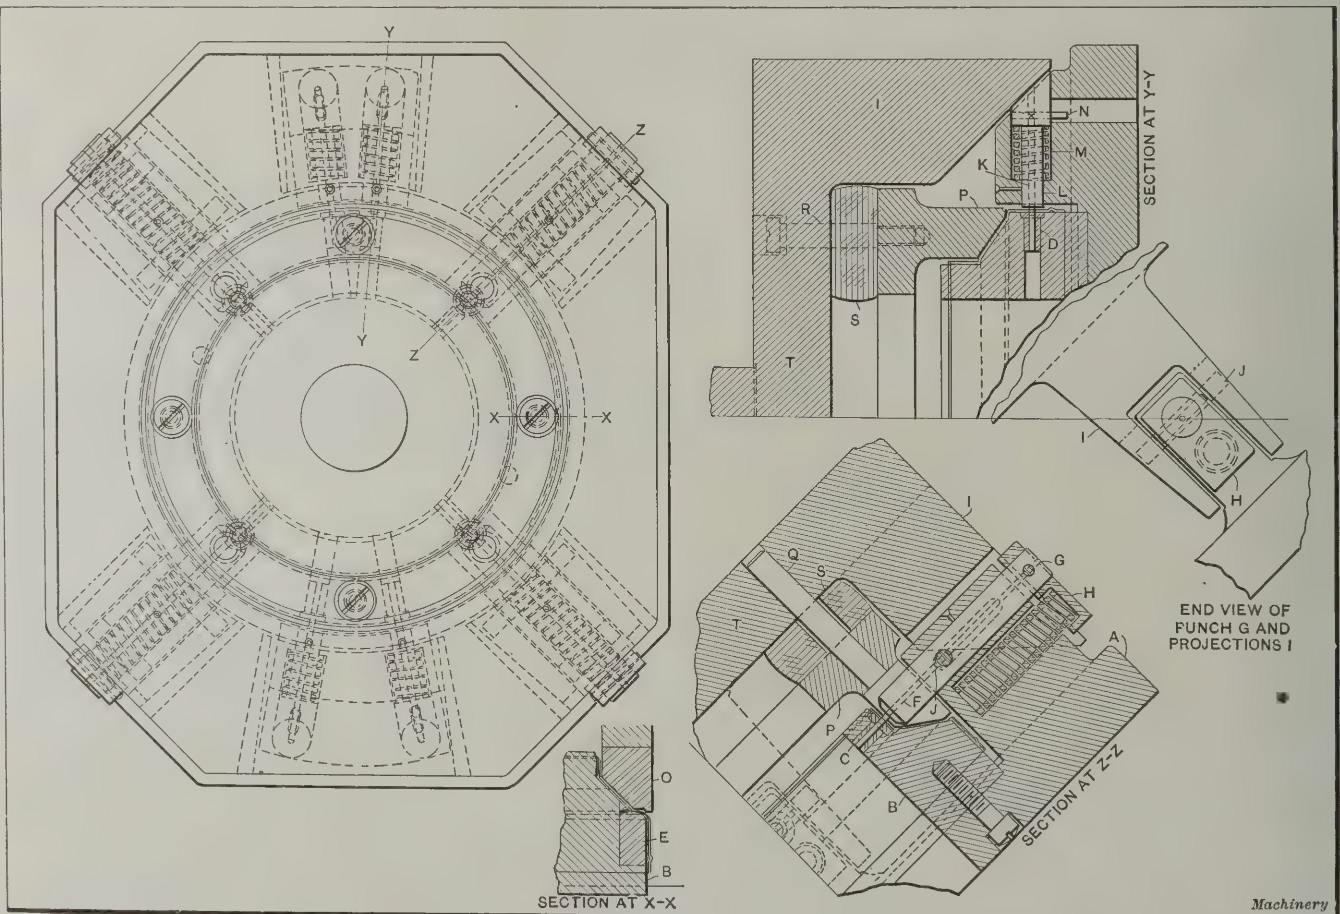

Fig. 2. Piercing and Embossing Die for Automobile Head Lamp Front

E is let into the ring *B*, as shown in the section at *X—X*, and is fastened to it by suitable screws.

Cast integral with the base *A* are two blocks projecting upward for the reception of the hinge and catch punches, and four blocks for the punches used in piercing the holes in the body. The shape of these blocks is clearly shown in the sectional views at *Y—Y* and *Z—Z*, respectively. The punches *F* are of hardened tool steel, set into the heavy punch carriers *G*, which are provided with a tool block *H* against which a helical compression spring acts to withdraw the punches. The

In operation, the die is used in a heavy arch press with a stroke of about 8 inches; the piece, Fig. 1, is located over the ring *B*, and the press is tripped. The arch-shaped rib is first embossed, after which the rubber ring compresses, allowing the piercing punches to be operated. This method of holding the work while forming and piercing insures the correct relation between the various holes.

GRINDING AND CORRUGATING FLOUR MILL ROLLS*

By F. B. JACOBS†

In the process of flour milling, the grain is first fed between spirally corrugated rolls, generally called breaking-down rolls. The rolls in common use are from six to twelve inches in diameter, and from one to three feet in length, and are made

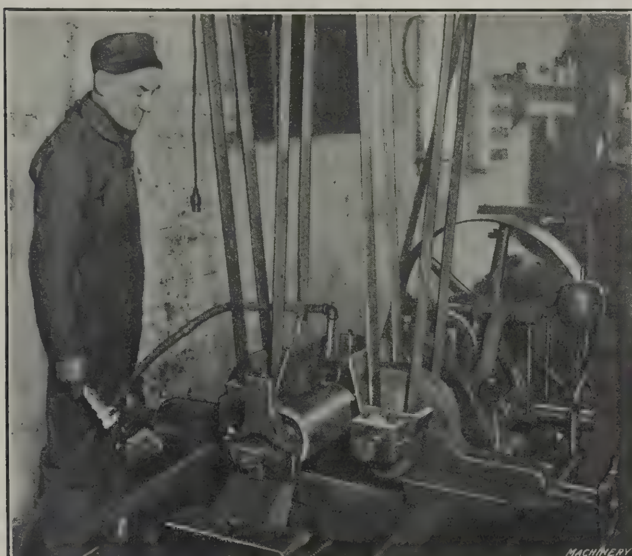

Fig. 1. The Grinding of Corrugated Flour Mill Rolls

of cast iron, the surface of which is chilled to a depth of from one-half to two inches. The crushing of the grain which often contains foreign substances, nails, pebbles, etc., soon wears away the corrugations. In this case the rolls are repaired by grinding away the worn corrugations in a regular roll-grinding machine, and cutting new corrugations in a machine built especially for the purpose. The machine shops of

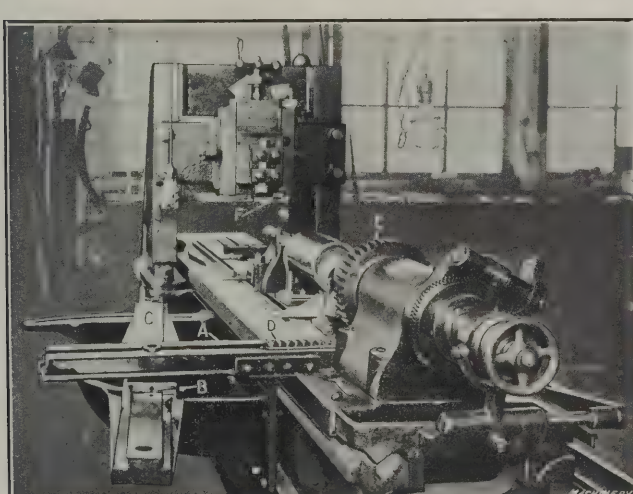

Fig. 2. Machine for Corrugating the Rolls

the larger milling concerns are equipped for this purpose; the smaller milling concerns, however, depend on contract shops which make a specialty of this class of work.

The grinding operation is shown in Fig. 1, the roll being located by its journals or necks and driven by a shaft having two toggle-joints. The object of the toggle-joints is to overcome the tendency of cramping. The grinding wheels used on this machine are carborundum, 10½ inches in diameter, 1½-inch face, 80 grit, K grade, G-4 bond, and are run at a surface speed of approximately 5000 feet per minute. The roll shown is 6 inches in diameter and 12 inches long, and is revolved at a speed of 40 revolutions per minute. The traverse speed is ¾ inch advance for each revolution of the work. When removing 1/32 inch, the grinding time on this roll was 12 minutes and the finish left was excellent. In grinding rolls of this kind, but little attention is paid to size, the object of the grinding being to remove the worn corrugations only. It may be added, however, that it is absolutely necessary that the rolls be parallel. This is accomplished by adjusting the rests that carry the shoes in which the journals run, until the roll is in line with the travel of the wheel carriage. In the roughing operation the depth of cut should be as great as the wheels will stand, which in some cases equals 1/64 inch. The final finish is produced by allowing the wheels to pass the work several times until they cease to spark heavily. With free-cutting wheels, this will be accomplished in a very few passes.

In Fig. 2 is shown the type of machine generally used for the corrugating operation; this, at first glance, looks like an ordinary iron planer equipped with a taper attachment. In Fig. 3 it is seen that the roll is located from its centers and also supported by its journals on V-blocks. In setting up the machine for the corrugating operation, the operator determines the amount of spiral by practically the same method as is used by a toolmaker in setting up a universal milling machine for cutting a spiral cutter. By referring to Fig. 2, it will be seen that the bar *A* is moved by the block *B* which

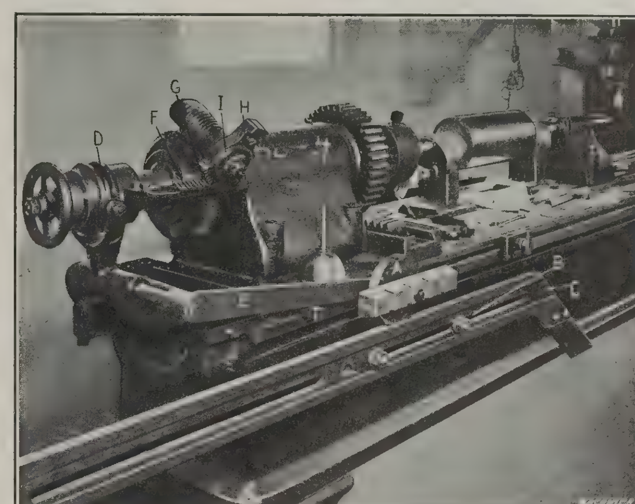

Fig. 3. Indexing Arrangement of Corrugating Machine

travels over the taper slide *C*. The rack *D* meshes with the gear *E* which imparts the spiral motion to the roll. By setting the taper slide at a greater or less angle, different spirals are obtained. This adjustment is of great importance as usually no two rolls, if they come from different milling concerns, have the same spiral, owing to the fact that the various milling concerns hold widely different views regarding the correct spiral for rolls of this kind.

At *A* in Fig. 4 are shown several corrugating tools. These are made of a high grade of tool steel, hardened and drawn to a straw color. As they have several teeth, they work on the principle of a gang tool, thus making it possible to corrugate a roll to the required depth by going around it once. The tool, which is securely clamped in a tool-holder as shown at *F* in Fig. 2, is set at an angle with the roll; thus the first tooth barely scratches the roll, the next going a little deeper and so

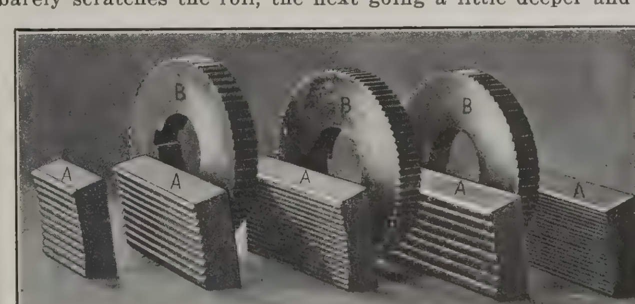

Fig. 4. Tools and Ratchets used in the Corrugating Machine

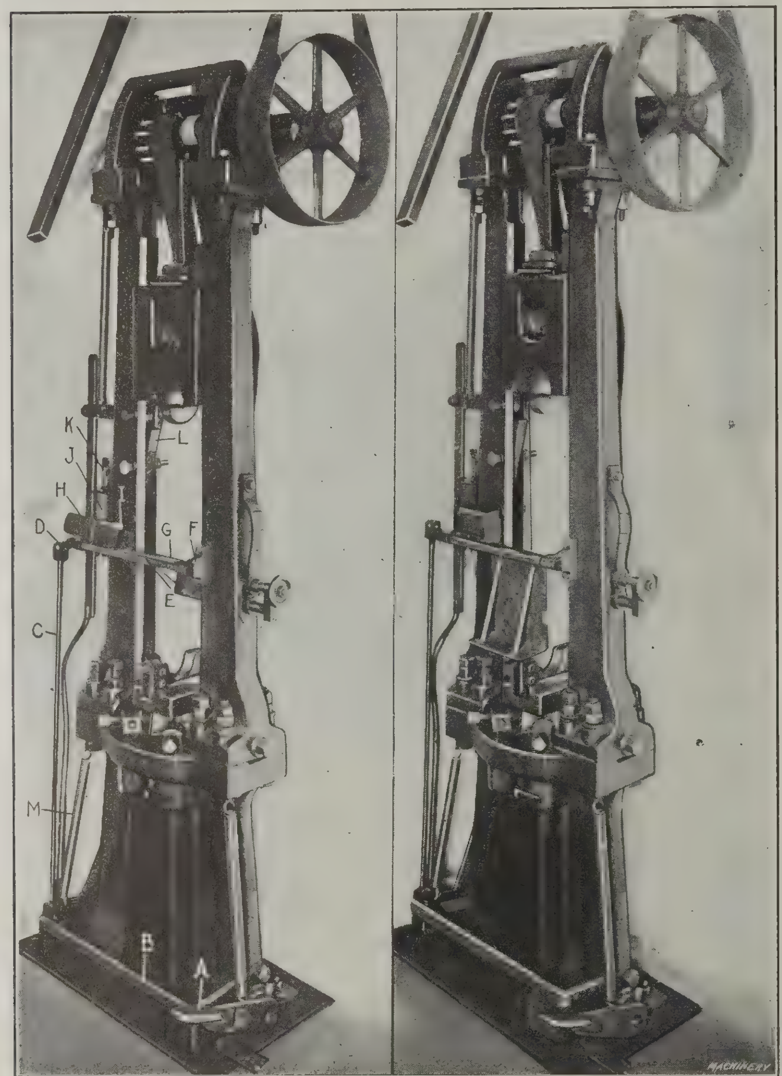
on until the correct depth is reached by the last tooth. As the material cut is hard chilled iron, the speed for this operation is necessarily slow—one foot in twenty-five seconds. For every stroke of the platen the roll is turned three teeth, this being accomplished by the ingenious arrangement shown in Fig. 3. When the platen is nearing its forward position, the roll *A*,

* See MACHINERY, May, 1909, "Grooving Chilled Flour Mill Rolls," and June, 1906, "Roll Corrugating Device."

† Address: Care of Carborundum Co., 826 Arch St., Philadelphia, Pa.

running over the guide *B*, drops upon reaching *C*. By means of the clutch *D*, the lever *E* actuates the rack *F* which turns the sector *G*, thus causing the pawl *H* to slide over the teeth of the ratchet *I*. At the return stroke of the platen, pawl *H* engages the ratchet teeth, thus turning the worm, worm-wheel and roll. By adjusting the slide *B* and substituting different ratchets, a few of which are shown at *B*, Fig. 4, the roll can be turned from one to as many teeth as the operator desires. Where very deep teeth are to be cut, the roll is generally turned one or two teeth for each stroke of the platen. In cutting fine teeth, however, it is often turned several teeth for each stroke.



Figs. 1 and 2. Safety Device applied to a Drop Hammer

As there are many different sizes and shapes of corrugations it is necessary that the machine be provided with adjustments to cover a wide field. The time for corrugating a roll of the same size as shown in the grinding operation, was one hour and fifteen minutes. The corrugations were 0.010 inch deep and spaced twenty to the inch. As roll grinding and corrugating is a special branch of the machinist's trade that calls for skill and judgment along special lines, an expert who is experienced on this particular line of work generally receives the highest wages paid to machinists in the locality in which he is employed.

* * *

In an article in *Industritidningen Norden*, issue of April 12, attention is called to the fact that the Tesla steam turbine described in the November, 1911, number of MACHINERY makes use of a principle which is by no means new, as in 1894, Messrs. P. Nordenfelt and A. Christophe, the former a Swede, the latter a Frenchman, applied for a Swedish patent on the same type of steam turbine, which was granted. This turbine, however, was never developed beyond the experimental stage. Whether or not the Tesla turbine, employing the same principle, will meet with a better fate remains to be seen.

A MECHANICALLY AND ELECTRICALLY OPERATED SAFETY DEVICE

By BENJAMIN C. WAITE, JR.*

The problem of properly equipping machine tools with safety devices is a difficult one and, as a rule, the older the machine, the more difficult it is to guard. A great many firms of late have been forced to properly safeguard their machine tools on account of the stringent laws recently passed for the safeguarding of workers. There is one machine especially which is very difficult to guard, and that is the drop hammer.

In the accompanying illustration an efficient guard for a machine of this type is shown. This guard is operated by moving the foot from the trip lever shown at the lower right-hand side at *A* to the treadle *B* in front of the machine and the operator. The tripping of this extra treadle does not require any more action or effort on the part of the operator than was required before the guard was put on, for previously the foot was in continuous motion from the floor to the trip lever, while now the foot movement is from the trip lever to the treadle, which is held down while the work is removed and replaced. While the foot is in this position, the swinging guard *G* is located as shown in Fig. 1, and is held practically in a horizontal position, being operated by the shaft, crank, and straight rod and spring shown to the left of the hammer. These parts constitute the mechanical connections of the swinging guard.

The electrically controlled parts of the safety device are also shown to the left of the frame immediately above shaft *E*. The box cover *H* protects a small carbon contact switch which opens the circuit when the swinging guard is in the horizontal position, thus causing the dog *L* which is controlled by the magnet *J* and connected to it by the link *K*, to fall into the path of the hammer head, thereby preventing the hammer from falling. Hence the hammer cannot "repeat" or be accidentally tripped, these being the usual causes of most accidents in hammers of this type. When the foot releases the safety treadle *B*, the guard swings down to a vertical position, the circuit is closed, and the magnet, pulling downward, draws dog *L* within the housing of the hammer, providing a clear path for the falling hammer, as soon as it is tripped. While the swinging guard is in the vertical position, as shown in Fig. 2, it is so located that the operator cannot conveniently reach underneath or around it.

This combination of a mechanically and an electrically operated safeguard has been in successful operation for nearly two years, and although there may not be many hammers in use of the exact type shown in the illustration, the principles can be applied to many other tools. An important and unique feature of the device is that should the electrical current fail, the hammer is instantly placed in the safety position, because dog *L* will then immediately fall into the path of the hammer. This condition is shown in Fig. 2.

* * *

TREATING TUNGSTEN FOR WIRE MAKING

A process for increasing the ductility of tungsten so that it can be made into wire for lamp filaments with less difficulty than formerly has recently been patented by Werner von Bolton of Charlottenburg, Germany. The tungsten is treated at a red heat with a mixture of hydrogen and chloride of sulphur. This serves to remove any oxide of tungsten in the metal which is a cause of brittleness. The oxide is converted into sulphide which is, in turn, decomposed by the hydrogen. The metal thus purified contains some sulphur. It is heated to a white heat in a vacuum furnace to expel it, when pure, metallic tungsten of great ductility is obtained which can be easily drawn into wire. When the oxide is reduced by hydrogen in the usual manner, some hydrogen is left which causes brittleness; by the sulphur method, this is avoided.

WATCH CASE MANUFACTURE*—1

COMPOSITION PLATE—TYPES OF CASES—FORMING CENTER, CAP, BACK AND BEZEL—THREADING

A watch case is simply a metal box which acts as a container for the movement and protects it from injury and dust. Watch cases are made from alloyed gold (pure gold—24 carat—is too soft), silver, gunmetal and other composition metals. A material which is used extensively is what is known as "gold filled"; this consists of a bar of composition metal to which a thin strip of gold is soldered. These built-up bars, shown at *A* and *B* in Fig. 2, are rolled out to the desired thickness, and worked up in punch presses to form the various members of the case. A gold filled watch case wears as well if not better than a solid gold case, does not tarnish, and is a stronger protector for the movement.

Preparing the Gold-plated Bars

Considerable experience is necessary, in preparing gold-plated bars, to produce a uniform thickness of gold on the surface of the bar. The gold plate, of course, is much softer than the composition metal to which it is soldered, and does not harden as quickly or as much during the rolling operation as does the composition metal. Hence, it is absolutely necessary to have a perfect union between the two metals.

Before uniting the gold strip and composition bar, it is necessary that the surfaces which come in contact should be made as nearly true planes as possible. The solder for uniting the composition bar and gold strip is made from alloyed silver, which is rolled out to the proper thickness. The composition bar, solder and gold strips are first coated with soldering acid on those faces which come in contact. If the plated bar is to be used for a bezel, center or cap, it is furnished with a gold plate on one side only, but if the bar is to be used for the back of either a screw or hinged case, a strip of gold is soldered to both faces, as shown at *B* in Fig. 2.

After the bar has been prepared in this manner it is wired so that the various strips will be held in close contact with each other. Then it is placed in a furnace where it is heated to about 1000 degrees F., which is sufficient to melt the solder and join the various strips. When the bar has remained in the furnace long enough for the solder to melt, it is taken out and allowed to cool off gradually. The wires used in binding are then removed, leaving the bar in a condition to be rolled out into a sheet of the desired thickness. The bar is first passed through "breaking-down" rolls, and after about ten passes through the rolls, it is annealed and pickled. This procedure is continued until the bar is rolled out into a strip of approximately the desired thickness. To bring the strip to the exact thickness, it is passed through finishing rolls which give it a better surface.

Types of Watch Cases Manufactured

At the present time there are six distinct types of watch cases made. The first and the most common is the open face case, shown at *A* in Fig. 1. This consists of a center *a*, cap *b*, back *c*, and bezel *d*. The stem *e*, pendant *f*, crown *g*, and bow *h*, of course, are common to all ordinary watch cases. Another type of case which has come into prominence of late is the screw case shown dismantled at *B*, *C* and *D*. This consists of a center, back and bezel, the center *B*, back *C*, and bezel *D* being threaded so that the various parts of the case can be screwed together. There are other cases which are made to suit individual requirements and consequently are of a special nature. There are four cases, however, which are made regularly: the hunting case, consisting of a center, cap, two backs and a bezel; the cup case, consisting of a screw-cup, bezel and a ring to hold the watch movement; the swing-ring case, consisting of a center, cap, bezel, and swing ring; and the bracelet case consisting of a back, center and bezel. The latter case is made in an open face.

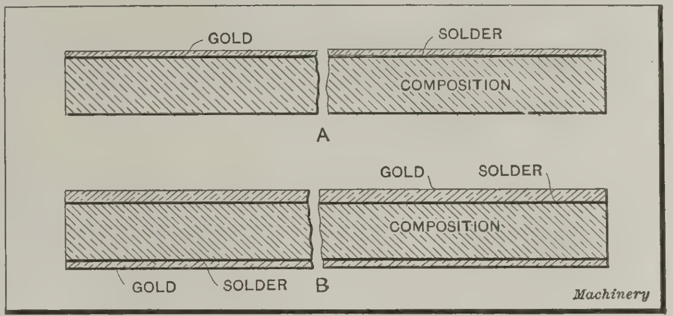

Fig. 2. How the Stock used in making "Gold Filled" Watch Cases is prepared

In this article is given a description of the methods employed in manufacturing an open face case of the type shown at *A*, Fig. 1. Occasional references are also made to the screw case, parts of which are shown at *B*, *C*, and *D*.

Making the Watch Case Center

After the bars previously referred to have been rolled out into strips of the desired thickness, they are cut up in a small power shear into squares, as shown at *A*, Fig. 3. These squares are then taken to the punch press department where they are worked up to form the various members of the case. The case centers are blanked out and cupped up in one operation in a double-action punch press, their condition after the operation being shown at *B*, Fig. 3.

From the punch press the cups are taken to the annealing furnace where they are annealed, and then pickled to remove the scale. They are then again taken to a punch press, the next operation consisting in "coaxing over" the top edge of the cup so that it assumes the shape shown at *C*. It is next taken to a spinning machine in which it is given the shape indicated at *D*. The next operation is what is known as the inletting operation for the movement; this consists in turning away the material on the inside edge of the case center, so that it will fit the movement, and is accomplished in the

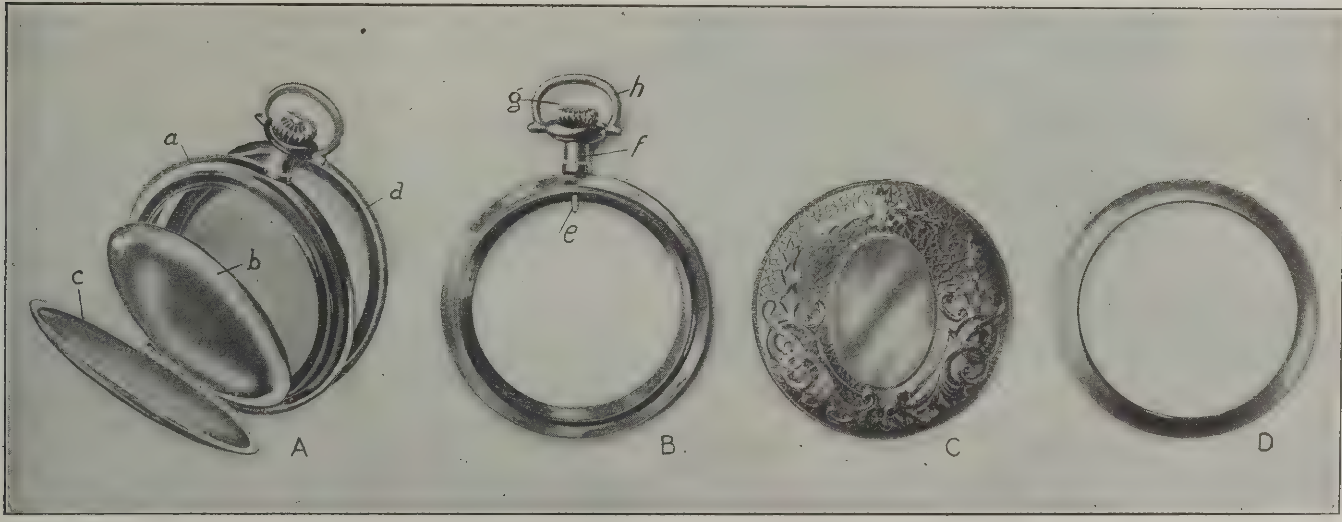

Fig. 1. Hinged and Screw Types of Open-face Watch Cases

* For articles on watch making previously published in MACHINERY, see "Watch Movement Manufacture," in the May and June, 1912, numbers, and articles there referred to.

inletting machine shown in Fig. 4. The center, which, by the way, has been fitted up with a pendant, is placed in the spring chuck *A*, the latter being tightened by the knurled nut *B* with a spanner wrench. Tool arbor *C* is now placed in the U-rests *D* and *E*, located at right angles to the axis of the spindle. This tool arbor *C* carries cutters *F*, which are used for making the various cuts, and are held by set-screws in the tool arbor.

In action, the operator grips the tool arbor *C* in both hands, holding it rigidly in the U-rests. He then brings the cutting tools *F*, one at a time, into contact with the work, allowing them to bear or rest on the strip *G*, which is placed across the face of the chuck. The tool arbor is located so that the cutting tools will cut to the correct diameter for the various steps on the case center by means of the stop-screw *H*, held in collar *I*, which comes against the rear face of the U-rest *E*.

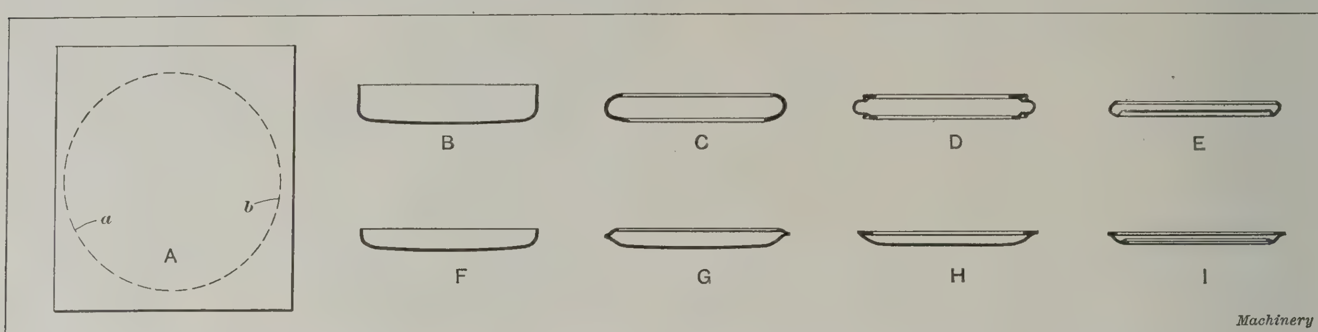

Fig. 3. Evolution and Development of a "Gold Filled" Open-face Jointed Watch Case—Punch Press and Spinning Operations

Threading the Case Center

The case center for the screw back and front type of case shown at *B*, Fig. 1, is threaded in the machine shown in Fig. 5. A case center of the type shown at *A* is placed in the spring chuck *B* and the nut *C* is tightened. The belt *D* is then shifted to run the spindle forward, and the work is prepared for threading by means of the tools held in the turret *E*, which latter is operated by handles *F* and *G*. When the turning is completed, the spindle is reversed to run backward, and the clutch which drives the rear driving shaft through change gears is thrown in by operating the handle *H*. The rear driving shaft carries cams *I* and *J* for operating the tool carriage which holds the circular threading tool *K*. Face cam *I* in conjunction with the change gears traverses the tool-slide longitudinally at the proper speed in relation to the rotation of the spindle, to cut a thread of the desired pitch—40 threads per inch.

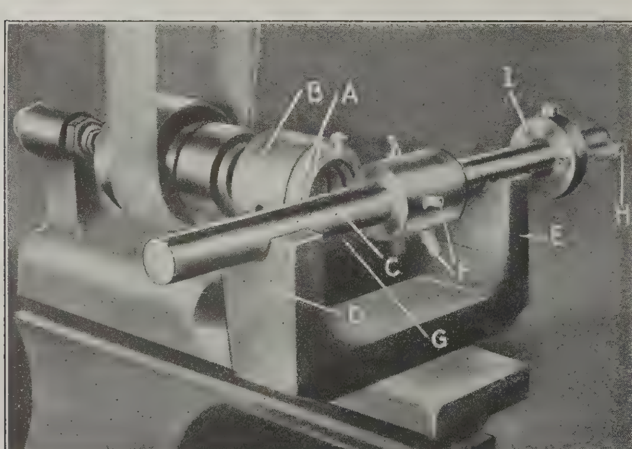

Fig. 4. Inletting the Watch Case Center for the Movement

The threading tool *K* is brought in to and out of action by means of the cam *J* which is timed with cam *I* to bring the tool in to action while the slide is being traversed toward the head of the machine. When the roll attached to the slide drops into a cut-away portion in both cams *I* and *J*, the tool *K* is withdrawn from the work and returned to the starting point by springs. The threading tool is fed in to the correct depth by means of handwheel *L*, operating the top slide *M*, which is provided with an adjustable stop. The case center for the hinged type of case is not threaded, but is jointed. This operation consists in cutting two grooves in the side of the case in which two short pieces of gold-plated hollow wire* are soldered. The grooves are cut with two slitting saws, thus enabling the grooves in both sides of the case center to be cut at the same time.

Making the Cap and Back

The cap and back *b* and *c*, Fig. 1, used in the hinged case for protecting the movement are also made from squares of gold-plated stock which are blanked and drawn up in a double-action punch press. The condition of the cap after this operation is shown at *F* in Fig. 3. The only difference between the back and cap is that the latter is slightly smaller in diameter than the former. After the back and cap are drawn up into the condition shown at *F* they are annealed and pickled after which they are "coaxed" over. The "coaxing" die and punch bend the top edge of the cap over slightly, as at *G*, Fig. 3. After the "coaxing over" operation, the cap is "snapped" by a punch and die, which operation consists in flattening out the edges and forming it so that it fits the center of the case, as indicated at *H*. The die used for the snapping operation also produces the little thumb catch on the edge, which is used for opening the cap. This finishes the cap with the exception of jointing and polishing. The same operations are performed on the back. The jointing consists in soldering a short piece of gold-plated hollow wire on the edge of the cap and back, which, in conjunction with the hollow wire soldered onto the case center, forms the hinges, a piece of gold wire being used as a pin. A seat for the hollow wire is milled in a small milling machine which is provided with a cutter for this purpose, and a chuck for holding the work. The polishing of the cap and back will be taken up in another installment of this article.

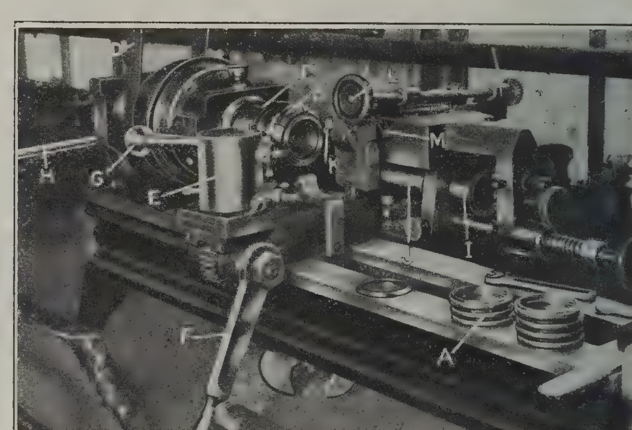

Fig. 5. Cutting the Thread on a Screw Watch Case Center

Threading the Back

The back shown at *c* in Fig. 1, which is used on the screw case is threaded in the machine shown in Fig. 6. The work is held in a draw-in chuck *A*, which is operated by handle *B*. The work spindle is provided with a master thread *C* of the same pitch as that which is to be reproduced on the back—40 threads per inch—and a leader held in the forward end of handle *D* is brought into contact with this master thread

* For information regarding the manufacture of gold-plated hollow wire, see the article entitled "The Making of Seamless Gold Wire." March, 1911, engineering edition.

by the operator. Shaft E is connected to the carriage which holds tool-slide F, and as this shaft is traversed by the master thread, it evidently carries the tool-slide with it.

Before cutting the thread, the back is prepared for it by a tool H which is held on slide I and is operated by a foot treadle. When ready for threading, the operator grasps handle D with one hand, and operates handle J with the other. The leader is brought into contact with the master thread, and at the same instant the circular tool G is fed into the work. The handle D is then dropped, and the carriage is returned by a spring. The handle J feeds the slide in to an adjustable stop. The screw back is practically completed after the threading operation with the exception of polishing and engine turning.

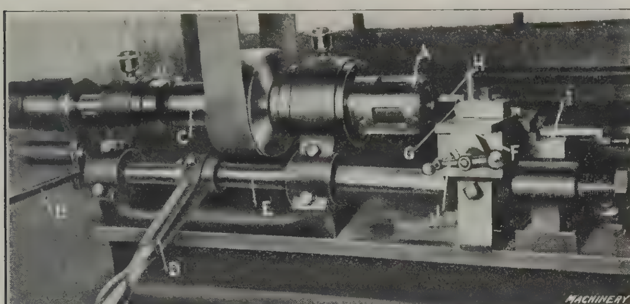

Fig. 6. Cutting the Thread in a Screw Back for a Watch Case of the Type shown at B, Fig. 1

Making the Bezel

The bezel for the hinged case is shown at d in Fig. 1, and also at E and I in Fig. 3; it is used to retain the glass and is made from a square of gold-plated stock in a similar manner to the other parts of the case. The first operation consists in forming it into a cup, similar to that shown at F in Fig. 3. This is accomplished by a combination blanking and cupping die A, punch B, and plunger C, shown in Fig. 7.

After blanking and cupping, the bezel is annealed and pickled; then it is coaxed over in the die D by punch E. This leaves it in the condition shown at E in Fig. 3. After this operation, the bezel is taken to the punch press and the center blanked out with the die F and punch G, shown in Fig. 7. This leaves the bezel in the condition shown at I in Fig. 3, when it is ready for inletting for the glass. This operation is accomplished in a machine of the type shown in Fig. 4. The bezel is then jointed and pinned to the center. The bezel D, shown in Fig. 1, which is used on the screw case is threaded in the machine shown in Fig. 6.

PATENT LAW INVESTIGATING COMMISSION

A special message sent by the president to Congress, relating to the appointment of a commission to investigate the patent laws and report on necessary changes, is one which will be endorsed by all persons who have a wish for the sound development of the country's industries at heart. One of the main reasons given by the president for this message is that the present patent laws make it possible for large corporations to buy up patents and suppress their manufacture, so that the public never receives the benefit of many inventions during the life of the patent. Meanwhile any other inventor is prevented from developing ideas of his own, if they should have enough similarity to the already patented but unused devices to constitute an infringement.

COMBINATION FORMING AND TESTING MACHINE

By F. B. HAYS*

Recently the writer had occasion to make a series of experiments with plastic masses pressed into hard substances of various shapes. As the experiments covered an entirely new field of development, special machines were required for treating the raw materials used in producing the plastic masses, for pressing the latter into the required shape, for accurately determining the pressure used in the compression, and for testing the compressive strength of the shapes after forming. After considerable study and a few preliminary tests the machine shown in Fig. 1 was designed and built for performing the last three operations.

The machine consisted of a heavy cast-iron frame A, and a screw B operated by a steel gear C. This was driven by the pinion D which was keyed and pinned to the shaft E. The screw was kept from turning by a key. The lower half of the casting was bored and reamed vertically and horizontally as shown, and then bushed by steel tubing R, ground externally and internally. The ends of these holes were closed by absolutely tight plugs and gaskets after the pistons F and H had been inserted into the bushed holes, and the space back of them filled with a very heavy oil.

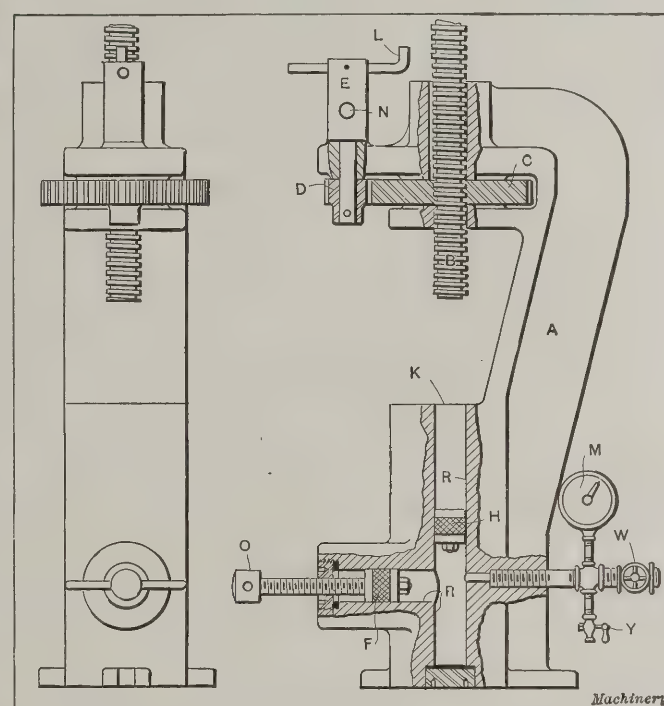

Fig. 1. Combination Forming and Testing Machine

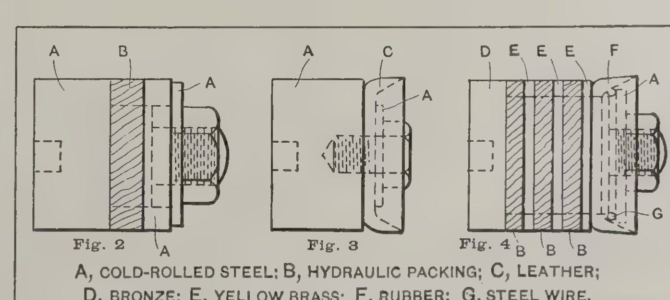

Figs. 2 to 4. Various Forms of Pistons for Hydraulic Testing Machine

The operation of the machine is as follows: A split die is inserted at K, so that it rests on the piston H. The die is partly filled with the plastic composition, and a steel plunger is inserted into it at the top. The screw B is then run down by means of the crank L until it presses on the top of the plunger. A round steel lever is then inserted into the hole N, and the screw B run down until the pressure desired is registered by the gage M. The screw is then run up, and the valve W per-

* Address: 107 W. Walnut St., Indianapolis, Ind.

mits water to enter from a city water main, which causes the piston *H* to rise to the top of hole *R*, thus pushing the die and plunger out of the machine.

When testing, the formed composition (after being treated) is placed on the piston *H* and the screw run down upon it until it cracks. The piston compresses the oil and water so that the pressure at which the test piece cracks is registered by the gage *M*, the valve *W* being closed. The cock *Y* is then opened and the water drains from the machine so that the piston may be pushed back into place. The heavy oil will not pass through the cock. The hand screw *O* and the piston *F* are used when the city water pressure is not sufficient to raise the piston *H*. In this manner the machine both made and tested the formed pieces.

In making experiments with this machine a number of interesting facts were noted which may be useful to persons coming in contact with high-pressure hydraulic work. The pressure used in the experiments varied from 40 to 20,000 pounds per square inch.

The first interesting fact noted was that water worked through the heavy cast-iron walls at about 1800 pounds pressure per square inch, and that it ran through so rapidly at 6000 pounds pressure that it was impossible to increase the gage pressure. Upon the substitution of heavy black oil this leakage was eliminated below 5000 pounds. Upon coating the internal walls with water glass and pressing in the steel bushings, practically all leakage was prevented up to 20,000 pounds per square inch, so long as oil was used. Originally the greatest source of leakage was around the pistons, which were first made as shown in Figs. 2 and 3. These pistons leaked a great deal at 1400 pounds when water was used, and at 2500 pounds when oil was used. Pistons of the type shown in Fig. 4 were then substituted with very satisfactory results up to 16,000 pounds pressure per square inch. This type of piston leaks less after being used for a short time than when first inserted.

* * *

An alloy of iron and cobalt in the proportions of iron from 65 to 70 per cent and cobalt from 30 to 35 per cent is highly magnetic; the magnetism of this alloy at saturation is stated to be 10 per cent greater than that of the pure iron.

CONTENTS OF HORIZONTAL CYLINDRICAL TANKS

By FRANCIS J. FRENCH*

When a cylindrical tank placed in a horizontal position is partly filled with a liquid, the cross-sectional area of the fluid in the tank is, of course, a circular segment. The usual way of calculating the volume of the fluid in the tank would be to find the area of this segment and multiply this area by the length of the tank. In this way, the volume of the fluid would be found in cubic feet or cubic inches, according to the unit of measurement used. This expression, then, would usually have to be converted into gallons.

A rapid approximate method is provided by the accompanying diagram, the use of which is illustrated by an example in dotted lines. The scale on the left-hand side of the diagram gives the ratio of the depth of the fluid in the tank to the total diameter. The diagonal lines on the diagram give, respectively, the diameter of the tank and the total length. The scale on the right-hand side of the diagram gives the volume of the contents in U. S. gallons per foot of length, while the scale at the bottom of the diagram gives the total contents of fluid in the tank.

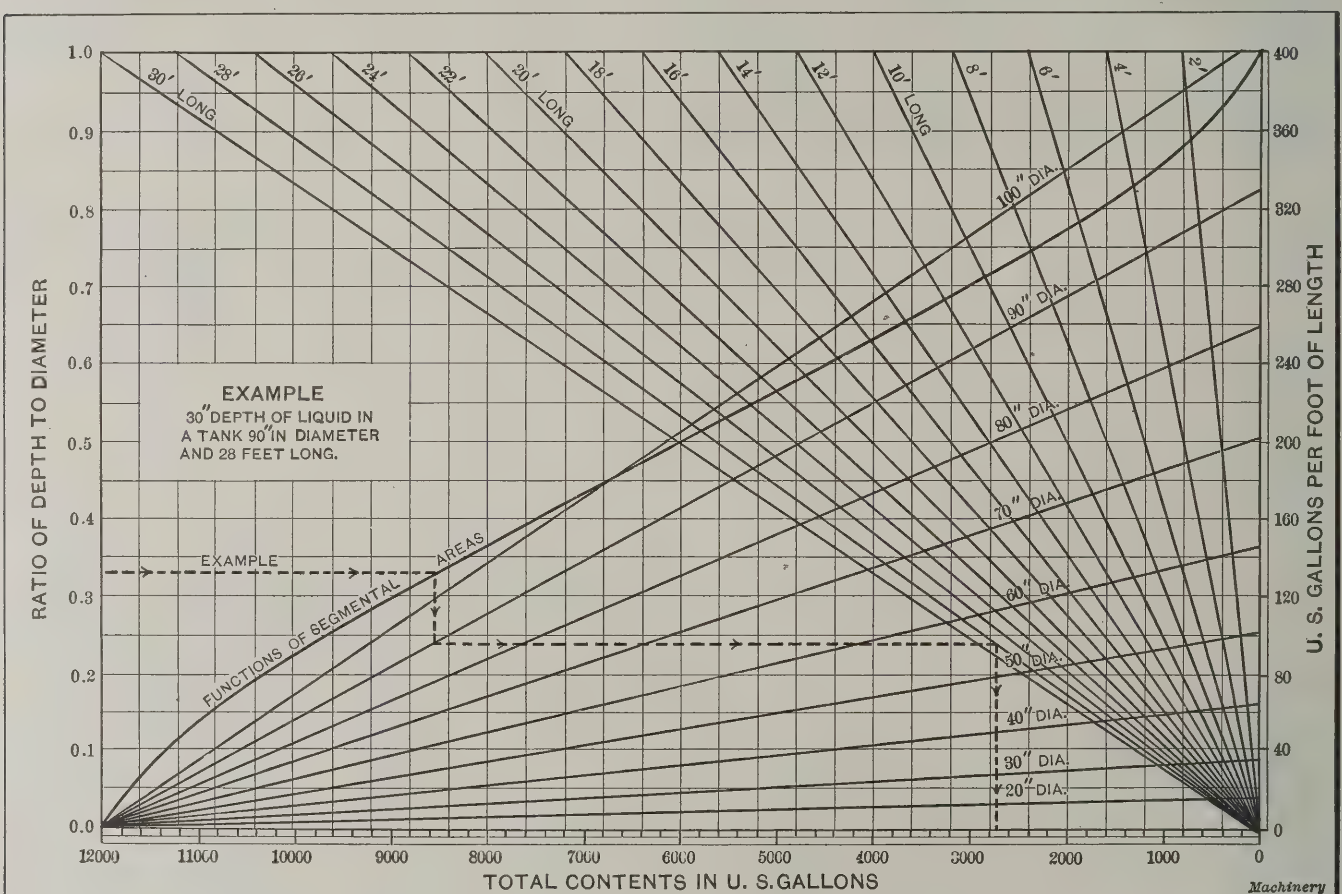

Diagram for Finding the Contents of partly filled Horizontal Cylindrical Tanks

As an example, let us assume that the liquid fills the tank to a depth of 30 inches, that the total diameter of the tank is 90 inches, and that it is 28 feet long. The ratio of depth to diameter is then one-third, and, beginning at this point on the scale to the left, we follow a horizontal line until it intersects the line marked "functions of segmental areas." From this line we follow a vertical line until it intersects the line denoting the diameter of the tank, and then again a horizontal line until it intersects the line for the total length of the tank; from this point we follow a vertical line to the bottom scale which gives the volume of the liquid in U. S. gallons. If from the last point of intersection we had continued following a horizontal line, instead of a vertical line to the bottom scale, we would have located a point on the scale to the right which would have given the volume of liquid per foot of length of tank in U. S. gallons.

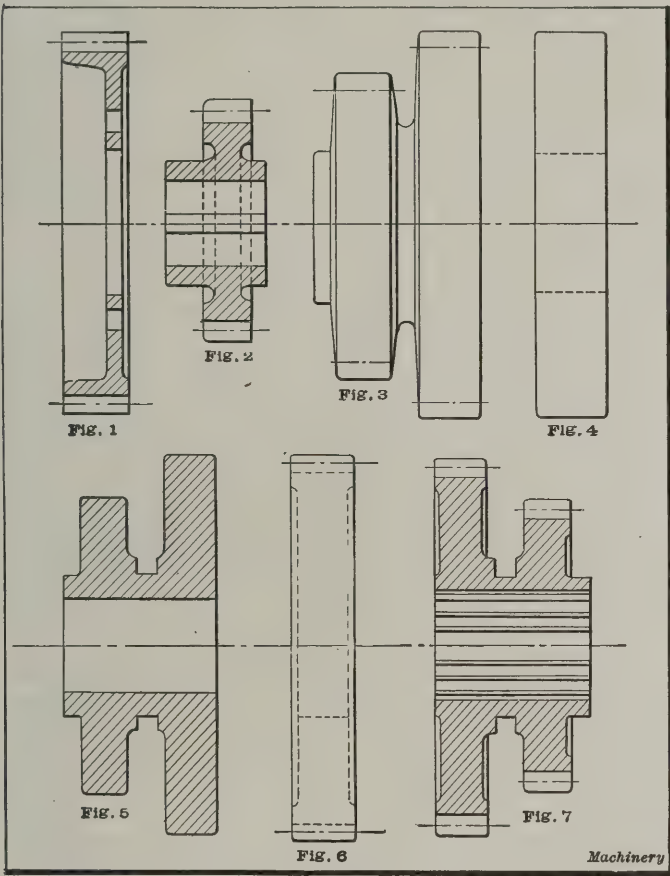
PROCESSES IN PRODUCTION OF AUTOMOBILE TRANSMISSION GEARS*†

One of the most important problems in modern automobile construction, and one which has received a great deal of attention from mechanical engineers during the past few years, is that of the quiet working of the running parts. Next to the engine itself, the gears have proved the greatest offenders in making noise. Therefore, the demand for gears which are accurate, interchangeable and silent, together with the necessity for producing them both rapidly and at a low cost, has caused a great deal of attention to be devoted to the various processes, tools and appliances whereby that demand may be satisfied. We thus find that there are being placed on the market an increasing number of machine tools, steels and carbonizing materials, each of which claims some advantage over its predecessors, such as increased output, greater simplicity, superior generating features, and better hardening results. It is the intention, however, to deal here chiefly with the processes of manufacturing gear-box gears by means of a complete equipment of gages, tools, jigs, etc., with the object of insuring interchangeability. To a very large extent fitting is thus dispensed with. After the final machining operation has been performed, the parts should be ready to be assembled. When a duplicate part is wanted it can be supplied from stock, as the methods here to be described insure that it will fit into its correct position without trouble.



Figs. 1 to 7. Automobile Transmission Gears at Various Stages of Completion

There is probably no part of an automobile that is subjected to greater use—and abuse—than the gears, especially the gear-box gears. Carrying, as they do, practically all the power developed by the engine, and receiving at the hands of a careless driver the strains imparted by suddenly applied load or by rapid changes, it is absolutely necessary that the gears be made of the highest grade materials, and that the very greatest care and the best workmanship should be bestowed upon them. As the saving in weight is an important factor in the design of the transmission, the gears must be made as small and as light as possible, and yet be sufficiently strong to carry suddenly applied loads with no danger of breaking. Owing to the methods by which the speeds are changed, and the clashing and bruising to which the gears are thus subjected, the transmission mechanism must be made of material which is both hard and tough. Different kinds of steel have been used, and each has been treated by various methods in the attempt to discover the perfect gear material. Although this has not yet been found, so much progress has already been made that the transmission gear of a modern well made automobile, when carefully handled, will last nearly as long as the car itself.

Steels used for Automobile Gears

Of the various kinds of steel which have hitherto been employed, nickel, nickel-chrome and chrome-vanadium steels seem to have more advocates than any others. In most factories the gears are casehardened, and it is this class of gear which will be dealt with in the following. Gears treated in this way have been taken out of cars which have been run many thousands of miles, and in some instances the original tool-marks on the face of the teeth were still visible.

The processes in the manufacture of low carbon nickel-steel casehardened gears, such as the finished gears shown by Figs. 1, 2 and 8, will be described in the following. The various processes will be explained in the order in which they are performed. The composition of nickel steel, suitable for high-speed gears, is as follows: Carbon, 0.20 per cent; manganese, 0.65 per cent; silicon, not exceeding 0.20 per cent; phosphorus, not exceeding 0.04 per cent; sulphur, not exceeding 0.04 per cent; and nickel, 3.50 per cent. Steel with 3.50 per cent nickel rolls and forges well, and when hardened, the ratio of the elastic limit to the ultimate strength is very great. The influence of nickel on steel is that it increases the tensile strength and the elastic limit.

Nickel steel of the composition just mentioned should have an elastic limit, after treatment, of about 30 tons per square inch. The influence of silicon on the results of quenching is similar in many ways to that of carbon. It is dependent on the co-existing amount of carbon and manganese, and it is difficult to obtain silicon in steel without the presence of manganese. Silicon appears to increase the tensile strength and diminish the ductility; but for various reasons it is generally considered objectionable.

Phosphorus is the least desirable element in steel, but up to one per cent it appears to increase the tensile strength. Sulphur tends to produce hot-shortness and difficulty in working, but in the presence of manganese the effect is diminished.

The Gear Blanks

Blanks for gears of the type shown in Fig. 1 should be cut from the bar, since it has been proved that steel is not improved by drop forging, although some steels are less sensitive to injury than others. An investigation of drop forged and bar-cut nickel steel gears, details of which were given in a paper read by Mr. John A. Mathews before the Franklin Institute (see MACHINERY, August, 1909, engineering edition, "Alloy Steels for Motor Car Construction"), showed that under static tests the bar-cut gears were fully 25 per cent stronger, and also that the resistance to shock was greater. The gears shown in Fig. 8 should be made from a drop forging, as shown by Fig. 3, although when only small quantities are required, it would not pay to make dies. In this case ordinary forgings should be considered. Gear blanks should be annealed previous to machining.

The reasons for leaving so much extra metal will be explained in the order in which they concern the various operations necessary in the attempt to get a perfect gear—an end which, it is needless to say, is seldom, if ever, attained. In the case of a gear as shown in Fig. 2, made from a bar, it is not necessary, for reasons which will be seen later, to leave any extra metal. Much of the trouble due to distortion in the heat-treatment is caused by the forging operations being done at too low a temperature, in which case the metal does not have a chance to flow properly, but is merely forced into shape by the die. This sets up internal strains that will be released when the part is annealed.

Rough-turning and Annealing

The first operation is to rough-turn the part all over for the purpose of removing the outer skin, previous to the second

* Paper read by Mr. Walter Betterton before the Graduates' Section of the Birmingham (England) Branch of the Institute of Automobile Engineers, April 25, 1912.

† See the following articles previously published in MACHINERY: "Alloy Steels for Motor Car Construction," August, 1909, engineering edition; "Casehardening," August, 1905, engineering edition. See also MACHINERY'S Reference Book No. 63, "Heat Treatment of Steel."

annealing, leaving a one-sixteenth inch case on the parts required to be hardened, such as the top diameter of the gear, and the sides of the teeth. For the bore a one-eighth inch allowance is required, in gears where the hole is to be a running fit, or castellated, and has to be hard. A one-quarter-inch allowance, however, is necessary when the gear has to be bolted to a center, or to another gear, in which case the bore need not be hard, as it is only used for locating the gear centrally. In rough-turning, allowance must be made for the extra metal, the gears, after machining, appearing as shown in Figs. 4 and 5.

When making gears it is, of course, necessary to have the steel carefully and uniformly annealed. The process of annealing is one of great importance, and is better performed in a specially designed sealed furnace, constructed as a muffle, so that the required heat is obtained uniformly by radiation, without any flame to impinge on the steel. In addition to softening the steel, and making it easy to machine, annealing has the effect of bringing it to a more homogeneous condition by eliminating the molecular strains which are set up by rolling, hammering and stamping. Hence, when the steel is heated preparatory to hardening, equal expansion should follow, and also equal contraction when cooled.

It will thus be seen that should the steel not be annealed uniformly throughout, the risks of warping when hardening are considerably increased. The object of rough-machining is to break down the scale preparatory to the second annealing, and as the strains set up by rough-machining are released by the second annealing, the metal is then in as normal a condition as possible. At the present time there are many compounds used for annealing. A few years ago, the ashes from the forge were considered sufficient for properly annealing steel, but today many special preparations are manufactured and sold for the purpose.

The more common materials used are powdered charcoal, charred leather and hydro-carbonated bone-black. These same materials are used for carbonizing, but after having been used once they are of very little use for that purpose. However, their use for annealing has the additional merit of economy, because they can be used repeatedly, adding each time a little that has only been used for the carbonizing process. Air-slacked lime may also be used for this process. The piece to be annealed is usually packed in a wrought-iron box, using one of the previously mentioned materials, or combinations of them, for the packing. The whole is then heated to the proper temperature,which is about 1760 degrees F. In the case of the gears in question, this temperature should be maintained for one hour. The box may then be set aside with the cover on in order to cool down to atmospheric temperature, or it may cool off with the furnace. It should be noted that the annealing temperature ought always to be higher than that for carbonizing. For all kinds of steel and for all grades of annealing, the slow-cooling furnace gives the best results, because the temperature can easily be raised to the right point, kept there as long as necessary, and then regulated to cool down as slowly as desired. Gas, oil, or electric furnaces are, of course, the easiest to regulate.

Finish-boring and Broaching

Gears to be broached as shown in Fig. 8, should be finish-bored with an allowance of 0.015 inch for grinding after hardening, and faced on one end true with the bore to take the thrust of the broaching on a La Pointe or similar broaching machine. The broaches should be made of carbon steel, oil hardened, tempered and ground, and should be specially treated. It is necessary to treat the steel with some carbonaceous material until it will harden in oil, as it is well known that steel hardened in oil is less likely to spring than if hardened in water. The tendency for steel to crack is almost eliminated and it has a maximum of toughness, unless, of course, the steel has been improperly treated in the fire. The special treatment consists essentially in supplying the surface of the steel with an additional amount of carbon by some material that will not injure the steel. No form of bone should be used on tool steel for this process, as bone contains a high percentage of phosphorus, and the effect of this is to make the steel weak and brittle. Charred leather gives the best results.
